Caustic exposures tend to fall into three distinct groups: (1) intentional teen or adult ingestions with suicidal ideation[7]; (2) unintentional ingestions (the majority of which are by curious children in the toddler age group)[8]; and (3) other incidental, often occupational or industrial contact exposures. The majority of reported exposures are unintentional or accidental, but although less frequent, intentional ingestions account for the majority of serious injuries.[1] The geographic variation in caustic ingestion circumstances, such as involved substances, intention, age of the patient, and extent of evaluation, make it difficult to create encompassing recommendations or a consensus approach.[4,9,10]

Many chemicals used in industry have caustic potential (**Table 200-1**). Household caustics are often less concentrated forms of industrial strength cleansers.

TABLE 200-1 Common Caustic Compounds

Alkali	Found in
Sodium hydroxide	Industrial chemicals, drain openers, oven cleaners
Potassium hydroxide	Drain openers, batteries
Calcium hydroxide	Cement, hair relaxers, and perm products
Ammonium hydroxide	Hair relaxers and perm products, dermal peeling/exfoliation, toilet bowl cleaners, glass cleaners, fertilizers
Lithium hydroxide	Photographic developer, batteries
Sodium tripolyphosphate	Detergents
Sodium hypochlorite	Bleach
Acids	
Sulfuric acid	Automobile batteries, drain openers, explosives, fertilizer
Acetic acid	Printing and photography, disinfectants, hair perm neutralizer
Hydrochloric acid	Cleaning agents, metal cleaning, chemical production, swimming pool products
Hydrofluoric acids	Rust remover, petroleum industry, glass and microchip etching, jewelry cleaners
Formic acid	Model glue, leather and textile manufacturing, tissue preservation
Chromic acid	Metal plating, photography
Nitric acid	Fertilizer, engraving, electroplating
Phosphoric acid	Rust proofing, metal cleaners, disinfectants

PATHOPHYSIOLOGY

The degree to which a caustic substance produces tissue injury is determined by a number of factors: pH, concentration, duration of contact, volume present, and titratable acid or alkaline reserve. Acids tend to cause significant injuries at a pH <3 and alkalis at a pH >11. The physical properties of the product formulation (i.e., liquid, gel, granular, or solid) can influence the nature of the contact with the tissue. Following ingestion, solid or granular caustics often injure the oropharynx and proximal esophagus, whereas liquid alkali ingestions are characterized by more extensive esophageal and gastric injuries. *Titratable acid or alkaline reserve* refers to the amount of acid or base required to neutralize the agent; the greater this value, the greater is the potential for tissue injury.

Esophageal mucosal burns from caustic ingestions are classified by a visual endoscopic grading system: **grade 1 burns** involve tissue edema and hyperemia; **grade 2 burns** include ulcerations, blisters, and whitish exudates, which are subdivided into grade 2A (noncircumferential) and 2B (deeper or circumferential) lesions; and **grade 3 burns** are defined by deep ulcerations and necrotic lesions. Following the initial mucosal injury, tissue remodeling occurs over roughly 2 months. In mild cases, normal esophageal function is restored, but in severe cases, dense scar tissue forms, resulting in stricture formation. Esophageal strictures are a source of significant morbidity and may require long-term treatments with dilations, stenting, or surgery. Early phases of remodeling, particularly days 2 to 14, are associated with increased tissue friability and higher risk of perforation, both spontaneous and iatrogenic.

ALKALI INJURIES

Following caustic alkali exposures, the hydroxide ion easily penetrates tissues, causing immediate cellular destruction via protein denaturation and lipid saponification. This is followed by thrombosis of local microvasculature that leads to further tissue necrosis. Alkali injuries induce a deep tissue injury called **liquefaction necrosis**. Severe intentional alkali ingestion may cause deep penetration into surrounding tissues with resultant multisystem organ injuries, including esophageal injury, gastric perforation, and necrosis of abdominal and mediastinal structures. Severe injuries to the pancreas, gallbladder, small intestine, and mediastinum after intentional ingestion have been reported. Solid alkali ingestions, such as some lye preparations, have a greater potential for oropharyngeal and proximal esophageal tract injury and less for distal injury.

The most common household alkali is **bleach**, a 3% to 6% sodium hypochlorite solution with a pH of approximately 11. Household liquid bleach is minimally corrosive to the esophagus and rarely causes significant injury beyond grade 1 esophageal burns. Esophageal stricture was not observed as a complication of household bleach ingestion in a series involving almost 400 patients.[11] However, ingestion of industrial strength bleach containing much higher concentrations of sodium hypochlorite may result in gastric and esophageal necrosis. Bleach ingestion may cause emesis secondary to gastric irritation and/or pneumonitis after aspiration. Pulmonary irritation related to chlorine gas production in the stomach or when mixed with other substances may also occur.[12,13] A common reaction is the production of the highly irritating **chloramine gas** when bleach and ammonia household cleaners are combined.[14]

ACIDS

Injuries by strong acids produce **coagulation necrosis**. Dissociated hydrogen ions and their associated anions penetrate tissues, leading to cell death and eschar formation. This process is believed to limit continued hydrogen ion penetration and protect against deeper injury. When ingested acids settle in the stomach, gastric necrosis, perforation, and hemorrhage may result. Although it was previously thought that acids were esophagus-sparing with most tissue injury concentrated in the stomach, endoscopy following an acid ingestion finds a similar incidence of gastric and esophageal injury.[15-17] Despite relatively less tissue destruction, strong acid ingestion results in high-grade gastric injuries (secondary to pylorospasm and pooling) and a higher mortality rate compared with strong alkali ingestions. Acid ingestion is sometimes complicated by systemic absorption of acid with associated metabolic acidosis, hemolysis, and renal failure.[18]

Hydrofluoric acid is a unique ingestion discussed in chapter 217, Chemical Burns (see Hydrofluoric Acid).

CLINICAL FEATURES

The cardinal features of caustic ingestion are a chemical burn to the oral mucosa,[19] sometimes associated with chemical burns to the skin or eyes from splashes or dribbling (see chapters 217, Chemical Burns and 241, Eye Emergencies). Pharyngeal burns from ingestion produce pain, odynophagia, drooling, and vocal hoarseness. Dyspnea may be caused by edema of the upper airway, aspiration of the caustic substance into the tracheobronchial tree, or inhalation of fumes, particularly acids. Esophageal burns produce dysphagia, odynophagia, and chest pain. Ocular burns are painful, reduce visual acuity, and produce visible damage to the anterior structures of the eye.

HISTORY

The key priority is rapid airway assessment and stabilization. Following that, obtain a directed history to determine the type and amount of caustic ingested and the presence of coingestants. Determine if the ingestion was intentional or unintentional.

PHYSICAL EXAMINATION

Look for signs of respiratory distress or circulatory shock. With ingestions, look for signs of pharyngeal injury (mucosal burns, drooling), respiratory injury (dysphonia, coughing, stridor, wheezing), and gastric injury (vomiting, epigastric tenderness) (**Figure 200-1**).[5,19-24] Streaks of caustic burns on the face or chest are called "dribble burns" (**Figure 200-2**).

DIAGNOSIS

Conflicting data exist on the reliability of presenting signs and symptoms to predict upper GI injuries.[25-29] **Intentional ingestions are associated with higher grades of GI tract injury, with or without clinically obvious signs.**[30] The incidence of serious GI injury after pediatric unintentional ingestions has been the focus of many studies.[5,25-27,29,31,32] Although serious esophageal injury can occur in the absence of oral burns, essentially all children with serious esophageal injuries (grade 2 or 3) after accidental caustic ingestion have some initial sign or symptom, such as stridor, drooling, or vomiting.[26,27,29] Pain alone is an inconsistent predictor of severity of injury, and pain may be absent initially and early in the clinical course.

Assess for hemodynamic instability. Causes of shock include GI bleeding, complications of GI perforation, volume depletion, and toxicity from coingestants. Examine for peritoneal signs due to hollow viscous perforation. Consider mediastinitis in patients complaining of chest discomfort, and palpate the chest wall and neck for signs of subcutaneous emphysema. Inspect the eyes for ocular burns and the skin for splash and dribble burns.

LABORATORY TESTING

For children who accidentally ingest common household alkalis (e.g., bleach) or acids (e.g., toilet bowl cleaner), the need for ancillary testing is only necessary in patients with signs or symptoms of significant injury: drooling, respiratory distress, or vomiting. For an intentional ingestion, or one from a strong acid or alkali, laboratory evaluation should include a venous or arterial blood gas, electrolyte panel, hepatic profile, complete blood count, coagulation profile, lactate, and blood type and screen. Caustic ingestions can cause an **anion gap acidosis** based on lactate production due to direct tissue injury or shock. Strong acid ingestions may be associated with both severe anion gap (e.g., sulfuric acid) and nongap acidoses (e.g., hydrochloric acid). Obtain acetaminophen and salicylate levels to screen for potential coingestants in suicidal patients. An ECG is indicated following a hydrofluoric acid exposure to check for QT-interval prolongation from hypocalcemia.

IMAGING

Obtain a chest radiograph in patients with chest pain, dyspnea, or vomiting to check for peritoneal and mediastinal air. Thoracoabdominal CT scanning is useful to assess for esophageal injury after ingestion of strong caustics or if intra-abdominal perforated viscus is suspected. Endoscopy is the gold standard for identifying the severity of esophageal injury. IV and oral contrast-enhanced CT scanning is an alternative when endoscopy is not readily available or during the postingestion time period when the risk of esophageal perforation by endoscopy is increased (see Endoscopy section).[33] Because oral contrast can interfere with subsequent endoscopic visualization, it is best to discuss the need for oral contrast administration with the endoscopist prior to the CT study. Ultrasound can be used to evaluate and follow-up corrosive gastric injury if there is perforation or severe edema preventing endoscopy.[34]

ENDOSCOPY

Endoscopy is the gold standard for evaluating the location and severity of injury to the esophagus, stomach, and duodenum after caustic ingestion. The controversy has been who needs endoscopy and when should it be done.[28,29,32,35,36] **Patients with intentional caustic ingestions should undergo early endoscopy because ingestions with suicidal intent carry the highest risk of clinically important injury.** In unintentional ingestions, particularly by children, the decision to perform endoscopy is not clear cut.[28,29,32,35,36] Most children with serious caustic esophageal injury will be symptomatic,[32] and although there is a correlation between clinical findings and corrosive severity, lack of symptoms is judged by some authors not to be an adequate predictor of no injury.[8,31,37] **Early endoscopy is recommended after unintentional caustic ingestions in adults and children with signs or symptoms of serious injury such as stridor or significant oropharyngeal burns and/or vomiting, drooling, or food refusal, with or without oropharyngeal burns.**[26,28,29,32,35,36,38]

The general purpose of endoscopy is diagnosis.[39-46] Early endoscopy permits grading of injuries, helps guide treatment, and predicts future morbidity (**Table 200-2**). Early endoscopy is safe and may decrease the time that patients will be without nutritional support. This is particularly important in children with low glycogen stores and in high-grade injuries, where caloric requirements will be high.

Tissue friability after a caustic burn increases significantly at 24 to 48 hours after injury and is maximal between days 5 and 14. **Most experts agree that endoscopy should be performed early after ingestion, ideally <12 hours and not >24 hours after ingestion to avoid iatrogenic perforation.**[36,47] Traditionally, endoscopists have terminated their examination at the first sign of severe esophageal injury (grade 2B or 3). Experienced operators using smaller, flexible endoscopes with minimal insufflation of air can decrease the incidence of perforation, permitting more distal visualization documenting all injuries to the esophagus, stomach, and duodenum.

TREATMENT

AIRWAY

The first priority is airway maintenance. Patients with respiratory distress may have significant oral, pharyngeal, and/or laryngotracheal injuries that require emergent airway management. If emergency airway management precedes patient decontamination, prevent exposure to the ED staff. Caustic airway injuries are difficult airways. Ideally, patients with potential airway injuries should have fiberoptic evaluation of the airway before intubation to determine the extent of the damage, but this may not always be possible. **Blind nasotracheal intubation is contraindicated** due to the potential for exacerbating airway injuries. **Oral intubation with direct visualization is the first choice for definitive airway management.** For potential airway compromise, establish a secure endotracheal airway early rather than risk greater difficulty later when secondary effects of injury, such as edema, complicate the situation.

TABLE 200-2 Correlation of Esophageal Injury Grade with Morbidity and Interventions

Endoscopic Injury Grade	Grade 1 Esophageal Injury	Grade 2A Esophageal Injury	Grade 2B and 3 Esophageal Injuries
Future morbidity	No risk of strictures or carcinoma	Strictures tend not to occur	At risk for hemorrhage and perforation (early), strictures (delayed), and carcinoma (late)
Nutritional support	Diet as tolerated	If unable to tolerate PO, provide nutritional support via nasogastric, orogastric, or percutaneous feeding tube *or* Total parenteral nutrition	Initiate early percutaneous feeding tube *or* Total parenteral nutrition
General interventions	Supportive care	Admission recommended, supportive care	Intensive care unit admission recommended; may require additional imaging or surgical exploration for gastric injuries

Cricothyrotomy may be needed if oropharyngeal edema, tissue friability, and bleeding make intubation difficult or impossible.

Avoid laryngeal mask airways, combination tubes with pharyngeal and tracheal balloons, retrograde intubation, and bougies because these devices/techniques can increase tissue damage or cause perforation.

DECONTAMINATION, NEUTRALIZATION, AND DILUTION

The ED staff should take precautions to prevent ongoing injury to the patient and staff from continued caustic exposure. ED staff involved should wear protective gowns, gloves, and masks with face shields. Standard decontamination, with removal of soiled or soaked clothing and copious irrigation with towels and soap (as needed), is adequate in most cases. Vomiting may re-expose patient and staff to the caustic agent.

Gastric decontamination with activated charcoal is contraindicated if a caustic is the only ingestion. Charcoal does not adhere well to most caustics and will impede visualization when endoscopy is performed. However, activated charcoal may be considered when coingestants pose a risk for severe systemic toxicity.[48] **Ipecac syrup is contraindicated**, because vomiting will result in repeat exposure of the airway and GI mucosa to the caustic agent and could precipitate perforation.[49]

In general, do not insert nasogastric tubes until after endoscopic evaluation. With high-grade esophageal burns, feeding tubes may be inserted under endoscopic guidance if clinically indicated.

Dilution and neutralization therapy are not recommended in the prehospital setting or ED because there is no proven human benefit and potential risk of gastric distension, vomiting, and perforation.[50-53]

FLUID RESUSCITATION

Establish large-bore IV access and resuscitate with crystalloids. Coingestants, bleeding, and third spacing, as well as metabolic disarray from acid-base derangements, can lead to shock. Central venous access may be required for monitoring of resuscitation.

SYSTEMIC STEROIDS AND PROPHYLACTIC ANTIBIOTICS

There is currently no evidence of consistent benefit from systemic steroids, so steroids are not recommended as part of ED treatment.[54-60]

The ability of steroids to inhibit the inflammatory response led to the hypothesis that steroids may decrease stricture formation after caustic ingestion, and animal models have suggested benefit. However, individual human trials and pooled meta-analysis have not shown benefit for injury,[54-60] and steroids may increase the risk of infection, perforation, and hemorrhage.[56]

One criticism of pooled meta-analysis data is that the individual studies did not clearly distinguish between grade 1 and 2A lesions, which do not typically lead to strictures, and grade 2B and 3 injuries, which might theoretically benefit from steroids.[59]

There is no current evidence to support the ED administration of prophylactic antibiotics after caustic ingestions in humans. However, in protocols in which steroids are used or in grade 2B or 3 injury, addition of penicillin or another antibiotic that covers oral flora has been part of treatment regimen.[56,61] Because steroids have largely fallen out of favor, the need for antibiotics in the ED is rare.

SURGERY AND ESOPHAGEAL STENTING AND DILATION

Major ingestions of caustic agents may result in perforation of the GI tract or extensive tissue necrosis requiring emergency surgery.[62-67] Laparotomy is generally preferred over laparoscopic evaluation for posterior gastric visualization. The indications for emergency laparotomy include esophageal perforation, peritoneal signs, or free intraperitoneal air. Large-volume ingestions (>150 mL), signs of shock, respiratory distress, persistent lactic acidosis, ascites, and pleural fluid may be other indications for surgical exploration.[62]

For grade 2B and 3 injuries without obvious perforation, recommendations include a period of esophageal rest,[68] early gastrostomy for enteral feeding,[38,69] and dilation therapy (in the first 3 weeks) with or without stenting.[70-73] Once strictures form, they may be difficult to treat and require stenting and/or multiple balloon dilatations or bouginage.[9] Controversy exists about the most appropriate treatment for esophageal stricture (i.e., long-term repetitive dilation therapy versus surgery).[9,72-74]

TREATMENT OF SYSTEMIC TOXICITY

Morbidity or death from alkali injuries usually results from the complications of direct tissue necrosis, but acid ingestions may result in additional systemic toxicity from absorption of the acid.[18] Acid-base disorders (increased anion gap or normal anion gap acidosis depending on acid ingested), hemolysis, coagulopathy, and renal failure may result. In cases of systemic toxicity, traditional critical-care principles should be applied to optimize the patient's hemodynamics. Acute lung injury (noncardiogenic pulmonary edema) may follow caustic ingestions as a complication of local or systemic effects.

NUTRITIONAL SUPPORT

Nutritional support is often necessary following a severe caustic injury to the esophagus or stomach. Support can be achieved by percutaneous (usually jejunostomy) feeding, nasoenteral feeding, or total parenteral nutrition.[61,75]

EXPERIMENTAL THERAPIES

Animal experiments have found that drugs affecting collagen deposition, including interferon-α-2b, octreotide, β-aminopropionitrile, colchicine, *N*-acetylcysteine, and D-penicillamine,[9,76] can prevent esophageal strictures after caustic alkali ingestion. Pentoxifylline, a local inflammatory and microcirculation mediator, has experimental benefit. Mitomycin C, a fibroblast proliferation inhibitor, has been used topically on strictures with some success.[9] Oral agents to coat and protect the GI tract from insult, including sucralfate, bismuth subsalicylate, and sodium polyacrylate, are beneficial in animal experiments. None of these agents have been evaluated in controlled human clinical trials, and no specific recommendation can be made regarding their use. H_2

blockers and proton pump inhibitors are often used in the treatment protocol,[61] but no evidence supports or refutes their use.

DISEASE COMPLICATIONS

Short-term prognosis is worse with grade 3 GI injury, systemic complications, and age >65 years.[47,77] Most long-term sequelae from caustic exposure are related to injuries to the GI tract. Acid ingestions may scar the pylorus and result in gastric outlet obstruction. Caustic alkali ingestions may result in esophageal strictures, which may result in dysphagia, odynophagia, and malnutrition. Persistent drooling, reluctance to eat, severe oropharyngeal burns, and persistent fever correlate with the development of esophageal stricture after accidental caustic ingestion in children.[78]

Patients with grade 3 caustic injuries to the esophagus have about a 1000-times increased risk for squamous cell cancer of the esophagus that can occur decades after the initial ingestion and resulting esophageal injury.[79] Because cancer can develop if a portion of the esophagus remains after reconstructive surgery for esophageal stricture, total removal of the esophagus is recommended.[80]

DISPOSITION AND FOLLOW-UP

Admit all patients with symptomatic caustic ingestions. Patients with grade 1 injuries can be discharged from hospital after endoscopy, provided they can tolerate oral fluids and food. Grade 2A injuries warrant hospitalization to ensure that symptoms and injury do not progress. Grade 2B and 3 injuries are significant, require enteral or parenteral nutrition, and have an early risk for bleeding or perforation; admit to an intensive care unit.[61] Organ perforation or extensive necrosis is an indication for surgery. Contact the regional poison control center for data collection purposes and assistance with management.

SPECIAL CONSIDERATIONS

LAUNDRY DETERGENT POD INGESTIONS

Laundry detergent pods, also known as capsules, liquitabs, or sachets, have been available in Europe for over a decade and were introduced to the U.S. market in 2010.[81,82] Each pod contains concentrated detergent within a dissolvable plastic membrane. An individual pod may have internal chambers that contain a stain remover and brightener separate from the detergent. Exposure to the concentrated preparation in these pods is more likely to produce symptoms than exposure to traditional laundry detergent products.[83]

Dermal or ocular exposure to the contents can produce irritation of the skin, conjunctiva, or cornea. **Ingestion by young children can produce serious toxicity with profuse vomiting, respiratory distress, and neurologic depression.**[84] The etiology of these systemic symptoms is unknown. Caustic injury to the pharynx and esophagus can produce difficulty swallowing with drooling and aspiration during recovery.[85] Treatment is supportive with airway protection and mechanical ventilation. In severe cases, ventilation may be required for days.

CHAPTER 201

Pesticides

Guillermo Burillo-Putze
Santiago Nogue Xarau

Pesticides include insecticides, herbicides, and rodenticides.[1] Pesticide toxicity results from intentional, accidental, and occupational exposures. More than 300,000 pesticide-poisoning deaths occur each year worldwide, with insecticides accounting for the majority of deaths.[2] **Pesticides are marketed as multiple formulations, often under shared brand names; therefore, complex clinical syndromes can result from exposure to both active and other ingredients.** Ingredients in proprietary formulations, such as petroleum distillates, are inert to pests during typical exposures, but can be toxic to humans, especially with excessive amounts. Pesticides have class-specific toxicities, with many having both local and systemic effects. Management often includes consultation with a hazardous materials and toxins database or with a poison control center. Supportive care is of utmost importance in pesticide poisonings, but for some compounds, antidotes are essential.

The World Health Organization classifies pesticides according to toxicity based on the median lethal dose for oral and dermal exposure in rats. This classification has been criticized because human case-fatality rates display large variation for compounds within the same chemical and/or World Health Organization toxicity classification.[3] **Toxicity classification should not be used to predict severity after human exposure.**

INSECTICIDES

Chemical insecticides are toxic to the nervous system, with acute and chronic manifestations, as well as delayed sequelae after acute exposure. Six major classes of insecticides are in common use (**Table 201-1**). Other compounds used to control insects include repellants.

ORGANOPHOSPHATES

Commonly used organophosphates include diazinon, acephate, malathion, parathion, and chlorpyrifos and many others in different countries. Organophosphate and carbamate compounds are the insecticides most commonly associated with systemic illness.[4,5] Potency among organophosphates varies; highly potent compounds, such as parathion, are used primarily in agriculture, whereas those of intermediate potency, including coumaphos and trichlorfon, are used in animal care. Diazinon and chlorpyrifos were phased out from household use in the United States in 2000 due to neurotoxicity, particularly on the developing brains of children, but they continue to be used in many other parts of the world.[6] The organophosphate structure can be modified into chemical agents of mass destruction (see chapter 8, Chemical Disasters).

Organophosphate poisoning results primarily from accidental exposure in the home, recently sprayed or fogged areas using pesticide applicators, agriculture, industry, and the transport of these products.[4] Inadvertent exposure can occur from flea-dip products in pet groomers and children and from contaminated food. In addition, these chemicals are involved in intentional poisonings from homicides and suicides.[7] Systemic absorption of organophosphates occurs by inhalation and after mucous membrane, transdermal, transconjunctival, and GI exposure.

Pathophysiology Organophosphate and carbamate compounds inhibit the enzyme cholinesterase.[1] Acetylcholinesterase (true or red

blood cell acetylcholinesterase) is found primarily in erythrocyte membranes, nervous tissue, and skeletal muscle. Plasma cholinesterase (pseudocholinesterase or butyrylcholinesterase) is found in the serum, liver, pancreas, heart, and brain. Inhibition of cholinesterase leads to acetylcholine accumulation at nerve synapses and neuromuscular junctions, resulting in overstimulation of acetylcholine receptors. This initial overstimulation is followed by paralysis of cholinergic synaptic transmission in the CNS, in autonomic ganglia, at parasympathetic and some sympathetic nerve endings (e.g., sweat glands), and in somatic nerves. Excess acetylcholine results in a ***cholinergic crisis*** that manifests as a central and peripheral clinical toxidrome.

Organophosphate compounds bind irreversibly to acetylcholinesterase, thus inactivating the enzyme through the process of phosphorylation. *Aging* is a term describing the permanent, irreversible binding of the organophosphorus compound to the cholinesterase. The time to aging is highly variable among different agents and can range from minutes to a day or more. **Once aging occurs, the enzymatic activity of cholinesterase is permanently destroyed,** and new enzyme must be resynthesized over a period of weeks before clinical symptoms resolve and normal enzymatic function returns. **Antidotes must be given before aging occurs to be effective.**

Clinical Features Clinical presentations depend on the specific agent involved, the quantity absorbed, and the route of exposure.[7,8] Organophosphate insecticide poisoning can have substantial variability in clinical course, response to treatment, and outcome.[7] Four clinical syndromes are described following organophosphate exposure: **acute poisoning, intermediate syndrome, chronic toxicity, and organophosphate-induced delayed neuropathy**.[9]

In **acute organophosphate poisoning**, most poisoned patients are symptomatic within the first 8 hours and nearly all within the first 24 hours. Organophosphate agents such as malathion are associated with local irritation of the skin and respiratory tract with resulting dermatitis and wheezing, respectively, without evidence of systemic absorption.

Acute organophosphate poisoning results in CNS, muscarinic, nicotinic, and somatic motor manifestations (**Table 201-2**). In mild to moderate poisoning, symptoms occur in various combinations. Time to symptom onset varies according to exposure route; it is most rapid with inhalation and least rapid with transdermal absorption; however, dermatitis or skin excoriation may hasten this. Symptoms can occur within minutes after massive ingestion that is uniformly fatal.

CNS symptoms of cholinergic excess include anxiety, restlessness, emotional lability, tremor, headache, dizziness, mental confusion, delirium, hallucinations, and seizures. Coma with depression of respiratory and circulatory centers may result. Inhibition of acetylcholinesterase in the parasympathetic system produces muscarinic effects (**Table 201-3**).

Acetylcholine is the presynaptic neurotransmitter at nicotinic receptors in the sympathetic ganglia and adrenal medulla. Inhibition of acetylcholinesterase at these locations results in sympathetic stimulation, producing pallor, mydriasis, tachycardia, and hypertension. In most patients, parasympathetic stimulation usually predominates, but mixed autonomic effects are common.

TABLE 201-3 Mnemonics for the Muscarinic Effects of Cholinesterase Inhibition

E	Emesis
L	Lacrimation
S	Salivation
"Killer B's"	Bradycardia, bronchorrhea, bronchospasm

Nicotinic stimulation at neuromuscular junctions results in muscle fasciculations, cramps, and muscle weakness. This syndrome may progress to paralysis and areflexia, making it difficult to detect seizure activity. Respiratory muscle paralysis can lead to ventilatory failure.

Abdominal pain is common with rare cases of pancreatitis and peritonitis.[10] The clinical course may be complicated by broncho-aspiration of gastric contents contributing to respiratory distress. Many of these insecticide preparations contain hydrocarbons that act as solvents, and in cases of aspiration, they cause lipoid pneumonia, with severe respiratory failure.

More lipid-soluble organophosphates may not produce immediate symptoms of toxicity, but instead produce delayed sequelae. Low-grade chronic organophosphate exposures occur among farm workers, pesticide manufacturing plant workers, exterminators, and patients taking cholinergic ophthalmologic preparations.[11] Symptoms and signs are often less dramatic and nonspecific, occurring without the cholinergic syndrome.

An **intermediate syndrome** may occur 1 to 5 days after an organophosphate exposure, reported in up to 40% of patients following ingestion.[12] Clinical features include paralysis of neck flexor muscles, muscles innervated by the cranial nerves, proximal limb muscles, and respiratory muscles; respiratory support may be needed. Symptoms or signs of cholinergic excess are absent in this syndrome. Electromyography may assist in making the diagnosis.[13] Aggressive, early antidote therapy and supportive measures may prevent or ameliorate the severity of this syndrome. Symptoms usually resolve within 7 days. Nerve gas poisoning has not been reported to cause the intermediate syndrome.

Chronic toxicity is seen primarily in agricultural workers with daily exposure, manifesting as symmetrical sensorimotor axonopathy.[14] This mixed sensorimotor syndrome may begin with leg cramps and progress

TABLE 201-2 Acute Organophosphate Poisoning Severity Grading*

Severity	Butyrylcholinesterase Activity (% normal) Measured from Plasma	Acetylcholinesterase Activity (% normal) Measured from Red Blood Cells	Clinical Features	Typical Initial Atropine Amount to Control Symptoms
Mild	40–50	50–90	Lightheadedness, nausea, headache, dyspnea Lacrimation, rhinorrhea, salivation, diaphoresis	<2 milligrams IV/IM
Moderate	10–40	10–50	Restless, confusion, vomiting, diarrhea, drowsiness Autonomic instability: bradycardia or tachycardia, hypotension or hypertension, miosis or mydriasis Muscle fasciculations Bronchorrhea and bronchospasm	2–10 milligrams IV/IM
Severe	<10	<10	Coma, seizures, flaccid paralysis, urinary or fecal incontinence, respiratory arrest	>10 milligrams IV/IM

*The correlation between cholinesterase activity, clinical symptoms, and atropine dose is inconsistent, and treatment should be guided predominately by clinical symptoms.

to weakness and paralysis, mimicking features of the Guillain-Barré syndrome.

Organophosphate-induced delayed neuropathy is characterized by cognitive dysfunction, impaired memory, mood changes, autonomic dysfunction, peripheral neuropathy, and extrapyramidal signs.[11] Chronic fatigue syndrome and multiple chemical sensitivity have been reported in some patients, predominantly female, after exposure to very low doses of organophosphate insecticides.[15] Children are at greater risk of toxicity when exposed due to smaller body size and lower baseline levels of cholinesterase activity.

Chemical warfare nerve agents, such as soman, sarin, tabun, and VX, are organophosphate compounds that inactivate acetylcholinesterases. They are rapid acting and extremely potent; death can occur within minutes of inhalation or dermal exposure, as occurred in the subway terrorist attack in Tokyo 1985. Soman ages within minutes, giving little time to administer antidotes.

Diagnosis **Diagnosis and treatment are based on history and the presence of a suggestive toxidrome; laboratory cholinesterase assays and reference laboratory testing for specific compounds take time and have limitations, and waiting for results delays administration of potentially life-saving therapy.** Diagnosis is often difficult due to a constellation of clinical findings that can be variable in both acute and chronic poisonings. Point-of-care testing tools are in development.[16]

Noting a characteristic hydrocarbon or garlic-like odor may assist in diagnosis. The cholinergic toxidrome may vary depending on the predominance of muscarinic, nicotinic, and CNS manifestations and the severity of the intoxication. Organophosphate insecticide poisoning should be considered in the differential diagnosis of a patient with altered mental status and pinpoint pupils. **Miosis and muscle fasciculations are considered reliable signs of organophosphate toxicity.**

Cholinesterase activity is used to assess potential toxicity, with red cell acetylcholinesterase enzymatic activity a more accurate indicator of synaptic cholinesterase inhibition, but plasma butyrylcholinesterase is easier to assay and more available (**Table 201-2**). The degree of cholinesterase inhibition necessary to produce symptomatic illness is variable, so although cholinesterase levels should correlate with toxicity, there is large individual variability in baseline measurements, and standardization of normal ranges among laboratories is poor, so deviation from a symptomatic patient's baseline may be significant when values are reported within the normal range for the testing laboratory.

When the cholinesterase function falls gradually, as in chronic exposure, clinical symptoms may be subtle. Plasma butyrylcholinesterase levels may be depressed in genetic variants, chronic disease states, liver dysfunction, cirrhosis, malnutrition and low serum albumin states, neoplasm, infection, and pregnancy. Red blood cell acetylcholinesterase is affected by factors that influence the circulating life of erythrocytes such as hemoglobinopathies. Unless pralidoxime is given before aging occurs, plasma butyrylcholinesterase takes up to 4 to 6 weeks and red blood cell acetylcholinesterase takes as long as 90 to 120 days to return to baseline after exposure.

Routine laboratory test abnormalities are nondiagnostic but may include evidence of pancreatitis, hypo- or hyperglycemia, leukocytosis, and abnormal liver function. In severe cases, a chest radiograph may show pulmonary edema. The ECG may be abnormal and correlate with the degree of toxicity and outcome. Common abnormalities include ventricular dysrhythmias, torsade de pointes, and idioventricular rhythms. Atrioventricular blocks and prolongation of the QT interval are common. A prolonged QT_c interval correlates with severity and mortality in severe organophosphate poisoning.[17] Electromyography may identify and quantify acetylcholinesterase inhibition at neuromuscular junctions.

Treatment Treatment consists of airway control, intensive respiratory support, general supportive measures, decontamination, prevention of absorption, and the administration of antidotes (**Table 201-4**).[9,18,19] **Therapy should not be withheld pending determination of cholinesterase levels.**

In cases of acute cutaneous exposure, protective clothing must be worn to prevent secondary poisoning of healthcare workers.[20] Neoprene or nitrile gloves should be used instead of latex. Patients with suspected exposure must be removed from the contaminated environment. All clothes and accessories must be removed completely, placed in plastic bags, and disposed of as hazardous materials.[21] The patient is immediately decontaminated externally with copious amounts of a mild detergent such as dishwashing liquid and water. Decontamination includes the scalp, hair, fingernails, skin, conjunctivae, and skin folds. Body fluids should be treated as contaminated. Abrasion or irritation of the skin should be avoided. Contaminated runoff water should be contained and disposed of as hazardous material. Instruments used can be decontaminated using chlorine bleach.

TABLE 201-4 Treatment for Organophosphate Poisoning

Decontamination	Protective clothing must be worn to prevent secondary poisoning of healthcare workers. Handle and dispose of all clothes as hazardous waste. Wash patient with soap and water. Handle and dispose of water runoff as hazardous waste.
Monitoring	Cardiac monitor, pulse oximeter, 100% oxygen.
Gastric lavage	No proven benefit (see text).
Activated charcoal	No proven benefit (see text).
Urinary alkalinization	No proven benefit (see text).
Atropine	1–3 milligrams IV in an adult or 0.01–0.04 milligram/kg IV (but never <0.1 milligram per dose) in children. Repeat every 5 min until tracheobronchial secretions attenuate. Followed by continuous infusion to maintain the anticholinergic state. Dose varies from 0.4 to 4 milligrams/h IV infusion in adults.
Pralidoxime	No proven benefit (see text). 1–2 grams for adults or 20–40 milligrams/kg IV (up to 1 gram) in children, mixed with normal saline and infused over 5–10 min. Followed by continuous infusion: 500 milligrams/h in adults or 5–10 milligrams/kg per hour in children.
Seizures	Benzodiazepines IV.

Patients with acute exposures should be placed on oxygen, a cardiac monitor, and pulse oximeter. A 100% nonrebreather mask will optimize oxygenation in the patient with excessive airway secretions and bronchospasm; however, atropine administration should not be delayed or withheld if oxygen is not immediately available.[22] Gentle suction will assist in clearing airway secretions from hypersalivation, bronchorrhea, or emesis. Coma, seizures, respiratory failure, excessive respiratory secretions, or severe bronchospasm necessitate endotracheal intubation. An IV line should be established with baseline blood sampling and determination of cholinesterase levels. **A nondepolarizing agent should be used when neuromuscular blockade is needed. Succinylcholine is metabolized by plasma butyrylcholinesterase, and therefore, prolonged paralysis may result.** Hypotension is initially treated with fluid boluses of isotonic crystalloid.

Gastric lavage is widely used in Asia following organophosphate ingestion despite the lack of evidence for improved outcome.[19,23] Given the sometimes rapid onset of symptoms after ingestion, it is unlikely that gastric lavage will be of benefit except in patients who present within 2 hours after a large ingestion. Activated charcoal is sometimes recommended because organophosphates do bind in vitro, although there is no evidence that single or multiple doses of activated charcoal improve patient outcome.[19] Urinary alkalinization is often used in Brazil and Iran for organophosphate poisoning, but there is no controlled evidence that shows benefit.[19] Hemodialysis, hemofiltration, and hemoperfusion are of no proven value.[19]

Atropine is the antidote for significant organophosphate poisonings (Table 201-4).[9,18,19] Atropine, a competitive antagonist of acetylcholine at central and peripheral muscarinic receptors, will reverse the effects secondary to excessive cholinergic stimulation. **The dose is repeated every 5 minutes until copious tracheobronchial secretions attenuate; large**

amounts may be necessary, in the order of hundreds of milligrams in massive ingestions. Pupillary dilatation is not a therapeutic end point. **Tachycardia is not a contraindication to the use of atropine in organophosphorus poisoning because tachycardia can occur secondary to bronchospasm or bronchorrhea with hypoxia, which can be reversed with atropine.**

The initial atropine should be IV when possible, but 2 to 6 milligrams IM should be considered when IV access is not possible. Normally, this initial dose of atropine should produce antimuscarinic symptoms; therefore, absence of anticholinergic symptoms after an initial dose is indicative of organophosphate poisoning. Once an effective amount of atropine has been given, an infusion should be started to maintain an anticholinergic state; the dose required varies according to severity,[24] and prolonged therapy may be necessary. **Importantly, atropine does not reverse muscle weakness.**

Glycopyrrolate, an alternate anticholinergic agent, may be used, but dosing is not well defined, and there is no proven benefit compared to atropine.[19] Nebulized atropine or ipratropium may be used to improve pulmonary symptoms. Glycopyrrolate and ipratropium do not cross the blood–brain barrier and are ineffective in treating central neurologic symptoms.

Compounds called *oximes* are used to displace organophosphates from the active site of acetylcholinesterase, thus reactivating the enzyme.[9,18,19] Pralidoxime is the oxime in common use, ameliorating muscarinic, nicotinic, and CNS symptoms. Importantly, pralidoxime reverses muscle paralysis if given early, before aging occurs. If possible, blood samples for acetylcholinesterase levels are obtained before administration of pralidoxime, but it is **important that pralidoxime be administered as soon as possible before permanent and irreversible aging occurs.** Although pralidoxime is more effective in acute than in chronic intoxications, it is recommended for use even after >24 to 48 hours after exposure.

Response to pralidoxime therapy with a decrease in muscle weakness and fasciculations and relief of muscarinic effects with atropine usually occurs within 10 to 40 minutes of administration. Pralidoxime can also be given by the IM route. A continuous infusion is preferable to repeated bolus dosing if paralysis does not resolve after the initial dose or if paralysis returns. The pralidoxime dose recommended by the World Health Organization is a 30-milligram/kg IV bolus followed by an IV infusion of 8 milligrams/kg per hour.

Pralidoxime should be continued for 24 to 48 hours while monitoring acetylcholinesterase levels. Despite theoretical and experimental benefit and worldwide clinical use, current evidence is inadequate to show that oximes, such as pralidoxime, reduce mortality or complication rate in acute organophosphate poisoning.[19,25,26] **Pralidoxime is not recommended for asymptomatic patients or for patients with known carbamate exposures presenting with minimal symptoms.**

Seizures are treated with airway protection, oxygen, atropine, and benzodiazepines.[19] **Atropine may prevent or abort seizures due to cholinergic overstimulation that occur within the first few minutes.** Pulmonary edema and bronchospasm are treated with oxygen, intubation, positive-pressure ventilation, atropine, and pralidoxime. Succinylcholine, ester anesthetics, and β-adrenergic blockers may potentiate poisoning and should be avoided.

Disposition and Follow-Up Minimal exposures may require only decontamination and 6 to 8 hours of observation in the ED to detect delayed effects. Reexposure should be avoided because sequential exposures can have cumulative toxicity, so patients returning to work should be limited from further exposure. All clothing, including shoes and belts, should be discarded properly as hazardous materials and not returned to the patient; recrudescence of poisoning has occurred from contaminated clothes and leather, even after washing or cleaning.[21]

Admission to the intensive care unit is necessary for significant poisonings. Most patients respond to pralidoxime therapy with an increase in acetylcholinesterase levels within 48 hours. If there is no posthypoxic brain damage, and if the patient is treated early, symptomatic recovery occurs in 10 days. If toxins are fat soluble, the patient may be symptomatic for prolonged periods of time and dependent on continuous pralidoxime infusion. During this period, which may last weeks while awaiting resynthesis of new enzyme, supportive care and respiratory support may be needed. The end point of therapy is determined by the absence of signs and symptoms on withholding pralidoxime therapy.

Following an acute exposure, the patient may have neurologic sequelae, such a paresthesias or limb weakness, along with nonspecific symptoms lasting days to months.[27] Death from organophosphate poisoning usually occurs in 24 hours in untreated patients, usually from respiratory failure secondary to paralysis of respiratory muscles,[28] neurologic depression, or bronchorrhea.

CARBAMATES

The carbamate insecticides (aldicarb, carbofuran, carbaryl, ethienocarb, fenobucarb, oxamyl, methomyl, pirimicarb, propoxur, and trimethacarb) are cholinesterase inhibitors that are structurally related to the organophosphate compounds.[1] These agents are primarily used as insecticides, but illegally imported rodenticides may contain aldicarb.[29]

Pathophysiology Carbamates can be toxic after dermal, inhalation, and GI exposure. Carbamates transiently and reversibly bind to and inhibit the cholinesterase enzyme. Regeneration of enzyme activity by dissociation of the carbamyl-cholinesterase bond occurs within minutes to a few hours involving rapid, spontaneous hydrolysis of the carbamate-cholinesterase bond. Therefore, aging does not occur, and as a major difference from organophosphate poisoning, new enzyme does not need to be synthesized before normal function is restored after carbamate poisoning.

Clinical Features **In adults, symptoms of acute carbamate poisoning are similar to the cholinergic syndrome observed with organophosphate agents but are of shorter duration.** Because carbamates do not effectively penetrate the CNS in adults, less central toxicity is seen, and seizures do not occur. However, in children, presentation of acute carbamate poisoning differs, with a predominance of CNS depression and nicotinic effects. Carbamates can also produce the intermediate syndrome.[12]

Diagnosis Diagnosis is based on clinical history and findings. Measurement of acetylcholinesterase activity is generally not helpful because enzymatic activity may return spontaneously to normal 4 to 8 hours after a carbamate exposure.

Treatment Initial treatment of carbamate poisoning is the same as for organophosphorus compounds. Atropine is the antidote of choice and is administered for muscarinic symptoms. Atropine is usually all that is necessary while waiting for the carbamylated acetylcholinesterase complex to dissociate spontaneously and recover function, usually within 24 hours. Therapy usually is not needed for more than 6 to 12 hours.

The use of pralidoxime in carbamate poisoning is controversial. The carbamate-binding half-life to cholinesterase is approximately 30 minutes, and irreversible binding does not occur; therefore, there is little need for pralidoxime. Human case reports and some but not all animal studies suggest that pralidoxime may potentiate the toxicity of carbamates, such as carbaryl.[30] Therefore, pralidoxime should be avoided in known single-agent carbaryl poisonings. However, pralidoxime should be considered in mixed poisonings with an organophosphorus compound and a carbamate or if the type of insecticide is unknown.

Disposition and Follow-Up Because carbamate poisonings have transient cholinesterase inhibition and rapid enzyme reactivation, the clinical course tends to be more benign than seen with organophosphates, and most patients recover completely within 24 hours. However, patients with depressed levels of consciousness have a significant mortality,[31] and methomyl poisoning is associated with a high risk of cardiac arrest at presentation and subsequent death after resuscitation.[32]

In mild poisonings, observation suffices, and the patient may be discharged with follow-up. Moderate poisonings necessitate 24 hours of observation that includes evaluation for possible concomitant exposure to or toxicity from inactive ingredients or vehicles such as hydrocarbons.

ORGANOCHLORINES

Dichlorodiphenyltrichloroethane (DDT) is the prototype insecticide of these chlorinated hydrocarbons. Chlordane, heptachlor, dieldrin, and

aldrin are compounds used for termite and roach control. Most have been restricted or banned in the United States, Europe, and many other countries because of their persistence in the environment, long half-life in the human body, and toxicity. Worldwide, these insecticides continue to be used. Hexachlorocyclohexane (lindane) is a general garden organochlorine insecticide that is also used in some countries to treat scabies and head lice infestations. This compound is well absorbed by ingestion and inhalation. Dermal absorption occurs, particularly if the skin is abraded or repeated applications are used. Children and the elderly can develop neurotoxicity and seizures with therapeutic use of lindane.

Pathophysiology Organochlorines are central neurologic stimulants that can be toxic after dermal, inhalation, and GI exposures. The physical state of the agent, whether a liquid or a solid, and the type of vehicle affect transdermal absorption. Organochlorines antagonize γ-aminobutyric acid–mediated inhibition of the central neurons, leading to hyperexcitability with repetitive neuronal discharges following the action potential. Organochlorines are highly lipid soluble and accumulate in human tissues. Most are capable of inducing the hepatic microsomal enzyme system. Therefore, the therapeutic efficacy of other chemicals and drugs that are inactivated by this system is reduced in the presence of organochlorines.

Clinical Features **Neurologic symptoms predominate in acute organochlorine intoxication.**[33] Mild poisoning presents with dizziness; ataxia; fatigue; malaise; headache; neurologic stimulation with hyperexcitability, irritability, and delirium; apprehension; tremulousness; myoclonus; and facial paresthesias. Fever is common. More severe exposures may result in seizures, coma, renal injury, and death.[34] Seizures may occur early, without prodromal syndromes, and are usually short lived, although some patients may have status epilepticus. Organochlorines are used dissolved in hydrocarbon solvents that, by themselves, can cause sedation, coma, and pneumonitis from aspiration. Sensitization of the myocardium to endogenous catecholamines with cardiac dysrhythmia can occur from both organochlorines and the solvents. Chronic neurotoxic effects from low-level exposure to the organochlorine compound chlordane include deficits in tests of balance, reaction time, and verbal recall.

A related agent, the halogenated pyrrole chlorfenapyr, has two unusual features. First, it is a prodrug that is converted into the active form after absorption by the insect. Second, it manifests biphasic neurotoxicity.[35] Initial symptoms are nonspecific and include headaches, body aches, drowsiness, and weakness; these symptoms last for a few days, followed by a latent period of apparent recovery. Around the seventh day after ingestion, neurologic symptoms recur with rapidly progressing paralysis and stupor leading to coma with a fatal outcome. No treatment is effective once the delayed symptoms start. The requirement for metabolism to an active toxin and the latent period suggest it may be possible to develop an agent to inhibit this metabolic conversion and reduce the risk of progression to the delayed fatal neurologic course.

Diagnosis History is important, and valuable information can be obtained from the package label regarding the product and vehicle involved. Laboratory evaluation generally is not helpful, but organochlorines can be detected in the serum and urine by specialty laboratories.

Treatment Treatment includes administration of oxygen, with intubation indicated to treat hypoxia secondary to seizures, aspiration, and respiratory failure. Benzodiazepines are indicated for seizure control. Dysrhythmia control may be indicated, but epinephrine should be avoided because both organochlorines and organic solvents can sensitize the myocardium to endogenous catecholamines. Hyperthermia is managed by external cooling techniques. Removal of clothing and skin decontamination with mild detergent and water are important. Avoid using oils on the skin because they promote absorption. Activated charcoal and possibly gastric lavage in large, recent ingestions are potentially useful. The exchange resin cholestyramine is potentially useful for symptomatic patients exposed to chlordecone.

Disposition and Follow-Up Exposed patients should be observed for 6 hours and admitted to the hospital if signs of toxicity develop or if ingestion involved a hydrocarbon.

PYRETHRINS AND PYRETHROIDS

Pyrethroid use and poisonings have increased since the phase-out of organophosphate insecticides for use in human dwellings. Pyrethrins are naturally occurring active extracts derived from the chrysanthemum plant. Pyrethroids are synthetic analogues of the pyrethrins with greater potency and environmental persistence, but are considered safer than organochlorine and organophosphate insecticides.[36] Pyrethroids are used commonly as aerosols in automated insect sprays in public areas; therefore, inhalation is the most common source of exposure. These agents are available as dusts and liquids in a hydrocarbon base. Pyrethrins are common ingredients in over-the-counter household insecticides, pediculicides, and scabicides. They are rapidly metabolized and therefore are of low toxicity in humans.

Pathophysiology Toxicity results from dermal absorption, inhalation, or ingestion. Pyrethroids block the sodium channel at the neuronal cell membrane, causing repetitive neuronal discharge.[1,37] Additional effects include inhibition on γ-aminobutyric acid receptors, increased nicotinic cholinergic transmission, norepinephrine release, and interference with sodium–calcium exchange across cell membranes. Pyrethrin antigens are cross-antigenic with ragweed pollen, so allergic reactions are common after exposure

Clinical Features These compounds can cause dermal, pulmonary, GI, and neurologic illness. **Allergic hypersensitivity reactions are the most common effects of pyrethrins, producing dermatitis, bronchospasm, rhinitis, hypersensitivity pneumonitis, or anaphylaxis.**[36,38] Skin contact may lead to paresthesias and burning within 30 minutes of exposure that usually dissipates within 24 hours. These compounds are well absorbed but are rapidly metabolized in the liver, usually resulting in minimal systemic toxicity.

Systemic toxicity can occur from occupational poisonings and following large intentional ingestions. Features of systemic toxicity include fatigue and lethargy, nausea and vomiting, paresthesias, hyperexcitability, tremors, muscle fasciculations, pulmonary edema, respiratory failure, and seizures.[39,40]

Diagnosis Diagnosis is dependent on a history of exposure. Differential diagnosis includes allergic reactions and ingestions with neurologic stimulants. Laboratory tests have no diagnostic value.

Treatment Treatment includes removal from exposure; dermal, ocular, and GI decontamination; treatment of allergic manifestations; and supportive care.

Disposition and Follow-Up Disposition is usually related to the severity of asthmatic and allergic manifestations. The clinical course is usually benign, and hospitalization is not necessary for most accidental exposures.

NEONICOTINOIDS

Neonicotinoids are structurally similar to nicotine, acting as agonists at the postsynaptic acetylcholine receptor. Neonicotinoids have high affinity for the receptors within the insect CNS, producing paralysis and death. Commercially available agents from this family include imidacloprid, thiamethoxam, clothianidin, acetamiprid, thiacloprid, dinotefuran, and nitenpyram.

Data regarding human toxicity are limited to case reports. Toxicity from imidacloprid poisoning is relatively mild to moderate in most cases, with symptoms of nausea, emesis, diarrhea, and headache.[41] However, uncommon cases of respiratory failure, encephalopathy, hypotension, rhabdomyolysis, and renal failure have occurred.[42-44] Toxicity from acetamiprid poisoning has been associated with severe nausea and vomiting, muscle weakness, hypothermia, convulsions, and hypothermia.[45] Treatment is supportive.

NEREISTOXIN ANALOGS

Analogs of nereistoxin are considered low-toxicity insecticides. Agents in common use include nensultap, cartap, thiocyclam and thiosultap. These insecticides induce neurotoxicity by promoting extracellular

calcium influx and stimulating the release of intracellular calcium from the sarcoplasmic reticulum.

Case reports of toxicity from occupational skin exposure report nausea, vomiting, muscles tremors, dyspnea, and mydriasis. Intentional ingestions are associated with depressed level of consciousness, muscle fasciculations and spasms, seizures, hypotension, and hypoxia.[46-48]

Animal studies suggest that sulfhydryl-containing compounds, such as l-cysteine, acetylcysteine, d-penicillamine, and dimercaprol, are effective antidotes, but human data are lacking, and suggested doses are conjectures. Recovery from severe toxicity associated with coma is possible, although death from multiple organ failure may occur.

AMITRAZ

Amitraz is a topical insecticide and acaricide, as well as an insect repellant. Amitraz is used as a spray on agricultural crops and as a wash-solution to treat ectoparasites found on farm animals, dogs, and cats. Amitraz possesses agonist activity at the postsynaptic α_2-adrenergic receptor, and interacts with the neuromodulator octopamine, inhibits monoamine oxidase, and impairs prostaglandin synthesis.

The clinical manifestations following human overdose include mental status depression, bradycardia, respiratory depression, miosis, hypotension, and hypothermia.[49,50] Mechanical ventilation may be required, and with supportive therapy, recovery is expected.

N,N-DIETHYL-3-METHYLBENZAMIDE (DEET)

DEET is used extensively as an over-the-counter insect repellant that comes in a variety of product formulations ranging in concentrations from 5% to 100%. When used as directed, they are generally safe. Toxicity can occur with ingestion or prolonged exposure on covered or damaged skin. DEET is absorbed through the skin and is a neurotoxin that causes seizures after large ingestions and extensive dermal exposures of high-concentration products. Small children are most susceptible to systemic toxicity from skin absorption. Skin absorption occurs within 2 hours of topical application, but peak concentrations may be delayed several hours.

Systemic toxicity is rare but manifests as restlessness, insomnia, altered behavior, confusion, neurologic depression, slurred speech, ataxia, tremors, muscle cramps, hypertonia, and seizures occurring with or without prodrome. DEET-induced hypotension and bradycardia have been reported with heavy dermal or oral exposure. Treatment includes benzodiazepines for seizures, skin decontamination with mild detergent and water, and activated charcoal for recent ingestions. Most patients recover with supportive care.

HERBICIDES

Herbicides are used to kill weeds. Mechanisms of plant toxicity includes inhibition of photosynthesis, respiration, protein synthesis, or growth stimulation mimicking plant hormones called *auxins*. Some classes pose a health hazard to humans (**Table 201-5**). Herbicidal formulations contain multiple ingredients such as organic solvents, surfactants, and preservatives that may have their own toxic effects; these may not be always disclosed on the product label.

CHLOROPHENOXY HERBICIDES

Chlorophenoxy herbicides are synthetic plant hormones. The most commonly used compounds are 2,4-dichlorophenoxyacetic acid (2,4-D) and 4-chloro-2-methylphenoxy-acetic acid. 2,4,5-Trichlorophenoxy acetic acid (2,4,5-T) has been banned in the United States because of its contamination with 2,3,7,8,-tetrachlorodibenzo-*p*-dioxin. The aerially applied defoliant Agent Orange used during the Vietnam War was a mixture of 2,4-D and 2,4,5-T. These compounds are effective against broadleaf plants and are used as weed killers on lawns and grain crops.

Pathophysiology The metabolic pathway or mechanism related to human toxicity is unknown. Toxicity can result from dermal contact, inhalation, or ingestion. Systemic absorption can produce neurologic, cardiac, and skeletal muscle toxicity.

Clinical Features Local exposure leads to eye and mucous membrane irritation that may last for days. After ingestion, nausea, vomiting, and diarrhea occur. Pulmonary toxicity may produce dyspnea, tachypnea, and signs of pulmonary edema. Cardiovascular findings include hypotension, tachycardia, and dysrhythmias. Mental status changes and seizures may occur. Muscle toxicity manifests as muscle tenderness, fasciculations, myotonia, and rhabdomyolysis. The patient may become hyperthermic. Peripheral neuropathy has been described in the recovery phase after acute exposure and with chronic exposure.

Diagnosis Diagnosis is based on a history of exposure. Ancillary tests generally are nonspecific but may demonstrate a metabolic acidosis, rhabdomyolysis, or evidence of hepatorenal dysfunction. Toxin levels are not immediately available. Differential diagnosis includes other causes of acute myopathy.

Treatment Treatment is supportive, including decontamination measures and respiratory support for myopathic-related respiratory failure.[51,52] Urinary alkalinization will increase the elimination of these compounds and is recommended for severely poisoned patients.[53] Hemodialysis can also be used to enhance chlorophenoxy herbicide clearance. Patients should be monitored for rhabdomyolysis and treated as necessary.

Disposition and Follow-Up Severe toxicity and serious complications are not common following chlorophenoxy herbicides. Because toxic effects usually appear within 4 to 6 hours, patients with mild symptoms can be observed and discharged after that time. Significant toxicity warrants admission.

BIPYRIDYL HERBICIDES

The bipyridyl compounds, **paraquat and diquat**, are nonselective contact herbicides. Both are used widely and are responsible for significant morbidity if ingested.[54] Paraquat is a fast-acting, nonselective herbicide. It is used for killing grass and weeds; is manufactured as a liquid, granules, or an aerosol; and is commonly combined with diquat and other herbicides. Most products contain a blue dye, a stenchant, and an emetic. Ingestion is responsible for the majority of paraquat deaths,[54] although deaths have been reported after transdermal exposure. Inhalation exposure to sprays can be very irritating to conjunctiva and the airway but are unlikely to cause systemic toxicity.

Pathophysiology Paraquat is a severe local irritant and devastating systemic toxin.[55] There is minimal transdermal absorption of paraquat in the absence of preexisting skin lesions. Ingested paraquat is absorbed rapidly, particularly if the stomach is empty. Plasma concentration peaks within minutes to 2 hours after ingestion. Paraquat is then distributed to most organs, with the highest concentrations found in the kidneys and lungs. A lethal oral dose of the 20% concentrate solution is about 10 to 20 mL in an adult and 4 to 5 mL in a child.

Paraquat actively accumulates in the alveolar cells of the lungs, where it is transformed into a reactive oxygen species, the superoxide radical.[55] This anion is responsible for lipid peroxidation that leads to degradation of cell membranes, cell dysfunction, and necrosis. Lung injury has two phases. An initial destructive phase is characterized by loss of type I and type II alveolar cells, infiltration by inflammatory cells, and hemorrhage. These changes may be reversible. The later, proliferative phase is characterized by fibrosis in the interstitium and alveolar spaces. Paraquat and oxygen enhance each other's toxicity by sustaining the redox cycle. Myocardial injury and necrosis of the adrenal glands may occur.

TABLE 201-6 Paraquat Toxicity from Ingestion

Category	Clinical Features	Approximate Amount Ingested
Mild	Asymptomatic or nausea, vomiting, and diarrhea. Renal and hepatic injury minimal or absent. Decreased pulmonary diffusion capacity may be present. Complete recovery expected.	<20 milligrams/kg or <7.5 mL of 20% concentrated solution in average adult
Severe	Initially nausea, vomiting, diarrhea, abdominal pain, mouth and throat ulceration. Positive colorimetric test for paraquat in the urine. 1–4 d: renal failure, hepatic impairment, hypotension. 1–2 wk: cough, hemoptysis, pleural effusion, pulmonary fibrosis. Survival possible, but majority of cases die within 2–3 wk from pulmonary failure.	Between 20 and 40 milligrams/kg or between 7.5 and 15 mL of 20% concentrated solution in average adult
Fulminant	Initially nausea, vomiting, diarrhea, and abdominal pain. Rapid development of renal and hepatic failure, GI ulceration, pancreatitis, toxic myocarditis, refractory hypotension, coma, convulsions. Death from cardiogenic shock and multiorgan failure within 1–4 d.	>40–50 milligrams/kg or >15–20 mL of 20% concentrated solution in average adult

Diquat has a similar structure and mechanism as paraquat. Formulations containing diquat do not contain the dye, stenching agent, or emetic usually added to paraquat. The lethal dose for diquat is similar to that of paraquat, but there is less occurrence of pulmonary injury and fibrosis because of diquat's lower affinity for pulmonary tissue. Diquat is caustic to the skin and GI tract, and exposure can result in renal and liver necrosis.

Clinical Features Clinical features depend on the route of exposure and amount. Paraquat's severe caustic effects produce local skin irritation and ulceration of epithelial surfaces. Severe corrosive corneal injury may result from eye exposure. Upper respiratory tract exposure may result in mucosal injury and epistaxis. Inhalation may lead to cough, dyspnea, chest pain, pulmonary edema, epistaxis, and hemoptysis. Respiratory symptoms may persist for several weeks after inhalation exposure.

Ingestion causes GI irritation and mucosal damage with ulcerations (**Table 201-6**). A burning sensation of the lips or mouth may occur within a few minutes to hours followed by ulceration 1 to 2 days later. Nausea, vomiting, diarrhea, buccopharyngeal pain, esophageal pain, and abdominal pain may develop. Hypovolemia occurs from GI fluid losses and decreased oral intake.

Multisystem effects include GI tract corrosion, acute renal failure, cardiac failure, hepatic failure, and extensive pulmonary injury. The effects can be evident within a few hours following large ingestions, but, more typically, manifestations of renal failure and hepatocellular necrosis develop between the second and fifth days, with progressive pulmonary fibrosis leading to refractory hypoxemia 5 days to several weeks later. Metabolic (lactic) acidosis is common as a result of pulmonary effects (hypoxemia) and multisystem failure.

Diagnosis Early diagnosis and therapy are important. Obtain details of the exposure, including accidental or intentional, route of exposure, concentration of the product, time of occurrence, and estimated amount. The differential diagnosis includes exposure to other corrosive agents and herbicides. Qualitative and quantitative analyses for paraquat in urine and blood can assist in the diagnosis, and nomograms are used for predicting survival based on plasma paraquat concentration and time of ingestion.[55] A commercially available semi-qualitative colorimetric test (Paraquat Test Kit®; Syngenta CTL, Surrey, United Kingdom) can be done on urine or plasma to detect paraquat within a few hours after ingestion; such detection indicates potentially severe course. Serial pulmonary function tests, chest radiographs, and arterial blood gas determinations, including alveolar-arterial gradient, and arterial lactate may be used to monitor toxicity.[56]

Laboratory abnormalities generally reflect multiorgan necrosis. Chest radiographs may show pneumomediastinum or pneumothorax due to corrosive rupture of the esophagus. Radiographic abnormalities of diffuse consolidation indicating parenchymal injury on the chest radiograph may not parallel the severity of clinical symptoms. Upper GI endoscopy should be performed to identify the extent and severity of mucosal lesions.

Treatment **The goal of early and vigorous decontamination is to prevent absorption and pulmonary toxicity. Any exposure to paraquat is a medical emergency, with hospitalization indicated even if the patient is asymptomatic.** Early treatment is mainly supportive but is an important determinant of survival. Do not administer supplemental oxygen unless the patient is severely hypoxic, because added oxygen stimulates superoxide radical formation and promotes oxidative stress.

Remove clothing and decontaminate skin with mild detergent and water. Take care to avoid skin abrasions that may increase absorption. If there is conjunctival irritation, irrigate with copious amounts of water or saline. Fluid and electrolytic losses can occur from GI tract damage, vomiting, and cathartics. Maintain intravascular volume and urine output to prevent prerenal kidney injury. Pain associated with oropharyngeal lesions should be treated with opioids. Emesis is common, and there is no proven benefit to gastric lavage.[55] In patients with pharyngeal or esophageal burns, prophylactic placement of a nasogastric tube for subsequent enteral nutrition is recommended.[55]

Immediate GI decontamination with absorbents that bind paraquat is indicated in patients with a protected airway. A single dose of activated charcoal (1 to 2 grams/kg), diatomaceous fuller's earth (1 to 2 grams/kg in 15% aqueous suspension), or bentonite (1 to 2 grams/kg in a 7% aqueous slurry) should be used.[55] **Charcoal hemoperfusion can remove paraquat and has been recommended to be started as soon as possible and continued for 6 to 8 hours, but there is no evidence to show that prognosis is improved.**[55] Repeated pulse doses of glucocorticoids and cyclophosphamide may improve survival in severe cases.[57-59]

Supportive care includes airway protection, maintaining intravascular volume, pain relief, treatment of renal failure and complications, and treatment of infection. Maintaining renal function will assist in avoiding toxic accumulation in other tissues.

Treatment for diquat poisoning is similar to that for paraquat, and despite the lower toxicity for diquat, mortality approaches 50% following intentional diquat ingestion.

Disposition and Follow-Up Outcome is determined by the amount ingested; therefore, intentional ingestions tend to have a worse prognosis.[60] Prognosis is worse ingesting a highly concentrated liquid formulation on an empty stomach. Conversely, ingestion of dilute solid formulations rarely cause death.

UREA-SUBSTITUTED HERBICIDES

Urea-substituted herbicides such as chlorimuron, diuron, fluometuron, and isoproturon are inhibitors of photosynthesis and have low systemic toxicity. In humans, methemoglobinuria may occur with ingestion.[61] Treatment includes decontamination, supportive care, and treatment for methemoglobinemia with methylene blue, as appropriate (see chapter 207, "Dyshemoglobinemias").

ORGANOPHOSPHATE HERBICIDES

In addition to their use as insecticides, some organophosphate compounds are effective herbicides. Butiphos is used commonly as a cotton defoliant before mechanical harvesting. Treatment is identical to that for organophosphate insecticides.

GLYPHOSATE

Glyphosate is the active ingredient in many widely used preparations available for consumer use on lawns and gardens. A problem with lawn and garden chemicals is that some products sold using a common or group brand name may contain different active ingredients; a common brand name may contain either glyphosate or the more toxic herbicide diquat.

Glyphosate can produce severe toxicity with massive ingestions of the diluted product or ingestions of concentrated solutions.[62] Preparations

TABLE 201-7 Nonanticoagulant Rodenticides

Rodenticide	Toxicity	Mechanism	Clinical Effects	Treatment
Arsenic	Severe	Binds sulfhydryl groups on proteins	Dysphagia, muscle cramps, nausea and vomiting, bloody diarrhea, cardiovascular collapse, altered mental status, seizures, and late peripheral neuropathies	Gastric lavage, activated charcoal, catharsis, chelation therapy using succimer, dimercaprol, or penicillamine
Barium carbonate and other soluble forms such as barium chlorides, hydroxides, and sulfides	Severe	Depolarizing neuromuscular blockade	Onset occurs within 1–8 h with nausea, vomiting, diarrhea, abdominal pain, dysrhythmias, respiratory failure, muscular weakness, paresthesias, and paralysis	Gastric lavage with sodium or magnesium sulfate added to lavage solution to convert carbonate to less toxic sulfate; potassium replacement
Elemental or yellow phosphorus	Severe, early cardiac and neurologic toxicity is a poor prognostic sign	Caustic; uncouples oxidative phosphorylation	Skin irritation, cutaneous burns, oral burns, abdominal pain, hematemesis, possible "smoking" luminescent vomitus and stool, garlicky odor, direct toxic effects on the myocardium, kidney, and peripheral vessels, cardiovascular collapse; late neurologic depression with multisystem toxicity and hepatorenal syndrome	Gastric lavage with dilute potassium permanganate solution may convert phosphorus to less toxic phosphates; activated charcoal; avoid emesis
N-3-Pyridylmethyl-*N*′-*p*-nitrophenylurea (PNU or Vacor)	Severe	Destroys pancreatic β cells within hours of ingestion by interfering with nicotinamide metabolism	Within 24 h of ingestion, GI symptoms, perforation, autonomic nervous system dysfunction, insulin-deficient hyperglycemia or diabetic ketoacidosis, dysrhythmias, neuropathies	Nicotinamide (niacinamide) IV or IM is an antidote; lavage for recent ingestions; activated charcoal and insulin for treatment of hyperglycemia and ketoacidosis
Sodium fluoroacetate (SFA)[67]	Severe	Blocks Krebs cycle	Nausea, vomiting, apprehension, lactic acidosis, seizures, coma, respiratory depression, cardiac dysrhythmias, and pulmonary edema; electrocardiographic abnormalities include ST-segment and T-wave changes, tachycardia, premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation; hyperkalemia and hypocalcemia are common	Activated charcoal, seizure and dysrhythmia control, and supportive care; experimental regimens include glycerol monoacetate, calcium gluconate, sodium succinate, and ethanol loading; consultation with a toxicologist is recommended
Strychnine	Severe	Competitive antagonism of the inhibitory neurotransmitter glycine at the postsynaptic brainstem and spinal cord motor neuron	Restlessness, muscle twitching, painful extensor spasms, opisthotonos, trismus, inability to swallow, and facial grimacing; medullary paralysis and death can follow	Airway control, quiet environment (minimize sensory stimulation), and activated charcoal; avoid lavage (may precipitate seizures); benzodiazepines, barbiturates, analgesia; neuromuscular blockage if necessary
Tetramine[68-70]	Severe	Blocks γ-aminobutyric acid receptors in the CNS	Rapidly acting; initial features include headache, nausea, dizziness, fatigue, anorexia, numbness, and listlessness; severe symptoms include loss of consciousness, seizures, and coma; death usually caused by respiratory failure	The median lethal dose for tetramine is ~0.1 milligram/kg; 6–12 milligrams sufficient to kill an adult; no antidote; supportive care; benzodiazepines or barbiturates for seizures
Thallium sulfate[71]	Severe	Combines with mitochondrial sulfhydryl groups, interfering with oxidative phosphorylation	Early GI symptoms: nausea, vomiting, and abdominal pain; after 2–5 d, painful paresthesias, myalgias, muscle weakness, headache, lethargy, tremors, ataxia, delirium, seizures, and coma; death from respiratory failure and dysrhythmias; alopecia after approximately 2 wk; chronic neurologic sequelae	Supportive care; multiple doses of activated charcoal or Prussian blue (potassium ferric hexaniacinate) to interrupt enterohepatic circulation and increase elimination in stool; hemodialysis
Zinc or aluminium phosphide[72-76]	Severe	Combines with water and stomach acid to produce phosphine gas; cellular toxicity and necrosis to the GI tract, kidney, and liver if ingested and to the lungs if inhaled	Immediate nausea, vomiting, epigastric pain, phosphorous or fishy breath, black vomitus, and GI irritation or ulceration; myocardial toxicity, shock, and acute lung injury; agitation, coma, seizures, hepatorenal injury, metabolic acidosis, hypocalcemia, tetany	Gastric lavage with potassium permanganate or combination coconut oil and sodium bicarbonate; magnesium sulfate IV[77]; treat acidosis and hypocalcemia; consider acetylcysteine[78]; supportive care
α-Naphthyl-thiourea (ANTU)	Moderate	Increases alveolar capillary permeability, causing pulmonary edema	Dyspnea, cyanosis, cough, pleuritic chest pain, noncardiogenic pulmonary edema, and pleural effusion	Supportive care; activated charcoal
Cholecalciferol (vitamin D_3)	Moderate	Mobilization of calcium from bones	Hypercalcemia, osteomalacia, and systemic metastatic calcifications	Treat hypercalcemia with IV normal saline, furosemide, steroids, calcitonin, and biphosphates as needed
Bromethalin	Low	Uncouples oxidative phosphorylation in CNS mitochondria, interrupting nerve conduction	Muscle tremors, myoclonic jerks, contractions of flexor muscles, ataxia, and focal motor seizures; personality changes, confusion, and coma	Decontamination; benzodiazepines for seizures
Norbormide or dicarboximide	Low	Irreversible smooth muscle vasoconstriction	Tissue hypoxia and ischemia	Supportive care; decontamination
Red squill	Low (limited toxicity in humans due to early onset of emesis with gastric emptying)	Blocks sodium-potassium adenosine triphosphatase (similar to digoxin poisoning)	Nausea, protracted vomiting, diarrhea, abdominal pain; massive ingestion causes hyperkalemia, atrioventricular block, ventricular irritability with dysrhythmias, and death	Treat as digoxin toxicity (atropine, external pacing, digoxin-specific antibody fragments, activated charcoal)

may contain the toxic surfactant polyoxyethyleneamine, which is a corrosive, and the combination is more toxic than glyphosate alone. Inhalational exposures cause respiratory irritation. Dermal absorption is poor, so symptomatic poisonings are generally from ingestion.

Clinical effects include mucous membrane irritation and erosions with nausea, vomiting, abdominal pain, and diarrhea.[63] Widespread organ failure with refractory cardiovascular collapse and dysrhythmias has been reported. Respiratory distress requiring intubation, metabolic acidosis, tachycardia, renal failure, and hyperkalemia portend a fatal outcome.

Treatment includes activated charcoal following a recent ingestion and supportive care, with attention to support of oxygenation and ventilation, ameliorating complications due to the corrosive effects on the GI tract, treating hyperkalemia, and supporting the circulation. Intravenous lipid emulsion is reported as useful in preventing hypotension[64] and treating refractory hypotension.[65] Hemodialysis may be supportive when severe acidosis and acute kidney injury are present.[66]

Patients with small, asymptomatic ingestions can be discharged after 6 hours of observation. Significant GI symptoms, altered level of consciousness, hypoxemia, metabolic acidosis, and cardiovascular abnormalities indicate admission to an intensive care unit.

RODENTICIDES

A number of agents with distinct toxicities are used as rodenticides. Rodenticides are commonly classified based on whether they are anticoagulants or nonanticoagulants. Although intentional ingestions are often associated with significant morbidity and mortality, most unintentional exposures occur in young children and result in minimal or no toxicity.

NONANTICOAGULANTS

A number of nonanticoagulant rodenticides have been used throughout history. Many have been discontinued, although poisonings still occur from old product stored in garages, barns, and homes (**Table 201-7**).

ANTICOAGULANTS

Warfarin-type anticoagulants were the first generation of anticoagulant rodenticides and distributed commonly disguised as yellow corn meal or rolled oats.[79] **Most one-time warfarin rodenticide ingestions are insignificant accidental poisonings and do not cause any bleeding problems. Significant coagulopathy requires large amounts in a single exposure or a repetitive exposure over several days.** Following a single large ingestion, onset of the anticoagulant effect takes place within 12 to 48 hours. Warfarin's biologic half-life is approximately 42 hours.

Therapy is not necessary for ingestion of a single mouthful of a warfarin rodenticide. For potentially toxic recent ingestion, consider activated charcoal. Obtain a baseline prothrombin time and INR determination and repeat it in 12 to 24 hours. Vitamin K_1 (phytonadione) administration is indicated if the INR is >2.0. The suggested total PO daily dose is 1 to 5 milligrams in children and 20 milligrams in adults, administered in two to four divided doses.

Second-generation superwarfarins and the indandione derivatives were introduced when rodent resistance to warfarin began to appear.[79] They are currently responsible for approximately 80% of human rodenticide exposures reported in the United States. Their mechanisms are the same as that of warfarin, but they are more potent, have more prolonged anticoagulant activity, and therefore have the potential to be highly toxic. Poisonings involving the indandione derivatives pindone, diphacinone, chlorophacinone, and valone have toxic and clinical characteristics similar to those of the superwarfarins.

The **superwarfarins** include the 4-hydroxy-coumarins brodifacoum, diphenacoum, coumafuryl, and bromadoline. These are readily available over the counter as grain-based bait. After intentional ingestions, adults often develop a coagulopathy within 24 to 48 hours. **Because the biologic half-life of brodifacoum is approximately 120 days, a single ingestion may result in marked anticoagulation effects for weeks to months.**[80] Intentional repeated ingestions can cause severe bleeding.

The diagnosis may not be readily apparent. Some patients may not report an intentional ingestion. Small children and depressed patients with an unexplained coagulopathy and/or bleeding should raise suspicion of superwarfarin poisoning. Although the prothrombin time and INR are usually monitored, large doses of warfarin can also cause prolongation of the activated partial thromboplastin time. **Superwarfarins are not detected by warfarin assays, but specific serum assays are available in reference laboratories.**

Unintentional superwarfarin ingestions in the pediatric patient are unlikely to result in significant toxicity.[81] Obtain a baseline INR and repeat 24 and 48 hours after ingestion. For acute intentional ingestions, gastric lavage is indicated for early presentations, and activated charcoal should be administered. Obtain a baseline INR and repeat in 12 and 24 hours. If the INR is elevated but there is no active hemorrhage, oral vitamin K_1 is recommended. Because of the extended half-life of the anticoagulant, prolonged therapy with high doses of vitamin K_1 may be required to maintain hemostasis.[82,83] Initial daily doses of 1 to 5 milligrams in children and 20 milligrams in adults are recommended with titration to maintain a normal INR. Doses up to 100 milligrams per day for 10 months have been reported. Upon discontinuation of vitamin K_1 therapy, serial INR determinations are required to ensure that further therapy is not needed.

Patients with acute hemorrhage may require repletion of volume losses with normal saline or blood transfusions. Fresh frozen plasma should be used if bleeding is severe or unresponsive to vitamin therapy. Vitamin K_1, 10 milligrams, should be administered by slow IV infusion to minimize the risk of a hypotensive reaction. Forms of vitamin K other than vitamin K_1 are ineffective because the conversion of these other forms to the active form is blocked by superwarfarins. Administration of prothrombin complex concentrates or recombinant activated factor VII can be considered for patients with ongoing hemorrhage despite fresh frozen plasma and vitamin K_1 therapy.

For asymptomatic patients who have accidentally ingested a superwarfarin, follow-up in 24 and 48 hours for coagulation studies should be arranged. Prevention measures should be emphasized.

CONSULTATION

Consultation with a poison control center or medical toxicologist is recommended to assist in patient management and to collect data for surveillance reports. When consulting, precise communication of the specific product name from the container label is essential to identify both active and inert ingredients. As noted, confusion can arise because similar brand names are used for more than one agent.

CHAPTER 202

Anticholinergics

Dan Quan
Frank Lovecchio

INTRODUCTION

Approximately 620 compounds have anticholinergic properties, including prescription drugs, over-the-counter medications, and plants (**Table 202-1**). Many of these substances possess anticholinergic activity as either a direct therapeutic effect or an adverse effect, in addition to their primary or predominant pharmacologic effect. Atropine (D,L-hyoscyamine), hyoscyamine, and scopolamine (L-hyoscine) are natural alkaloids that represent prototypical anticholinergic compounds.

Antihistamine (particularly diphenhydramine) overdose is the most common overdose that produces anticholinergic toxicity.[1] Toxicity in

TABLE 202-1 Major Groups of Substances with Anticholinergic Activity

Class and Subclass	Prototypical Agent(s)
Cyclic antidepressants	Amitriptyline hydrochloride, imipramine hydrochloride, doxepin hydrochloride
Antihistamines	
Ethanolamines	Diphenhydramine, dimenhydrinate
Ethylenediamines	Tripelennamine
Alkylamines	Chlorpheniramine
Piperazines	Loratadine, meclizine, cetirizine
Phenothiazines	Prochlorperazine, promethazine
Antiparkinson drugs	
Tropanes	Benztropine mesylate
Piperidines	Trihexyphenidyl
Antipsychotics	
Phenothiazines	Chlorpromazine, thioridazine, perphenazine
Nonphenothiazines	Clozapine, olanzapine, molindone, loxapine, quetiapine
Antispasmodics	
Cyclohexane carboxylic acids	Dicyclomine
Quaternary ammonium	Methantheline bromide
Belladonna alkaloids	
Tropanes	Atropine, homatropine, scopolamine hydrobromide
Pyrrolidines	Glycopyrrolate
Mydriatics	
Phenylacetates	Cyclopentolate hydrochloride
Pyridines	Tropicamide
Skeletal muscle relaxants	
Tricyclics	Cyclobenzaprine hydrochloride
Ethylamines	Orphenadrine citrate
Plants	
Datura species	*Datura stramonium* (Jimson weed), *Datura candida* (angel's trumpet)
Mandragora species	*Mandragora officinarum* (mandrake)
Brugmansia species	*Brugmansia suaveolens* (angel's tear, maikoa, or white angel's trumpet), *Brugmansia versicolor* (angel's tear or angel's trumpet)
Mushrooms	
Amanita species	*Amanita muscaria, Amanita pantherina*

children may result from accidental ingestion of an anticholinergic medication, administration of hyoscyamine-containing agents to treat colic, the topical use of diphenhydramine-containing salves, and therapeutic application of a transdermal hyoscine patch.[2-5] In the elderly, therapeutic doses of one or multiple medications with anticholinergic properties may produce anticholinergic symptoms or ileus without all the signs of the anticholinergic toxidrome.[6,7] Ophthalmologic instillation of anticholinergic mydriatic agents can cause toxicity, especially in the elderly or young children; thus patients are instructed to lie down and apply 5 minutes of gentle pressure on the nasolacrimal duct when instilling these agents.[8]

Atropine is the antidote for a cholinergic syndrome produced from a nerve agent or an organophosphate insecticide.[9] Use of high-dose atropine by someone without cholinesterase poisoning may result in anticholinergic toxicity within 1 hour. This occurred in Israel during the first Gulf War in 1991 when frightened civilians dosed themselves with atropine fearing an incoming Scud missile chemical weapon attack.

Plant poisonings may result in an anticholinergic toxidrome. In Taiwan, the anticholinergic toxidrome is most commonly associated with plant exposures.[10] Belladonna alkaloid-containing plants have potent anticholinergic effects producing toxicity 1 to 4 hours after ingestion or sooner if smoked. Alkaloid plants are abused for their hallucinogenic effects.[11,12] Group anticholinergic plant poisonings are common in adolescents seeking these psychoactive hallucinogenic effects.[13,14] Inadvertent poisoning from the ingestion of belladonna-contaminated herbal teas and Chinese traditional medicines has been reported.[15,16] Ingestion of seeds and berries, sometimes due to mistaken identity, can produce anticholinergic toxicity.[17,18] Anticholinergics have been substituted for other abused psychoactive drugs and then sold to unwitting customers.[19] Adulteration of commonly abused drugs, such as heroin or cocaine, with scopolamine or atropine has been observed.[20-22]

PHARMACOLOGY

Anticholinergic drug absorption can occur after ingestion, smoking, or ocular use. With oral ingestion, the onset of anticholinergic toxicity usually occurs within 1 to 2 hours. Because muscarinic blockade slows gastric emptying and decreases GI motility, absorption and peak clinical effects are often delayed. An example is diphenoxylate-atropine (e.g., Lomotil®), an antidiarrheal agent that may present with toxicity up to 12 hours after ingestion.

Cholinergic receptors exist as two major subtypes: muscarinic receptors and nicotinic receptors. Muscarinic receptors are found predominantly on autonomic effector cells that are innervated by postganglionic parasympathetic nerves, on some ganglia, and in the brain, particularly the hippocampus, cortex, and thalamus. Nicotinic receptors are found at peripheral autonomic ganglia, neuromuscular junctions, and also the brain. Acetylcholine is the neurotransmitter that modulates both receptor types. Five genes encode for muscarinic receptors through G protein receptor activation; four seem to be physiologically active (**Table 202-2**).

The structure of nicotinic receptors is complex, composed of several subunits that are encoded by multiple genes. The subunits are combined into four main families of nicotinic receptors: the muscle type, found at the neuromuscular junction; the ganglion type, found in autonomic ganglia; and two brain types, found in the CNS.

Anticholinergic drugs and plant toxins competitively inhibit or antagonize the binding of the neurotransmitter acetylcholine to muscarinic acetylcholine receptors. The term *anticholinergic* is technically a misnomer; a more accurate term is *antimuscarinic* agents, because anticholinergic agents do not antagonize the effects at nicotinic acetylcholine receptors, such as at the neuromuscular junction. Clinical manifestations from these drugs are modulated through disturbances in the CNS (central effects) and the parasympathetic nervous system (peripheral effects) (**Table 202-3**).

The signs and symptoms of anticholinergic toxicity are a result of both central and peripheral cholinergic blockade. The *central anticholinergic*

TABLE 202-2 Muscarinic Receptors

Receptor	Target Organ	Receptor Action When Stimulated
M_1	Autonomic ganglia Brain Salivary glands Stomach	Decreases activity in autonomic ganglia Increases salivary and gastric acid secretion
M_2	Heart	Decreases sinus node rate and slows conduction through the atrioventricular node Decreases the force of atrial contraction and possibly ventricular contraction
M_3	Smooth muscle Endocrine/exocrine glands Iris	Bronchospasm Mild vasodilation Increases saliva and gastric acid production Constricts the pupil
M_4	CNS	Multiple actions
M_5	Has not been elucidated	

TABLE 202-3 Muscarinic and Antimuscarinic Effects

Organ	Stimulation or Muscarinic Effect	Antagonism or Antimuscarinic Effect
Brain	Complex interactions Possible improvement in memory	Complex interactions Impairs memory Produces agitation, delirium, and hallucinations Fever
Eye	↓ pupil size (miosis) ↓ intraocular pressure ↑ tear production	↑ pupil size (mydriasis) ↑ intraocular pressure Loss of accommodation (blurred vision)
Mouth	↑ saliva production	↓ saliva production Dry mucous membranes
Lungs	Bronchospasm ↑ bronchial secretions	Bronchodilation
Heart	↓ heart rate Slows atrioventricular conduction	↑ heart rate Enhances atrioventricular conduction
Peripheral vasculature	Vasodilation (modest)	Vasoconstriction (very modest)
GI	↑ motility ↑ gastric acid production Produces emesis	↓ motility ↓ gastric acid production
Urinary	Stimulates bladder contraction and expulsion of urine	↓ bladder activity Promotes urinary retention
Skin	↑ sweat production	↓ sweat production (dry skin) Cutaneous vasodilation (flushed appearance)

syndrome refers to the clinical state when the central effects of muscarinic receptor antagonism predominate, with fever, agitation, delirium, and coma. The *peripheral anticholinergic syndrome* refers to the syndrome seen with peripheral muscarinic antagonism, such as tachycardia, flushed dry skin, dry mouth, ileus, and urinary retention.

The full range of clinical manifestations associated with anticholinergic overdose may only be partly explained by muscarinic receptor blockade. Many of these anticholinergic agents possess activity at other cell membrane receptors, and toxicity after overdose can be a mixture of multiple pharmacologic mechanisms. For example, the clinical findings associated with cyclic antidepressant overdose are only partly characterized by the anticholinergic effects that vary considerably among different cyclic antidepressants. The most life-threatening complications of cyclic antidepressant overdose are a result of the sodium-channel blocking effects on the heart, producing wide-complex tachydysrhythmias, not the anticholinergic effects.

Intravenous injection of antihistamines, particularly those affecting the H_1 histamine receptor antagonists (diphenhydramine), seems to cause euphoria in some patients. This effect may be attributed to the drug increasing dopamine levels in the nucleus accumbens area of the brain that stimulates the reward and motivation system.[23]

CLINICAL FEATURES

The classic features of the anticholinergic toxidrome can be stated as:

- Dry as a bone
- Red as a beet
- Hot as a hare
- Blind as a bat
- Mad as a hatter
- Stuffed as a pipe

Dry skin (especially dry axillae) and dry mucous membranes (e.g., dry mouth) are the typical peripheral clinical manifestations, the result of impaired sweat gland and salivary gland secretions, respectively. The skin may be warm and flushed (red) from cutaneous vasodilatation. Other typical peripheral features of muscarinic blockade include hypoactive or absent bowel sounds secondary to decreased peristalsis and GI motility. A palpable bladder or enlargement on bedside US secondary to urinary retention may be seen.

Sinus tachycardia is usually present. More malignant dysrhythmias are less common. Ingestions of large amounts of diphenhydramine have been associated with wide-complex tachydysrhythmias from a sodium-channel blocking effect and not from an anticholinergic effect.[24,25] Diphenhydramine overdose has been reported to cause QT-interval prolongation.[26,27] Dilated pupils are often a delayed clinical finding (12 to 24 hours) that may not be observed despite the presence of other anticholinergic signs.

The **delirium** of the central anticholinergic syndrome is characterized by restlessness, irritability, disorientation, confusion, agitation, auditory and visual hallucinations, and incoherent speech. The anticholinergic toxic patient has great difficulty interacting appropriately with environmental stimuli. Lilliputian ("little people") hallucinations have been described in this setting. Repetitive picking at the bed clothes or imaginary objects is also characteristic. A characteristic feature of anticholinergic delirium is dysarthria, manifested by a staccato speech pattern and difficult-to-comprehend speech. This may be exacerbated by severe dysphasia from decreased mucous secretion. High-pitched cries may sometimes be heard. Patients may also exhibit jerking movements of the extremities and seizures.

Although this delirium is usually accompanied by the peripheral manifestations discussed above, clinical presentations vary, and tachycardia without delirium or delirium without tachycardia may occur. "Agitated depression" can occur from both central excitation and depression. Depression is usually associated with higher doses, and features include lethargy, somnolence, and coma. Overdose with olanzapine, an atypical antipsychotic with significant anticholinergic properties, produces unpredictable fluctuations in mental status, from somnolence to agitation lasting hours.[28]

Agitation-induced hyperthermia is a worrisome complication of anticholinergic toxicity, and its development may be significantly potentiated by decreased sweating and the inability to dissipate heat. A markedly elevated body temperature may lead to multisystem organ dysfunction and rhabdomyolysis, resulting in liver, kidney, and brain injury and coagulopathy. Fatalities associated with anticholinergic overdose are characterized by severe agitation, status epilepticus, hyperthermia, wide-complex tachydysrhythmias (usually from sodium channel–blocker effect), and cardiovascular collapse.[29]

The risk of toxicity for most anticholinergic agents is dose related. For example, severity of diphenhydramine overdose correlates with the amount ingested, with moderate symptoms occurring after ingestion of 300 milligrams[30] and 7.5 milligrams/kg in children,[31] and severe symptoms seen only after ingestions of 1000 milligrams or more in adults.[30]

DIAGNOSIS

DRUG SCREENING

In patients with altered mental status, obtain routine laboratory evaluation, including measurement of electrolytes, glucose, creatine kinase, and pulse oximetry. In most cases of isolated anticholinergic toxicity, these tests should be normal. Limited urine drugs-of-abuse screening generally does not detect anticholinergic agents, although some rapid screens may produce positive results for cyclic antidepressants due to the structural similarities of some anticholinergic compounds, particularly diphenhydramine and hydroxyzine. Comprehensive urine drug screens, usually performed by thin layer chromatography or mass spectrometry, may detect most antihistamines and phenothiazines, although such testing does not usually detect plant alkaloids, scopolamine, or atropine. A positive drug screen for an anticholinergic agent only indicates exposure, such as a therapeutic dose, and does not necessarily imply an overdose or supratherapeutic ingestion.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of anticholinergic toxicity includes life-threatening presentations such as viral encephalitis, Reye's syndrome, head trauma, alcohol and sedative-hypnotic withdrawal, postictal state, other intoxications, neuroleptic malignant syndrome, and an acute psychotic disorder. The difference between anticholinergic toxicity and sympathomimetic toxicity (e.g., cocaine toxicity or delirium tremens) can be subtle, because patients with either may develop tachycardia, mydriasis, and delirium. The presence of red dry skin and the absence of bowel sounds suggest anticholinergic poisoning.[32] At times, patients presenting with acute psychotic disorders may have an abnormal mental status, suggesting anticholinergic toxicity, but true delirium and attention deficits are much more characteristic of the latter condition. Other CNS disorders, such as viral encephalitis, may also affect cholinergic outflow and produce similar anticholinergic clinical signs not related to a toxic exposure.[33]

TREATMENT

Treatment of anticholinergic toxicity primarily includes observation, monitoring, and good supportive care (**Table 202-4**). Temperature monitoring and treatment of hyperthermia are essential. GI decontamination with activated charcoal may be warranted to decrease absorption if the ingestion occurred within 1 hour. Although the benefit of activated charcoal is equivocal after 1 hour from ingestion, the decreased gut motility associated with anticholinergic ingestions may warrant charcoal administration beyond this 1-hour window.[34-36] Multidose activated charcoal is not recommended in patients with impaired GI motility, such as with anticholinergic toxicity.[37] Ipecac syrup is contraindicated in an anticholinergic overdose, and its use in any overdose patient should be abandoned.[31,38]

The major therapeutic challenge in the treatment of moderate to severe anticholinergic poisoning involves obtaining adequate control of the agitated individual. Inadequate sedation may lead to worsening hyperthermia, rhabdomyolysis, and traumatic injuries. Although physical restraints may be required to gain initial control, **pharmacologic sedation is strongly recommended**, because prolonged use of physical restraints in the struggling and agitated patient may lead to further complications.

Pharmacologic sedation should begin with IV administration of a benzodiazepine, such as lorazepam or diazepam. Benzodiazepines are not a specific antidote, and some patients may be refractory to large doses. Phenothiazines should be avoided because of their own anticholinergic effects. In severe cases of agitation when adequate sedation cannot be achieved without impairing respiration, mechanical ventilation and deep sedation may be necessary.

Intravenous sodium bicarbonate should be used to treat wide-complex tachydysrhythmias.[24,25] Class IA antiarrhythmic agents should be avoided because of their own sodium-channel blockade properties.

Physostigmine is a reversible acetylcholinesterase inhibitor (mechanistically related to the carbamate insecticides) that crosses the blood–brain barrier because of its lipophilic tertiary ammonium properties. Acetylcholinesterase inhibition results in acetylcholine accumulation that reverses both central and peripheral anticholinergic effects. Using physostigmine to reverse anticholinergic toxicity is controversial.[39,40]

The major adverse effects of physostigmine—profound bradycardia and seizures—were historically touted as common, but evidence for this belief is lacking.[41] Importantly, **the risk of these adverse effects appears greater in patients without anticholinergic toxicity, so accurate diagnosis of anticholinergic toxicity is important before administering physostigmine.**[40,41]

Evidence for benefits of physostigmine in anticholinergic toxicity is mixed. Retrospective analysis of 52 patients[42] and case reports[43-45] found that physostigmine was significantly better in controlling agitation and reversing delirium compared with benzodiazepines and was associated with fewer complications and a shorter recovery time. There was no difference in adverse effects between the two groups. Conversely, a different case series did not find that physostigmine use reduced complications or shortened length of stay in 17 patients with severe agitation and delirium after Jimson weed ingestion.[46] However, no adverse effects or complications were observed from physostigmine use.

Physostigmine can be used in cases of severe agitation and delirium from pure anticholinergic toxicity, especially in cases necessitating physical restraints and resistant to benzodiazepines. The adult dose of physostigmine is 0.5 to 2 milligrams (pediatric dose is 0.02 milligram/kg with a maximum dose of 2 milligrams) by slow IV administration over 5 minutes. When effective, a significant decrease in agitation may be apparent within 15 to 20 minutes. Provide continuous cardiac monitoring before and during administration of physostigmine to assess for potential bradycardia. Monitor the patient for signs of cholinergic excess, such as diarrhea, urination, miosis, bradycardia, bronchospasm, bronchorrhea, emesis, lacrimation, and salivation. **In cases of uncertain anticholinergic poisoning, a diagnostic challenge with physostigmine is *not* recommended because of the small but increased risk of adverse effects in patients *without* anticholinergic toxicity.**[40,41]

Physostigmine may be repeated in the same dose if required. Patients who remain asymptomatic for more than 6 hours after the first dose of physostigmine will not require repeat physostigmine dosing.[47] Contraindications to physostigmine use include asthma, nonpharmacologically mediated intestinal or bladder obstruction, cardiac conduction disturbances, and suspected concomitant sodium-channel antagonist poisoning.

DISPOSITION AND FOLLOW-UP

Patients with mild symptoms of anticholinergic toxicity that resolve after 6 hours of ED observation may be considered for disposition. Because the duration of action of physostigmine is generally shorter than the duration of action of many anticholinergic agents, the reversal effect may dissipate, resulting in recurrent toxicity. Most symptomatic patients, including those patients who have received physostigmine, require hospital observation for at least 24 hours.

REFERENCES

The complete reference list is available online at www.TintinalliEM.com.

TABLE 202-4 Treatment of Anticholinergic Toxicity

Action	Agent	Comments
GI decontamination	Activated charcoal	May be more effective due to the decreased GI motility.
Sedation	Benzodiazepines	Decreases the risk of hyperthermia, rhabdomyolysis, and traumatic injuries.
Wide-complex tachyarrhythmias	Sodium bicarbonate	Arrhythmia due to sodium-channel blockade; avoid class IA antiarrhythmics (procainamide).
Cholinesterase inhibition	Physostigmine	Use for cases of severe agitation or delirium; avoid when cardiac conduction abnormalities are present (see "Treatment" section).

CHAPTER 203

Metals and Metalloids

Heather Long
Lewis S. Nelson

INTRODUCTION

Acute metal and metalloid toxicity is uncommon but can cause significant morbidity and mortality if unrecognized and inappropriately treated. **Metals** are chemical elements that possess three general properties: (1) they are a good conductor of heat and electricity, (2) they are able to form cations, and (3) they can combine with nonmetals through ionic bonds. The term *heavy metal* has a historical tradition in clinical

medicine, but has been criticized by chemists as lacking in a precise definition or scientific merit. An alternative term, *toxic metal*, which also lacks firm definition, is sometimes used instead. In clinical toxicology, the following metals, noted in ascending atomic weight, are usually considered under the concept of "heavy" or "toxic" metal poisoning: beryllium, vanadium, cadmium, barium, osmium, mercury, thallium, and lead, with lead and mercury being the metals most clinically significant concerning human poisoning.

Metalloids are chemical elements with properties intermediate to those of metals and nonmetals. Although there is no precise definition, metalloids tend to have these two general properties: (1) they are semiconductors of electricity, and (2) they form amphoteric oxides. In order of ascending atomic weight, the following elements are generally considered metalloids: boron, silicon, germanium, arsenic, antimony, tellurium, and polonium; arsenic is the most clinically significant metalloid.

Exposure to either metals or nonmetals can be from (1) the pure element, (2) an organic compound containing the toxic element (defined as those compounds that contain carbon), or (3) an inorganic compound containing the element (defined as those that do not contain carbon). Depending on the metal or metalloid, potential toxicity is affected by which chemical form is responsible for the exposure.

Because of their effects on numerous enzymatic systems in the body, the metals and metalloids often present with protean manifestations primarily affecting five systems: neurologic, cardiovascular, GI, hematologic, and renal. Effects on the endocrine and reproductive systems are less clinically apparent. **It is important to recognize an initial "index case" of metal poisoning to prevent others from being poisoned when the metal source is environmental or industrial (Table 203-1).**

TABLE 203-1 Sources of Metal and Metalloid Poisoning

Element	Source
Lead	
Elemental, inorganic	Soldering; battery burning/reclamation; bronzing; brass-making; glassmaking; ingesting ceramic lead glaze; stripping old paint; "deleading" homes; "moonshine" whiskey; liquids in improperly glazed pottery; contaminated herbal medications and cosmetics; indoor shooting ranges; ingestion of paint chips, lead-laden floor dust, lead foreign bodies; lead bullets in abdomen or joint spaces
	Workers at risk: jewelers, painters, lead burners and smelters, including stained glass designers, pipe cutters, pigment makers, printers, welders, pottery makers, radiator repair personnel, battery reclamation workers, construction workers
Organic	Leaded gasoline (tetraethyl lead)
Arsenic	
Inorganic (arsenite [trivalent] or arsenate [pentavalent])	Insecticides, rodenticides, herbicides, mining, smelting/refining, Ayurvedic and homeopathic medicines, well water contaminated by leaching mineral ores and/or industrial waste
Organic	Seafood, parasitical medicines (veterinary)
Gas (arsine)	Mining smelting/refining, semiconductor industry; made by mixing acids with arsenic-containing insecticides
Mercury	
Elemental	Battery and thermometer manufacture; sphygmomanometer repair; dentistry; jewelry and lamp manufacture; photography; mercury mining; manufacture of scientific instruments
Inorganic (mercury salts)	Cosmetic products, especially skin-lightening products; taxidermy; fur processing; tannery work; chemical laboratories; manufacture of explosives, fireworks, disinfectants, button batteries, inks, and vinyl chloride
Organic (methyl mercury, ethyl mercury, and phenyl mercury)	Contaminated seafood; embalming; manufacture of drugs, fungicides, bactericides; handling of insecticides; pesticides, coated seeds; use of chlor-alkali process; working with wood preservatives

LEAD

EPIDEMIOLOGY

Lead is the most common cause of chronic metal poisoning and remains a major environmental contaminant, especially in developing countries. Exposure to lead can occur from inhalation or ingestion, and both inorganic and organic forms of lead produce clinical toxicity. Nonpaint sources include foreign medications, herbal and dietary supplements, Ayurvedic medications, traditional remedies, metallic charms, and cosmetics, especially products from Asia and Africa.[1] Although no safe blood lead level has been identified, the Centers for Disease Control and Prevention reference value for an elevated level is ≥5 micrograms/dL (0.24 micromol/L).[2]

The United States has banned lead in household paints, gasoline, plumbing systems, food, and drink cans; created lead abatement programs; and enforced standards for industrial use of lead.[2,3] Elevated blood levels in children age 1 to 5 years old are associated with residence in urban dwellings, residence in dwellings built before 1974 (especially those built before 1946), poverty, non-Hispanic black race or ethnicity, and higher population density.[4] Chronic lead exposure and toxicity in children is a significant public health problem because of the effect on intellectual development.[5] Worldwide, 16% of all children are estimated to have lead levels >10 micrograms/dL (0.48 micromol/L). Common sources in low-income countries are substandard or marginal living conditions near landfills and industries such as smelters, mines, and refineries, and leaded gasoline. Child labor in highly polluted conditions is another source of exposure.[4] In developing countries, informal recycling of used lead-acid batteries and processing of gold ore rich in lead have caused mass lead poisonings.[6,7]

PHARMACOLOGY

Absorption of inorganic lead is usually via the respiratory and GI tracts; skin absorption is negligible. Dietary deficiencies in calcium, iron, copper, and zinc may contribute to increased GI absorption in children. There is usually minimal absorption of lead from bullets or shot lodged in bone or muscle, but increased absorption and toxicity have been reported when bullets or shot are in constant contact with body fluids, such as synovial fluid or cerebrospinal fluid. Absorption of organic lead can occur after inhalation, ingestion, and dermal exposure. Exposure to organic lead can occur from sniffing gasoline (see chapter 199, "Hydrocarbons and Volatile Substances"), which may contain tetraethyl lead ("leaded gasoline"). After absorption, tetraethyl lead is metabolized to inorganic lead and triethyl lead; the latter is responsible for the neurotoxicity from leaded gasoline.

Greater than 90% of the total body lead is stored in bone, where it easily exchanges with the blood. Lead can be transferred across the placenta, a process exacerbated by increased bone turnover during pregnancy. Excretion of lead occurs slowly; the biologic half-life of lead in bone has been estimated to be 30 years.

PATHOPHYSIOLOGY

Lead toxicity primarily affects the nervous, cardiovascular, hematopoietic, and renal systems. In the CNS, the toxic effects of lead include (1) injuries to astrocytes, with secondary damage to the microvasculature and resultant disruption of the blood–brain barrier, cerebral edema, and increased intracranial pressure; (2) decreases in cyclic adenosine monophosphate and protein phosphorylation, which contribute to memory and learning deficits; and (3) alteration with calcium homeostasis, which leads to spontaneous and uncontrolled neurotransmitter release.[8] In the peripheral nervous system, lead causes primary segmental demyelination, followed by secondary axonal degeneration, mostly of the motor nerves.[9]

In the cardiovascular system, small but statistically significant increases in the prevalence of hypertension and atherosclerotic vascular disease are found in individuals with elevated blood lead levels.

In the hematopoietic system, lead interferes with porphyrin metabolism, which may contribute to lead-induced anemia. Coexisting iron deficiency may act synergistically with lead toxicity to produce a more profound anemia and, in children, may be more important than lead as

the cause of a microcytic anemia. Hemolytic anemia also occurs as a result of inhibition of red blood cell pyrimidine 5′-nucleotidase, an enzyme responsible for clearing cellular RNA degradation products.

In the kidney, lead affects the proximal tubule, producing Fanconi's syndrome with aminoaciduria, glycosuria, phosphaturia, and renal tubular acidosis.[10] Chronic interstitial nephritis and increased uric acid levels are due to increased tubular reabsorption of urate. Chronic lead toxicity has been linked to gout and chronic renal failure.

Lead adversely affects osteoblast and osteoclast function in bone. With chronic lead exposure, increased calcium deposition at growth plates may be seen as "**lead lines**" on radiographs of long bones. Lead-induced adverse effects on the reproductive system include increased fetal wastage, premature rupture of membranes, depressed sperm counts, abnormal or nonmotile sperm, and sterility.

CLINICAL FEATURES

Signs and symptoms of lead toxicity vary according to the type of exposure (acute vs chronic) and, to a lesser extent, according to the age of the individual and type of lead (inorganic vs organic) involved (**Table 203-2**). Young children are more susceptible than adults to the effects of lead. Encephalopathy, a major cause of morbidity and mortality, may begin dramatically with seizures and coma or develop indolently over weeks to months with decreased alertness and memory progressing to mania and delirium.[11] Encephalopathy due to lead poisoning typically occurs in toddlers age 15 to 30 months old with blood lead levels >100 micrograms/dL (4.8 micromol/L) but has been reported with blood lead levels of 70 micrograms/dL (3.4 micromol/L) or lower.

GI and hematologic manifestations occur more frequently with acute than with chronic poisoning, and the colicky abdominal pains may be associated with concurrent hemolysis. Patients may complain of a metallic taste and, with long-term exposure, have bluish-gray gingival lead lines. Lead toxicity also causes constitutional symptoms, including arthralgias, generalized weakness, and weight loss. Delayed cognitive development can occur in infants and children whose blood lead levels are 10 micrograms/dL (0.48 micromol/L) or higher.[12] Conversely, adult and pediatric patients may be asymptomatic in the face of significantly elevated blood lead levels.

With organic lead poisoning, neurologic abnormalities predominate. Symptoms range from behavioral changes, with irritability, insomnia, restlessness, and nausea and vomiting, to tremor, chorea, convulsions, and mania.

DIAGNOSIS

Exposure history, whether occupational or environmental, related to recent travel or immigration, a hobby, or a retained lead bullet, is the most important clue in making the diagnosis. The clinician should focus on symptoms, developmental and dietary histories (in children), pica, and any house or day care remodeling. Occupational, travel, medication, dietary supplement, cosmetic, and hobby histories should be elicited for adults being evaluated and for children who may be exposed to lead secondarily from these adult activities. Toxicity due to retained lead bullets may manifest several decades after being shot. Hyperthyroidism, pregnancy, fever, reinjury, or immobilization of the affected extremity can promote lead release from these retained objects after years of dormancy. **The combination of abdominal or neurologic dysfunction with a hemolysis should raise suspicion for lead toxicity. Consider the diagnosis in all children presenting with encephalopathy.**

The definitive diagnosis rests on finding an elevated blood lead level, with or without symptoms. The blood lead level is the best single test for evaluating lead toxicity, and levels at or >5 micrograms/dL (0.24 micromol/L) are considered elevated in children. Screening may be performed on fingerstick capillary blood, but because of the potential for environmental lead contamination, elevated levels always should be confirmed on a venous blood sample.[13] The edetate calcium disodium provocation test and testing for erythrocyte protoporphyrin (e.g., free erythrocyte protoporphyrin, zinc protoporphyrin) are no longer recommended.

Although it is important to order a blood lead level for confirmatory diagnosis and assistance in monitoring therapy, the laboratory turnaround time for results may be days. **Diagnostic studies in the ED should therefore focus on evaluation for anemia and examination of radiographs for evidence of lead exposure.**

The anemia from lead toxicity can be normocytic or microcytic, possibly with evidence of hemolysis, such as an elevated reticulocyte count and increased serum-free hemoglobin. Basophilic stippling in red blood cells from impaired clearing of cellular RNA degradation products is sometimes seen in lead-poisoned patients. This finding is nonspecific for lead toxicity; it is also found in arsenic toxicity, sideroblastic anemia, and the thalassemias. **Anemia and basophilic stippling occur variably, and their absence does not exclude lead toxicity.**

Following acute or subacute ingestion of lead, abdominal radiographs may show radiopaque material in the GI tract. In children, radiographs of long bones, especially of the knee, may reveal horizontal, metaphyseal "lead lines," which represent failure of bone remodeling rather than deposition of lead.

The differential diagnosis of lead toxicity includes causes of encephalopathy, such as Wernicke's encephalopathy; withdrawal from ethanol and other sedative-hypnotic drugs; meningitis; encephalitis; human immunodeficiency virus infection; intracerebral hemorrhage; hypoglycemia; severe fluid and electrolyte imbalances; hypoxia; arsenic, thallium, and mercury toxicity; and poisoning with cyclic antidepressants, anticholinergic drugs, ethylene glycol, or carbon monoxide. The abdominal pains of lead toxicity can mimic sickle cell crisis, the hepatic porphyrias, and even appendicitis. Chronic lead toxicity can mimic major depression, hypothyroidism, polyneuritis, gout, iron deficiency anemia, and learning disability.

TABLE 203-2 Clinical Features of Lead Poisoning

System	Clinical Manifestations
CNS	Acute toxicity: encephalopathy, seizures, altered mental status, papilledema, optic neuritis, ataxia
	Chronic toxicity: headache, irritability, depression, fatigue, mood and behavioral changes, memory deficit, sleep disturbance
Peripheral nervous system	Paresthesias, motor weakness (classic is wrist drop), depressed or absent deep tendon reflexes, sensory function intact
GI	Abdominal pain (mostly with acute poisoning), constipation, diarrhea, toxic hepatitis
Renal	Acute toxicity: Fanconi's syndrome (renal tubular acidosis with aminoaciduria, glucosuria, and phosphaturia)
	Chronic toxicity: interstitial nephritis, renal insufficiency, hypertension, gout
Hematologic	Hypoproliferative and/or hemolytic anemia; basophilic stippling (rare and nonspecific)
Reproductive	Decreased libido, impotence, sterility, abortions, premature births, decreased or abnormal sperm production

TREATMENT

Patients with appropriate signs and symptoms and an elevated blood lead level are classified as lead toxic and should be treated.

Lead-induced encephalopathy is rare but causes serious morbidity and mortality. In severely toxic patients, standard life support measures should be instituted. Seizures are treated with benzodiazepines and general anesthesia, if necessary. Lumbar puncture may precipitate cerebral herniation and should be performed carefully, if at all, with the removal of only a small amount of cerebrospinal fluid. If lead encephalopathy is suspected, initiate chelation therapy promptly (i.e., in the ED) without waiting for the results of a blood lead level (**Table 203-3**). If abdominal films demonstrate radiopaque flecks consistent with lead, whole-bowel irrigation with a polyethylene glycol electrolyte solution should be instituted. Larger lead bodies, such as fishing sinkers and jewelry, may require endoscopic or surgical removal.

Chelation therapy for lead toxicity uses dimercaprol (previously known as *British anti-Lewisite*), edetate calcium disodium (sometimes

TABLE 203-3 Guidelines for Chelation Therapy in Lead-Poisoned Patients*

Severity (blood lead level [micrograms/dL])	Dose
Encephalopathy	Dimercaprol, 75 milligrams/m^2 (or 4 milligrams/kg) IM every 4 h for 5 d *and* Edetate calcium disodium, 1500 milligrams/m^2 per day via continuous infusion or in 2–4 divided doses IV for 5 d; start 4 h after dimercaprol
Symptomatic and/or Adults: blood lead >100 Children: blood lead >69	Dimercaprol *and* Edetate calcium disodium (as described above) *or* Edetate calcium disodium (alone) *or* Succimer (as described below)
Asymptomatic Adults: blood lead 70–100 Children: blood lead 45–69	Succimer, 350 milligrams/m^2 (or 10 milligrams/kg) PO every 8 h for 5 d, then every 12 h for 14 d
Asymptomatic Adults: blood lead <70 Children: blood lead <45	Routine chelation not indicated; remove patient from source of exposure

*General guidelines. Consult with medical toxicologist or regional poison center for specifics and dosing.

abbreviated *$CaNa_2$-EDTA*), and succimer (also known as *dimercaptosuccinic acid*) (Table 203-3). Another chelating agent, penicillamine, has not received approval for use in the treatment of lead toxicity by the U.S. Food and Drug Administration, but there is published experience demonstrating benefit, and penicillamine is used in Europe for lead poisoning. **The chelation dosing schedules are guided by the blood lead levels, the presence or absence of symptoms, and the age of the patient.** Adverse side effects from chelation therapy are common, and consultation with a medical toxicologist is recommended to assist in management.

Dimercaprol crosses the blood–brain barrier and is indicated when neurotoxicity or high blood lead levels are present. Dimercaprol is administered IM and is typically used with edetate calcium disodium to prevent lead from being transported into the brain. **The diluent for dimercaprol includes peanut oil, and therefore, dimercaprol should be used with great caution in patients with peanut allergy.** Side effects of dimercaprol include hypertension; fever, pain, and sterile abscess at injection site; nausea; vomiting; diarrhea; abdominal pain; headache; lacrimation; rhinorrhea; and hemolysis in glucose-6-phosphate dehydrogenase–deficient patients. Side effects with dimercaprol are dose dependent and occur in up to 65% of treated patients using recommended doses.

Edetate calcium disodium can be used as a single agent in the treatment of lead toxicity, although there is some concern that mobilization of lead from bone by this agent may lead to increased transport of lead into the brain. Edetate calcium disodium does not cross the blood–brain barrier, and therefore, dimercaprol, which does cross, should be given before and during the entire course of edetate calcium disodium when there are CNS symptoms. **An important precaution is to not confuse this product for treatment of lead toxicity with edetate disodium, used to treat hypercalcemia.** This confusion can lead to serious toxicity and even death, if the wrong drug is used. Side effects from edetate calcium disodium include renal toxicity (especially if dehydrated), dermatitis, headache, fever, chills, and myalgias.

Succimer, an oral analog of dimercaprol, effectively chelates lead. Although succimer does not cross the blood–brain barrier, its use as a sole agent is not associated with exacerbation of lead-induced encephalopathy.[14] Some toxicologists consider succimer the preferred chelator for lead poisoning in all but the most severe cases. Its advantages include oral administration without increasing lead absorption from the GI tract, no serious adverse effects, and minimal chelation of essential metals. Repeat treatment may be necessary after a 2-week drug-free period. Side effects from succimer include nausea, vomiting, diarrhea, abdominal pain, rash, pruritus, sore throat, rhinorrhea, drowsiness, paresthesias, transient elevations in serum transaminases and alkaline phosphatase, thrombocytosis, and eosinophilia.

Chelation was not associated with any increased risk of birth defects in the few published cases, and pregnant women with elevated blood lead levels should be chelated following the same guidelines (Table 203-3).[15] Neonatal blood lead levels may be elevated despite maternal chelation, and similarly, neonates should also be chelated following birth.

DISPOSITION AND FOLLOW-UP

Removal of the source of lead is the most important action for all individuals with lead poisoning, and patients should not be returned to their former environments until appropriate lead decontamination and abatement measures have been addressed. Family members and coworkers should be evaluated for occult lead toxicity. Hospital admission is recommended for (1) children with symptoms or with a blood lead level >70 micrograms/dL (>3.4 micromol/L), (2) adults with central neurologic symptoms, and (3) patients with suspected lead toxicity when returning to the environment is considered dangerous.

Approximately 85% of patients who suffer lead-toxic encephalopathy develop permanent central neurologic damage, including seizures, mental retardation in children, and cognitive deficits in adults. Abdominal colic usually subsides within days after beginning chelation therapy, and other acute manifestations clear within 1 to 16 weeks with therapy. Lead-induced nephropathy may be partly reversible with chelation therapy.

ARSENIC

EPIDEMIOLOGY

Arsenic is a nearly tasteless, odorless metalloid that causes significant acute and chronic toxicity worldwide.[16] Arsenicals are found in a variety of compounds and industries (Table 203-1) and continue to be used as a means for homicide and suicide.

Arsenic exists in elemental, inorganic salts, organic salts, and gaseous forms. Elemental and organic forms have little to no toxicity, whereas inorganic compounds, including arsenite (trivalent or As^{3+}) and arsenate (pentavalent or As^{5+}), are highly toxic. Arsine is a colorless, nonirritating toxic gas encountered in the semiconductor industry, ore smelting, and refining processes and is produced when arsenic-containing insecticides are mixed with acids.

PHARMACOLOGY

Arsenic is well absorbed by GI, respiratory, and parenteral routes and may be absorbed through nonintact skin. Due to its water solubility, pentavalent arsenic (arsenate) is more readily absorbed through mucous membranes, such as the GI tract, than is trivalent arsenic (arsenite), which penetrates the skin more readily due to its increased lipid solubility. After absorption, arsenic localizes in erythrocytes and leukocytes or binds to serum proteins. Within 24 hours, redistribution into the liver, kidney, spleen, lung, GI tract, muscle, and nervous tissues occurs, with subsequent integration into hair, nails, and bone. Elimination from the blood is rapid, and excretion is predominantly renal. Toxicity of the various forms is partly determined by excretory rates, with the more toxic arsenite being excreted at a slower rate than arsenate or the organic arsenical compounds. Arsenic crosses the placenta and is teratogenic in animals and humans.

PATHOPHYSIOLOGY

Ingested or absorbed arsenic reversibly binds with sulfhydryl groups found in many tissues and enzyme systems. Acute exposure produces dilatation and increased permeability of small blood vessels, resulting in GI mucosal and submucosal inflammation and necrosis, cerebral edema and hemorrhage, myocardial tissue destruction, and fatty degeneration

of the liver and kidneys. Subacute or chronic exposure can cause a primary peripheral axonal neuropathy with secondary demyelination. Inhaled arsine attaches to sulfhydryl groups of hemoglobin, producing an acute hemolytic anemia with resulting jaundice, abdominal pain, and hemoglobinuria-induced acute renal failure.[17]

CLINICAL FEATURES

The signs and symptoms of toxicity vary with the form, amount, and concentration ingested and the rates of absorption and excretion of the various arsenical compounds (**Table 203-4**).

With acute toxicity, clinical effects usually develop within minutes to hours of ingestion. Severe gastroenteritis with nausea, vomiting, and cholera-like diarrhea is the hallmark of acute poisoning and may last several days to weeks, frequently necessitating hospitalization. Patients may complain of a metallic taste. Hypotension and tachycardia secondary to volume depletion, capillary leak, and myocardial dysfunction occur in moderate to severe cases. The ECG may demonstrate nonspecific ST-segment and T-wave changes with a prolonged QT interval, although these findings are more common in chronic intoxication. Ventricular tachycardia with a *torsade de pointes* morphology has been reported.[18] Secondary myocardial ischemia may occur, leading to an erroneous diagnosis of primary myocardial infarction. Acute encephalopathy, acute respiratory distress syndrome, acute kidney injury, and rhabdomyolysis may ensue.

Survivors of acute poisonings and patients who are poisoned slowly may develop subacute toxicity, typically presenting with complaints of weakness, muscle aches, abdominal pain, memory loss, personality changes, periorbital and extremity edema, or skin rash, often with a history of gastroenteritis occurring 1 to 6 weeks earlier.[19] Central neurologic symptoms include headache, confusion, delirium, and personality changes. Chronic encephalopathy with delirium, hallucinations, disorientation, agitation, and confabulation resembling Korsakoff's syndrome may occur. Peripheral neuropathy develops in a stocking-glove distribution and is initially sensory, with motor symptoms developing later. Patients with severe poisoning can develop an ascending paralysis mimicking Guillain-Barré syndrome. Dermatologic manifestations vary and include morbilliform rash, alopecia, and desquamation. Mees lines (1- to 2-mm–wide transverse white lines in the nails) due to disrupted keratinization of the nail matrix may be seen 4 to 6 weeks after an acute ingestion.

Chronic toxicity from arsenic occurs with ongoing low-level occupational or environmental exposure and has been linked to the development of hypertension, peripheral vascular disease, diabetes mellitus, epidermoid cancer, respiratory tract cancer, hepatic angiosarcoma, and, possibly, leukemia. Dermatologic manifestations are prominent and include hyperpigmentation, hyperkeratosis of the palms and soles, Bowen's disease, and squamous and basal cell carcinomas. Perforation of the nasal septum has been found in workers exposed occupationally to arsenic.

TABLE 203-4 Clinical Features of Arsenic Toxicity

Onset of Symptoms	Clinical Features
Acute toxicity (10 min to several hours)	GI: nausea, vomiting, cholera-like diarrhea
	Cardiovascular: hypotension; tachycardia; dysrhythmias, including torsade de pointes; secondary myocardial ischemia
	Pulmonary: acute respiratory distress syndrome
	Renal: acute renal failure
	Central neurologic: encephalopathy
Subacute toxicity (1–3 wk after acute exposure or with chronic exposure)	Central neurologic: headache, confusion, delirium, personality changes
	Peripheral neurologic: sensory and motor neuropathy
	Cardiovascular: QT-interval prolongation
	Pulmonary: cough, alveolar infiltrates
	Dermatologic: rash, alopecia, Mees lines
Chronic toxicity (ongoing low-level occupational or environmental exposure)	Dermatologic: hyperpigmentation, keratoses, Bowen's disease, squamous and basal cell carcinoma
	Cardiovascular: hypertension, peripheral arterial disease
	Endocrine: diabetes mellitus
	Oncologic: lung and skin cancer

DIAGNOSIS

The diagnosis is easily missed without a history of known exposure to arsenic. Physicians rarely encounter arsenic toxicity, and unfortunately, criminal poisonings often go undetected. The diagnosis of **acute arsenic poisoning should be considered in a patient with hypotension that was preceded by severe gastroenteritis**. The diagnosis of chronic arsenic toxicity should be considered in a patient with a peripheral neuropathy, typical skin manifestations, or recurrent bouts of unexplained gastroenteritis.

An abdominal radiograph may demonstrate intestinal radiopaque metallic flecks in cases of arsenic ingestions. The ECG often reveals a prolonged QT interval, especially in subacute poisoning. The CBC may reveal a normocytic, normochromic, or megaloblastic anemia, and/or a thrombocytopenia. The WBC count may be elevated in acute toxicity and decreased in chronic toxicity. A relative eosinophilia and red cell basophilic stippling may be observed. Elevated reticulocyte counts are found in cases with a component of hemolytic anemia.

Definitive diagnosis of acute poisoning depends on finding elevated arsenic levels in a 24-hour urine collection. All urinary measurements of metals should be collected in metal-free containers after a 5-day seafood-free diet. Normal urinary arsenic level is below 50 micrograms/L (0.67 micromol/L), and total urinary arsenic excretion in an unexposed patient typically does not exceed 100 micrograms/d (1.3 micromol/d). If the baseline urinary level is within normal limits and arsenic intoxication is still suspected, hair and nail clippings should be harvested for laboratory analysis. Due to the rapid distribution of arsenic in tissues, blood arsenic levels are unreliable.

Include arsenic toxicity in the differential diagnosis for septic shock, encephalopathy, peripheral neuropathy (including Guillain-Barré syndrome), Addison's disease, hypo- and hyperthyroidism, patients with the previously mentioned dermatologic manifestations, Korsakoff's syndrome, persistent gastroenteritis and/or cholera-like diarrhea, porphyria, other metal toxicities such as thallium and mercury, and unexplained, prolonged malaise and weakness.

TREATMENT

Acute arsenic toxicity is a life-threatening illness requiring aggressive management. The first task is to stabilize circulatory function, because hypotension and dysrhythmias are the chief causes of death. Hypotension, usually due to volume depletion, should be managed initially with crystalloid volume replacement, and vasopressor therapy with dopamine or norepinephrine may be required. Overhydration should be avoided because pulmonary and cerebral edema can occur. Ventricular tachycardia and fibrillation may be treated with lidocaine, amiodarone, and electrical defibrillation as necessary. Magnesium sulfate, isoproterenol, and overdrive pacing therapies should be considered for torsade de pointes. Drugs that prolong the QT interval, including classes IA (procainamide, quinidine, and disopyramide), IC, and III antidysrhythmics, should be avoided. Potassium, calcium, and magnesium levels should be monitored and corrected as necessary to prevent further prolongation of the QT interval and exacerbation of torsade de pointes dysrhythmias.

Gastric lavage with a large-bore orogastric tube should be performed in cases of acute ingestion, and activated charcoal, although it poorly adsorbs arsenic, may be effective if co-ingestants were taken. Whole-bowel irrigation should be considered if abdominal radiographs reveal intestinal radiopaque materials consistent with arsenic. Seizures can be treated with benzodiazepines and general anesthesia as necessary.

Initial management of chronic toxicity should be directed toward prevention of further arsenic absorption and GI decontamination, if appropriate. In cases of suspected homicidal intent, patients should be

TABLE 203-5 Guidelines for Chelation Therapy in Arsenic-Poisoned Patients

Chelator	Dose
Dimercaprol	3–5 milligrams/kg IM every 4 h for 2 d, followed by 3–5 milligrams/kg IM every 6–12 h until able to switch to succimer
Succimer	10 milligrams/kg PO every 8 h for 5 d, followed by 10 milligrams/kg PO every 12 h

advised to avoid food and drinks prepared by others, and visitor contact with hospitalized patients should be monitored carefully.

Chelation therapy for arsenic toxicity uses dimercaprol or succimer (**Table 203-5**). Treat patients with acute arsenical poisoning or severe, life-threatening toxicity with dimercaprol until the clinical condition stabilizes and succimer, the less toxic oral chelating agent, can be substituted.[20] **Do not delay chelation in severely ill patients until laboratory confirmation because chelation is most effective when given within minutes to hours of exposure.** Conversely, hold chelation therapy in clinically stable patients with suspected chronic arsenic toxicity pending diagnosis. Chelation with the oral agent succimer may lower the tissue content of arsenic and speed urinary excretion but does not appear to decrease morbidity or mortality in chronic arsenic poisoning.[20] Early consultation with a regional poison control center or medical toxicologist for assistance with treatment and chelation is recommended.

Patients with acute arsine poisoning are managed with blood transfusions, exchange transfusion to remove the nondialyzable arsine, and hemodialysis for the acute kidney injury.[17] Chelation therapy has no role in the management of arsine toxicity.

DISPOSITION AND FOLLOW-UP

Hospitalization is recommended for (1) patients with acute or life-threatening known or suspected arsenic poisoning, (2) chronically poisoned patients requiring dimercaprol therapy, and (3) patients in whom suicidal or homicidal intent is suspected. In patients with acute arsenic toxicity, prognosis may be influenced favorably by the rapid institution of dimercaprol therapy. Recovery from arsenical neuropathy appears to be related more to the initial severity of symptoms than to institution of chelation therapy, although in patients who do recover, dimercaprol appears to significantly shorten the duration of illness. Often, neurologic recovery occurs slowly over months to years. Normalization of hematologic values can occur in the absence of any specific therapy. Dermatologic manifestations of chronic toxicity are unresponsive to chelation.[20]

MERCURY

EPIDEMIOLOGY

Mercury occurs in inorganic and organic forms. Inorganic mercury compounds are subdivided into elemental mercury (quicksilver), mercurous (Hg^{+}) salts (e.g., mercurous chloride or calomel), and mercuric (Hg^{2+}) salts (e.g., cinnabar or mercuric sulfide). Organic mercurials exist as short- and long-chained alkyl and aryl compounds. The short-chained alkyls, such as methyl mercury and ethyl mercury, are more toxic to humans, with dimethyl mercury being lethal in small amounts. All forms of mercury are toxic but differ in the means of exposure, routes of absorption, constellations of clinical findings, and responses to therapy (Table 203-1).[21,22]

PHARMACOLOGY

Elemental mercury is absorbed primarily by vapor inhalation. Vacuuming elemental mercury, as from a broken thermometer or fluorescent light bulb, causes volatilization due to both the heat and the airflow through the canister. Absorption by the GI tract is usually negligible so that **swallowing mercury contained in a glass thermometer (elemental mercury) does not produce adverse effects unless the mucosa is damaged**. Elemental mercury can be absorbed dermally. IM injections of mercury can induce abscess and granuloma formation. Slow absorption and delayed systemic toxicity after IM injections of elemental mercury have been reported.[23] IV injections have produced mercury pulmonary and systemic emboli.[24] Elemental mercury crosses the blood–brain barrier, where it is ionized and trapped in the CNS.

Inorganic mercury salts are absorbed primarily through the GI tract, but they may also be absorbed across intact skin.[25] Mercuric salts deposit in the ionized form primarily in the kidney, followed by the liver and spleen. Mercury salts do not enter the CNS in consequential amounts nor do they cross the placenta.

Organic mercury compounds are also primarily absorbed by the GI tract. The highly lipid-soluble short-chained alkyls easily cross membranes, accumulating in red blood cells, the CNS, liver, kidney, and fetus. Longer-chained alkyl and the aryl compounds are biotransformed into inorganic mercuric ions in the body. Therefore, toxicity with these compounds more closely resembles inorganic mercury toxicity.

Inorganic and the aryl organic mercurials are eliminated in the urine and feces. The short-chained alkyl compounds are excreted primarily in the bile, where they undergo significant enterohepatic circulation.

PATHOPHYSIOLOGY

Mercury binds with sulfhydryl groups, affecting a diverse number of enzyme and protein systems. Methyl mercury also inhibits choline acetyl transferase, which catalyzes the final step in the production of acetylcholine and may produce symptoms of acetylcholine deficiency.[26] Mercuric salts produce proximal renal tubular necrosis.[21]

CLINICAL FEATURES

The clinical effects of mercury poisoning depend on the form and, in some cases, the route of administration.[21,22] In general, the neurologic, GI, and renal systems are predominantly affected.

Elemental Mercury Acute symptoms following inhalation of elemental mercury vapor include shortness of breath, fever/chills, cough, nausea, vomiting, diarrhea, metallic taste, headaches, weakness, and blurry vision. In severe cases, patients may develop acute lung injury and severe respiratory distress. Following metabolism of ingested or injected elemental mercury to inorganic salts, patients may also develop signs of inorganic mercury toxicity, including tremor and renal failure.

Inorganic Mercury Mercury salts are caustic, and an acute ingestion produces a severe hemorrhagic gastroenteritis with abdominal pain often associated with a characteristic graying of the oral mucosa and metallic taste. Shock and cardiovascular collapse may rapidly ensue. Acute kidney injury results from both direct toxicity of the mercury ions and from decreased renal perfusion due to shock.

GI symptoms of chronic inorganic mercury toxicity include metallic taste, burning sensation in the mouth, loose teeth, mucosal lesions and fissures, excessive salivation, and nausea. Hallmarks of chronic neurologic toxicity include tremor, neurasthenia, and erethism.[21,22] *Neurasthenia* is characterized by fatigue, depression, headaches, and difficulty concentrating. *Erethism* refers to behavioral changes characterized by shyness, emotional lability, irritability, insomnia, and delirium. Chronic renal toxicity ranges from reversible proteinuria to the nephrotic syndrome. Acrodynia, also known as *pink disease*, is an immune-mediated reaction characterized by a generalized rash; edema and erythema of the palms, soles, and face; excessive sweating; fever; irritability; splenomegaly; and generalized hypotonia with particular weakness of the pelvic and pectoral muscles.

Organic Mercury The short-chained alkyl compounds, methyl, dimethyl, and ethyl mercury, have the most devastating effects on the CNS. After a latent period of weeks to months, orofacial paresthesias are a common initial symptom, followed by headache, tremor, and fatigue. In severe cases, patients may develop ataxia, muscle rigidity and spasticity, blindness, hearing deficits, and dementia.[21,22] Although less prominent than the neurotoxicity, mild GI, renal, and pulmonary abnormalities may develop with organic mercury poisoning.

DIAGNOSIS

An occupational exposure history, in either the index patient or a household member, along with typical physical findings, especially tremor or a constellation of signs and symptoms suggesting erethism or acrodynia,

TABLE 203-6 Guidelines for Chelation Therapy in Mercury-Poisoned Patients

	Elemental and Inorganic Mercury	Organic Mercury
Severe acute poisoning	Dimercaprol, 5 milligrams/kg IM every 4 h for 2 d, followed by 2.5 milligrams/kg IM every 6 h for 2 d, followed by 2.5 milligrams/kg IM every 12–24 h until clinical improvement occurs or until able to switch to succimer therapy	Succimer, 10 milligrams/kg PO every 8 h for 5 d, then every 12 h for 14 d
Mild acute poisoning and chronic poisoning	Succimer, 10 milligrams/kg PO every 8 h for 5 d, then every 12 h for 14 d	No proven benefit for chelation therapy

suggests mercury toxicity. Ingestion of mercuric chloride can produce a rapidly fatal course and should be considered in a patient presenting with a corrosive gastroenteritis.[27] Often, however, the diagnosis of mercury toxicity is subtle, arrived at only after many other diagnoses have been investigated.

For poisoning from all forms of mercury, except short-chained alkyls, a 24-hour urinary measurement of mercury should be performed after a 5-day seafood-free diet. A seafood meal (contaminated with mercury) can temporarily elevate the mercury level to the toxic range until the mercury is eliminated. Most unexposed individuals will have 24-hour urine mercury levels <10 to 15 micrograms/L (<0.05 to 0.075 micromol/L). A level >20 micrograms/L (>0.1 micromol/L) may indicate meaningful exposure.

Short-chained alkyl mercury compounds are excreted predominantly by the bile, rendering urinary measurements invalid to assess toxicity from these agents. Laboratory diagnosis after this exposure rests on finding elevated whole-blood mercury levels, because these compounds concentrate in erythrocytes. Whole-blood mercury levels are normally <5 micrograms/L (<0.025 micromol/L).

Although elevated blood or urine values are necessary to confirm the diagnosis, they correlate poorly with toxicity and are unable to distinguish the asymptomatic exposure from mercury poisoning. Furthermore, because of significant redistribution within the body, blood or urine levels do not represent total-body burden. They are most useful in confirming exposure and in following the effects of chelation therapy (see "Treatment," below).

MRI findings in methyl mercury toxicity from ingestion of contaminated seafood include marked atrophy of the visual cortex, cerebellar vermis and hemispheres, and postcentral cortex.[28]

Behavioral changes or tremor similar to those caused by mercury can be seen with hypothyroidism, apathetic hyperthyroidism, metabolic encephalopathy, senile dementia, adverse effects of therapeutic drugs (such as lithium, theophylline, or phenytoin), Parkinson's disease, delayed neuropsychiatric sequelae of carbon monoxide poisoning, lacunar infarction, cerebellar degenerative disease or tumor, and ethanol or

TABLE 203-7 Miscellaneous Metal Poisoning: Unique Manifestations and Treatments of Patients Poisoned by Less Common Metals

Metal	Poisoning Source	Acute Clinical Manifestations	Chronic Clinical Manifestations	Specific Treatment
Bismuth	Antidiarrheals (bismuth subsalicylate), impregnated surgical packing paste	Abdominal pain, acute renal failure	Myoclonic encephalopathy	Dimercaprol (limited evidence)
Cadmium	Contaminated soil in cadmium-rich areas; alloys used in welding, soldering, jewelry, and batteries	Ingestion: hemorrhagic gastroenteritis Inhalation: pneumonitis, acute respiratory distress syndrome	Proteinuria, osteomalacia (itai-itai or ouch-ouch disease), lung cancer (questionable)	Ingestion: succimer (limited evidence; not generally indicated) Pneumonitis: chelation not indicated
Chromium	Corrosion inhibitors (e.g., heating systems), pigment production, leather tanning, metal finishing, dietary supplements, prosthetic joints	Skin irritation and ulceration, contact dermatitis; GI irritation, renal and pulmonary failure	Mucous membrane irritation, perforation of nasal septum, chronic cough, contact dermatitis, skin ulcers ("chrome holes"), lung cancer	Acetylcysteine (animal studies suggest efficacy as chelator)
Cobalt	"Hard metal dust" (tungsten–cobalt mixture), flexible magnets, drying agents, prosthetic joints	Contact dermatitis, asthma	Hard metal lung disease (spectrum ranging from alveolitis to fibrosis), cardiomyopathy, thyroid hyperplasia	Acetylcysteine (animal studies suggest efficacy as chelator)
Copper	Leaching from copper pipes and containers; fungicide (copper sulfate); welding (copper oxide)	Ingestion: resembles iron poisoning; blue vomitus (copper salts), hepatotoxicity, hemolysis, methemoglobinemia Inhalation: metal fume fever (self-limited fever, chills, cough, dyspnea)	Hepatotoxicity (childhood cirrhosis or idiopathic copper toxicosis)	Dimercaprol for hepatic or hematologic toxicity Succimer in mild poisoning
Silver	Colloidal (metallic) silver used for medicinal purposes as oral solutions, aerosols, and douches; cauterizing and antiseptic agent (silver nitrate); jewelry, wire	Mucosal irritation (silver oxide and nitrate)	Argyria (permanent skin discoloration due to silver deposition and melanocyte stimulation)	Selenium (possible role)
Thallium	Rodenticides (use prohibited in the United States); contaminated herbal products; medical radioisotope (miniscule dose); most poisonings related to homicide	Early: nausea, vomiting, abdominal pain, tachycardia Intermediate (>24 h): painful ascending neuropathy, cardiac dysrhythmias, altered mental status Delayed (2 wk): alopecia	Sensorimotor neuropathy, psychosis, dermatitis, hepatotoxicity	Multidose activated charcoal Prussian blue, 125 milligrams/kg PO every 12 h (usually dissolved in 50 mL of 15% mannitol)
Zinc	Smelting, electroplating, military smoke bombs, zinc lozenges, welding/galvanizing (zinc oxide)	Ingestion: nausea, vomiting, abdominal pain (resembles iron poisoning) Inhalation: mucosal irritation, metal fume fever (zinc oxide)	Copper deficiency, sideroblastic anemia, neutropenia	Edetate calcium disodium Supportive care for metal fume fever

sedative-hypnotic drug withdrawal. Corrosive gastroenteritis can be caused by iron, arsenic, phosphorus, acids, or alkali ingestion. Cerebral palsy, intrauterine hypoxia, and teratogenic effects of therapeutic and illicit drugs and environmental contaminants should be considered when evaluating an infant thought to be affected in utero by short-chained alkyl mercury compounds.

TREATMENT

General therapeutic measures include removal from exposure and supportive therapy, including supplemental oxygen and IV hydration. Hemodialysis does not enhance mercury clearance but may be indicated for treatment of acute kidney injury.

For **elemental mercury**, the severe respiratory failure following inhalation of volatilized elemental mercury or aspiration of elemental mercury may require endotracheal intubation and positive-pressure ventilation.

For ingestion of **inorganic mercury salts**, treat with aggressive IV hydration and GI decontamination, including gastric lavage if the patient has not had significant emesis, and consider activated charcoal. Given the profuse diarrhea that may ensue, a cathartic is not indicated.

For **organic mercury** toxicity, institute gastric decontamination in the setting of acute ingestion. Neostigmine may improve motor function in methyl mercury–poisoned patients by improving acetylcholine levels at the neuromuscular junction.[26]

Chelation is indicated if it can be given within a few hours after ingestion of mercury salts.[20] Chelation therapy for chronic exposures, especially to organic mercury, is much less effective. A history of significant mercury exposure, signs and symptoms consistent with mercury poisoning, and elevated blood or urine mercury levels may assist in the decision making and help determine duration of treatment for chronic mercury toxicity. Dimercaprol and succimer are the preferred chelators for mercury poisoning (**Table 203-6**).

The chelation regimen is adjusted according to clinical response and development of adverse reactions. Adverse reactions with dimercaprol increase with dose and include nausea, vomiting, headache, paresthesias, and diaphoresis. Fever is frequently seen in children during dimercaprol therapy. The dimercaprol-mercury complex is dialyzable, and hemodialysis may be helpful in patients receiving dimercaprol who have diminished renal function. Plasma exchange transfusion also was beneficial in a case of mercuric chloride ingestion.[27] **Dimercaprol is contraindicated in methyl mercury poisoning due to the potential for exacerbation of central neurologic symptoms.** Succimer is generally well tolerated. Consultation with a poison control center or medical toxicologist is recommended for further assistance with chelation treatment.

DISPOSITION AND FOLLOW-UP

Hospital admission is recommended for (1) patients known or suspected to have ingested mercury salts, (2) patients known or suspected to have inhaled elemental mercury vapor with pulmonary injury, and (3) patients requiring dimercaprol therapy.

Outcome depends on the form of mercury and the severity of toxicity. Mild cases of elemental and mercury salt poisoning and very mild cases of organic mercury toxicity may have complete recovery. Death can occur in severe cases of mercuric chloride poisoning and with dimethyl mercury exposure. Most patients with symptomatic organic mercury poisoning are left with residual neurologic deficits. Environmental decontamination and removal of the patient, family members, and coworkers from a site of ongoing contamination play a critical role in preventing injury to others.

OTHER METALS AND METAL SALTS

Other metals and their salts may cause toxicity (**Table 203-7**). Metal salts typically cause early GI irritation (nausea, vomiting, diarrhea, cramping, and hemorrhage) with subsequent neurologic, renal, hematologic, and cutaneous abnormalities. Symptoms are often vague, and without an explicit history of metal salt exposure, patients are usually misdiagnosed.[29] Treatment universally involves removal of the patient from the source, topical decontamination, administration of activated charcoal (if exposure involves ingestion), and supportive care, including aggressive fluid and electrolyte repletion and hemodialysis, if required. Indications for chelation and its efficacy in treating metal toxicity vary with the specific metal (Table 203-7).[30] Consult with a medical toxicologist or a regional poison control center for specific indications and drug doses.

CHAPTER 204

Industrial Toxins

Chip Gresham
Frank LoVecchio

INTRODUCTION AND EPIDEMIOLOGY

A **hazardous chemical** is defined by the U.S. Occupational Safety and Health Administration as any chemical that has been scientifically shown to be a health hazard (causes acute or chronic health effects) or a physical hazard (combustible liquid, explosive, flammable, etc.). This federal agency estimates that there are 575,000 chemicals in the workplace, with 53,000 being potentially hazardous.[1] Considering that unplanned exposures and contamination can occur at any time during manufacturing, transport, storage, usage, or disposal of these chemicals, inevitably, emergency physicians can expect to occasionally be responsible for the management and care of a hazardous materials patient (see chapter 5, Disaster Preparedness).[2]

When managing a patient exposed to an industrial chemical, it is helpful to refer to the Material Safety Data Sheet and adhere to the recommendations regarding decontamination. Although the Material Safety Data Sheet will also include "first aid" recommendations (**Table 204-1**), the provider should also consult with a medical toxicologist or a regional poison control center to discuss case-specific hazards, optimal treatments, and dispositions. Contacting the regional poison control center facilitates data collection and analysis of toxicologic exposures. While many exposures produce immediate effects, some agents may result in delayed onset of symptoms that require at least 24 hours of observation (**Table 204-2**).

This chapter discusses common industrial toxins that produce primarily respiratory toxicity (**Table 204-3**) and those that cause metabolic toxicity. Toxic chemicals discussed elsewhere include nerve agents and

TABLE 204-1 Agents Absorbed through Intact Skin That May Result in Systemic Toxicity*

Acrylamide	Methyl bromide
Acrylonitrile, acetonitrile, propionitrile	Methylene chloride (slow)
Aniline	Nerve agents
Chlordane	Nitrates
Dinitrophenol	Nitrobenzene
Hydrocarbons: benzene, gasoline, toluene, xylene (all slowly absorbed)	Pesticides
Hydrogen cyanide, cyanide salts	Phenol
Hydrogen fluoride (hydrofluoric acid)	T2 toxin (biologic)
Metals (organic mercury, thallium)	

*Many toxins may be absorbed through abraded skin.

TABLE 204-2 Toxins with Delayed Onset of Symptoms or Requiring Prolonged Monitoring

Agent	Potential Delayed Toxicity
Acrylonitrile, acetonitrile, propionitrile	Cyanide toxicity
Aniline	Methemoglobinemia
Arsine	Hemolysis
Benzene	Bone marrow suppression and leukemia
Cadmium	Pulmonary toxicity
Chlorine	Pulmonary edema
Ethylene oxide	Pulmonary edema and neurotoxicity
Halogenated solvents	Hepatorenal toxicity
Hydrofluoric acid	Pulmonary edema, dermal burns, electrolyte changes (hypocalcemia)
Hydrogen sulfide	Pulmonary edema
Metals	Hepatorenal, neurotoxicity
Methanol	Neurologic, acid-base disturbance
Methyl bromide	Pulmonary edema
Methylene chloride	Carbon monoxide toxicity, dysrhythmias
Organophosphates (highly lipid soluble), or dermal exposure to nerve agents	Cholinergic toxicity
Nitrogen oxides	Pulmonary edema, methemoglobinemia
Paraquat	Pulmonary edema/fibrosis
Phosgene	Pulmonary edema
Phosphine	Pulmonary edema
Zinc phosphide	Pulmonary edema

vesicants (see chapter 8, Chemical Disasters); hydrocarbons (see chapter 199, Hydrocarbons and Volatile Substances); acids and alkalis (see chapter 200, Caustic Ingestions); organophosphates and carbamates (see chapter 201, Pesticides); metals (see chapter 203, Metals and Metalloids); oxidants (see chapter 207, Dyshemoglobinemias); and carbon monoxide (see chapter 222, Carbon Monoxide).

Several factors render children sensitive to chemical exposures.[3-5] Children have increased exposure to respiratory toxins because their minute volumes are higher, resulting in greater inhalational exposure. The smaller airway diameters and lesser ability to clear secretions render children more susceptible to inhaled toxins. Dermal absorption after exposure is also increased, because their skin is thinner and more permeable and they have a larger body surface-to-mass ratio. Children also are at risk for profound dehydration, resulting from vomiting and diarrhea secondary to toxic exposures. Many emergency protocols and antidote kits were developed for healthy adults, so dosing and care for pediatric exposures is usually scaled down from that used in adults.

A pregnant woman should be treated as any other adult patient because the best care for the fetus is proper care of the mother.[6] Consult an obstetrician if there is a significant exposure or evidence of systemic toxicity.

RESPIRATORY TOXINS

Determinants of airborne agent toxicity primarily include factors such as concentration of the inhaled toxin, duration of exposure, and whether the exposure occurred in an enclosed space. Other influential factors include vapor density, allergic or nonallergic bronchospastic response, exertional state or metabolic rate of the victim, and unique host susceptibility such as underlying reactive airway disease, history of smoking, or extreme age. Aspiration of gastric contents may cause further pulmonary insult.

General management of the patient with toxic inhalation injury begins with removal from the source, supplemental oxygen for hypoxemia, and inhaled bronchodilators for bronchospasm. The physical examination should include inspection of the upper airway for evidence of singed nasal hair, soot in the oropharynx, facial or oropharyngeal burns, stridor, hoarseness, dysphagia, cough, carbonaceous sputum, tachypnea, retractions, accessory muscle use, wheezing, or cyanosis. Because of the potential for sudden deterioration in patients with upper airway injury, there should be a low threshold for endotracheal intubation. Irrigate the eyes and skin as appropriate.

Copious airway secretions, hypoxia, bronchospasm, and pulmonary edema should be anticipated. Prophylactic antibiotics and steroids are not *routinely* indicated following toxic gas inhalation. Steroids can be given if the patient has underlying reactive airway disease or toxin-induced bronchospasm, and prophylactic steroids and antibiotics can be considered after **nitrogen dioxide** exposure.[7]

TABLE 204-3 Toxic Industrial Exposures That Cause Respiratory Symptoms

Agent	Irritant	Signs/Symptoms/Findings	Treatment
Phosgene	Mild/none	I—Eye and upper airway irritation; possibly none D—Dyspnea, noncardiogenic pulmonary edema	Supplemental oxygen only if hypoxemic (Sa_{02} <92%) Respiratory supportive care Consider nebulized β-agonists Mandatory rest Ocular care
Chlorine	Yes	I—Eye and upper airway irritation, nausea and vomiting (low-level exposure) D—Pulmonary edema (high-level exposure)	Humidified oxygen Respiratory supportive care Consider nebulized β-agonists Consider nebulized sodium bicarbonate Ocular care
Nitrogen dioxide	Yes	I—Dyspnea with transient improvement D—Worsening dyspnea due to pulmonary edema 24–72 h after exposure; methemoglobinemia	Humidified oxygen Respiratory supportive care Consider early corticosteroid treatment
Ammonia	Yes	I—Coughing, hoarseness, bronchospasm, eye and upper airway irritation	Humidified oxygen Consider nebulized β-agonists Consider nebulized anticholinergics Respiratory supportive care Ocular care

Abbreviations: D = delayed; I = immediate; Sa_{02} = arterial oxygen saturation.

Pertinent laboratory studies include arterial blood gas analysis with carboxyhemoglobin, methemoglobin, and lactate levels; whole-blood cyanide levels if persistent acidosis occurs (although this will not change immediate management); electrocardiogram monitoring; and chest radiography. The role for diagnostic or therapeutic bronchoscopy in inhaled toxin exposure is controversial.

Many highly toxic gases produced in large quantities in the industrial sector are potential agents for malicious use. Toxic gases of particular concern are those used in the battlefield or stockpiled—phosgene, chlorine, or ammonia. Additional toxicity can result from products of combustion such as hydrocarbons (see chapter 199, Hydrocarbons and Volatile Substances) or carbon monoxide (see chapter 222, Carbon Monoxide).

PHOSGENE

Phosgene was first used as a chemical agent of warfare in World War I, where it was responsible for 80% of all chemical gas fatalities. While stockpiled for potential use in World War II, it was never used in combat. Phosgene is no longer stockpiled by the U.S. military; however, it has widespread use in manufacturing and industry as a chemical precursor in the production of plastics, pharmaceuticals, dyes, polyurethane, and pesticides.[8,9] The heating of chlorinated fluorocarbons (Freon®) will also form phosgene gas and has caused poisonings in the refrigerator/air conditioner manufacturing and repairing industry.[10]

Phosgene release and contamination can be insidious. The gas is relatively water insoluble and therefore has poor warning properties. Only mild initial eye, nose, throat, and upper airway irritation are expected, and these may be entirely absent.[8] Classically, when released, it forms a white cloud with a characteristic odor of newly mown hay. The major injury is an acid burn to lower airways as phosgene reaches the alveoli and hydrolyzes to carbon dioxide and hydrochloric acid.[11] Acylation of alveolar capillary membranes results in diffuse capillary leak and noncardiogenic pulmonary edema, which may be delayed for up to 24 hours.[11,12] Symptoms are typically dyspnea and chest tightness. If the exposure is massive, immediate dyspnea and mucous membrane and eye irritation may occur. The onset of dyspnea or pulmonary edema within 4 hours of exposure suggests a very poor prognosis.[11]

Recovery usually occurs with respiratory supportive care and management of acute lung injury (noncardiogenic pulmonary edema).[13] Do not provide supplemental oxygen until symptoms and signs of hypoxia develop or arterial oxygen saturation falls, and then administer at the lowest fraction of inspired oxygen to maintain arterial oxygen saturation above 94%.[14] There is no benefit from IV and inhaled steroids or nebulized acetylcysteine.[15] Nebulized β-agonists may reduce lung inflammation if given within 1 hour of exposure.[13,16] Exertion increases pulmonary edema from phosgene, so rest is mandatory.[12] If patients require intubation and mechanical ventilation for respiratory failure, a protective ventilation strategy with low tidal volume, low plateau pressures, and high positive end expiratory pressure should be used.[17,18] Observe and monitor even asymptomatic patients for 24 hours after acute exposure.

CHLORINE

Chlorine is widely available in the industrial sector, in the setting of laboratories, paper manufacturing, swimming pool chemical distribution, and municipal water treatment.[19-22] Chlorine gas also has potential for use by terrorists.[23] When dispersed, this dense green-yellow gas has an acrid, pungent odor and, unlike phosgene, has excellent warning properties. Chlorine gas has intermediate water solubility, which is consistent with the observation that moderately exposed World War I soldiers exhibited both central airway damage and pulmonary edema.[24]

Early inflammatory injury results from the formation of hydrochloric and hypochlorous acids and oxidants upon contact with moist membranes.[25] Immediate ocular and upper airway irritation along with nausea and vomiting are common following mild exposures.[19,26] More significant exposure results in coughing, hoarseness, and pulmonary edema, usually within 6 hours, with some exposures leading to acute respiratory distress syndrome.[20,27] Severe exposures may produce pulmonary infiltrates or edema visible on radiographs or CT scan.[28]

Care is primarily supportive, with the use of humidified oxygen and bronchodilators as needed. Prophylactic antibiotics are not recommended. Nebulized sodium bicarbonate as a neutralizing therapy may improve pulmonary function during the initial 4 hours of treatment, but the long-term benefits are unproven.[21,29,30] Uncontrolled studies of both parenteral and inhaled steroids show improvement in airway resistance and arterial oxygenation but no improvement in the outcome with severe lung injury.[7] Chlorine causes dermal injury at high concentration, and skin decontamination may be required. In patients with ocular symptoms, the cornea should be evaluated for a chemical burn. A moderately symptomatic patient should be observed for 24 hours, monitoring for delayed onset of respiratory complications.

NITROGEN DIOXIDE

Nitrogen dioxide and other **nitrogen oxides** are encountered in the form of silo gas (**"silo filler disease"**), as products of combustion, in industrial processes, or as components of military blast weapons, smokes, and obscurants.[31,32] These oxides have limited water solubility that results in primarily lower airway toxicity.[33] An exposure to a high concentration may only produce very mild initial discomfort. Slow conversion of nitrogen dioxide to nitric acid in the alveoli results in delayed alveolar injury and pulmonary edema.[31,34-36] A triphasic illness typically is seen with initial dyspnea and flulike symptoms, transient improvement, and then worsening dyspnea, which heralds the onset of pulmonary edema 12 hours after exposure.[32,34,36-38] **Methemoglobinemia** has been reported from nitrogen oxide exposure. Case reports describe benefit with early corticosteroid treatment for acute lung injury following nitrogen dioxide exposure,[38] although overall evidence is inconclusive.[7]

AMMONIA

Ammonia is widely available; it is found in household and industrial chemicals and fertilizers and is used in the synthesis of plastics and explosives.[39] Ammonia is a highly water-soluble, colorless, alkaline, corrosive gas with a characteristic pungent odor that rapidly reacts with wet surfaces to form ammonium hydroxide. Ammonia has good warning properties due to its odor and immediate symptoms of mucous membrane, eye, and throat irritation. Lower airway involvement resulting in bronchospasm, pulmonary edema, residual reactive airway disease, and even permanent lung injury have been described following massive exposures, especially in those who are entrapped in enclosed spaces.[40]

Treatment is supportive with humidified oxygen, bronchodilators, and anticholinergics.[41] Concentrated ammonia, such as 8.4% ammonia hydroxide, is hazardous to the eyes, and symptomatic patients should undergo ocular irrigation followed by evaluation for corneal burns.

CYANIDE

Cyanide has an infamous history. It was the agent used by Nazi Germany (Zyklon B) in the gas chambers during the Holocaust, by Jim Jones in the mass cult suicide at the People's Temple in Guyana (commonly called "Jonestown"), for murder in over-the-counter drug-tampering incidents, and at the World Trade Center bombing in 1993.[42,43] Cyanide can be generated through natural and industrial processes (**Table 204-4**).

PATHOPHYSIOLOGY

Cyanide inhibits many metabolic processes, with its most toxic effect from binding with very high affinity to the ferric ion cytochrome a_3 portion of cytochrome oxidase within the mitochondria, resulting in an abrupt cessation of electron transport and oxidative phosphorylation, thus inhibiting cellular respiration.[43] This results in significantly impaired ATP production, even in the presence of sufficient oxygen, and profound disruption of aerobic metabolism. Thus following an acute exposure, organs and tissues with high oxygen consumption are the first and most severely affected.

TABLE 204-4 Sources of Cyanide

Burning of: wool, nylon, silk, acrylic, polyurethane, melamine, polyacrylonitrile, polyamide plastics
Industries: fabrication of plastics, electroplating, mining, photography, precious metal reclamation, solvents, hair removal from hides
Fumigants and fertilizers
Vermin extermination: cyanide spread into burrows and dens
Chemistry laboratories
Medicinal: Laetrile,* sodium nitroprusside
Plants: seeds from *Prunus* species (apricots, cherries, plums, peaches), cassava, bamboo shoots
Illicit phencyclidine manufacturing
Cigarette smoke
Vehicle exhausts

*No longer available in the United States, but widely available via the Internet and sold outside the United States.

Apnea	Severe

Adverse physiologic effects due to chronic subacute cyanide exposure are poorly defined. Studies of workers chronically exposed to cyanide demonstrated a higher incidence of thyroid disease and vitamin B_{12} deficiency.

Cassava, a tropical root that is the food staple in many countries, contains the cyanogenic glycosides *linamarin* and *lotaustralin* that liberate cyanide when metabolized in the body.[44] Chronic exposure to **dietary cyanide** is linked to tropical ataxic neuropathy and is endemic in countries where cassava consumption is high.[45,46] The combination of chronic tobacco use and a diet poor in cyanide-scavenging carotenes is associated with the development of optic neuropathy.[47] Techniques to reduce cyanoglucoside content in the raw tuber and different processing methods to reduce levels in prepared food have promise to reduce toxicity.[48]

Natural products, such as cyanogenic foods, or manmade sources, such as cigarettes, result in low cyanide concentrations in humans. Smokers' whole-blood levels of cyanide are roughly 2.5-fold higher than nonsmokers' levels.[49] The primary mechanism for detoxification of cyanide is its metabolism in the liver by rhodanese to thiocyanate, a nontoxic compound that is renally excreted. Toxicity occurs when this mechanism is rapidly overwhelmed.

CLINICAL FEATURES

Clinical presentation of the cyanide-poisoned patient depends on the cyanide-containing compound, the route of exposure, the concentration to which the patient is exposed, and the time since exposure. The onset of symptoms following inhalational exposure to hydrogen cyanide gas is immediate.[50] Exposure to concentrations <50 parts per million causes restlessness, anxiety, palpitations, dyspnea, and headache.[51] Higher concentrations of hydrogen cyanide gas cause severe dyspnea, loss of consciousness, seizures, and cardiac dysrhythmias. Coma, cardiovascular collapse, and death may occur immediately on exposure to very high levels. The median lethal dose for humans from hydrogen cyanide gas is estimated to be 200 parts per million for a 30-minute exposure and 600 to 700 parts per million for a 5-minute exposure.[51] The onset of symptoms following ingestion of a cyanide salt typically occurs within minutes. The median lethal dose of potassium or sodium cyanide in an untreated adult is estimated at 140 to 250 milligrams, but death has been reported with ingestion of as little as 50 milligrams, and survival has been reported in much larger ingestions when antidotes are used.[51]

The typical seriously poisoned patient has an altered level of consciousness and is hyperventilating, hypotensive, and bradycardic (**Table 204-5**).[42,52] Cutaneous manifestations vary, but, importantly, the patient is not initially cyanotic, as cyanide does not significantly alter the oxygen-carrying capacity of hemoglobin. However, cyanosis does follow if there is significant respiratory compromise or arrest. A smell of **bitter almonds** supports the diagnosis of cyanide poisoning, but reliability varies because only approximately 60% to 80% of the population can detect the odor. **Cherry-red skin color** has been described as a result of the increased venous hemoglobin oxygen saturation, but this is uncommon.

Severe unexplained metabolic acidosis is a consistent clinical feature (Table 204-6). In victims of smoke inhalation, toxic cyanide levels correlate with plasma lactate levels >90 milligrams/dL (>10 mmol/L), independent of the carbon monoxide level.[53] The decision to institute antidotal treatment of cyanide poisoning must be made long before confirmatory laboratory studies can be obtained. Although cyanide levels are not closely correlated with toxicity, they can be used to retrospectively confirm a clinical diagnosis or for forensic purposes. A variety of methods are available to measure cyanide in the environment and in biologic fluids,[54] but whole-blood cyanide level is the most commonly available test.[51]

Symptoms of poisoning are delayed following the ingestion of compounds that require metabolic activation to release free cyanide, such as **acetonitrile**, a solvent sold commercially as a cosmetic nail remover,[55] and **amygdalin** from apricot pits.[56] The slow release of cyanide by the spontaneous degradation of **sodium nitroprusside**, which is increased by exposure to sunlight, also results in delayed toxicity, particularly during prolonged or high-dose infusions.[57]

TABLE 204-6 Anticipated Laboratory Findings in Cyanide Poisoning

Test	Result	Cause
Serum electrolytes	Elevated anion gap	Lactic acidosis from anaerobic metabolism
Arterial blood gases	Metabolic acidosis Normal Pa_{O_2}	Oxygenation initially normal
Lactate	>90 milligrams/dL (>10 mmol/L)	Correlates with toxic cyanide level
Measured oxygen saturation by co-oximetry	Normal	Hemoglobin retains normal oxygen-carrying capacity
Measured arterial-mixed venous oxygen difference	Decreased	Decreased tissue oxygen consumption
Whole-blood cyanide level	Toxic >0.5 microgram/mL (>12 micromoles/L) Fatal >2.5 micrograms/mL (>60 micromoles/L)	Note: plasma cyanide levels are roughly one tenth of the whole-blood cyanide levels.
Fire victims	Elevated carboxyhemoglobin level	Carbon monoxide generated by incomplete combustion Synergistic toxicity with cyanide

Abbreviation: Pa_{O_2} = partial pressure of arterial oxygen.

TREATMENT

There are multiple antidotes for cyanide toxicity with variation in regional availability.[52,58-60] The two antidotes most commonly used in the United States are the **cyanide antidote kit** (containing nitrites and thiosulfate) and **hydroxocobalamin**. Aggressive supportive care with 100% oxygen, crystalloids, and vasopressors for hypotension is important.[61] Treat profound acidemia with sodium bicarbonate, because it enhances the effect of the nitrites and thiosulfate.[62]

The cyanide antidote kit has been well established for cyanide poisoning in the United States and is based on experimental and chemical principles developed by Chen and colleagues in 1933.[63,64] The antidotes contained in the cyanide treatment kit include ampules of amyl nitrite for inhalation, 10-mL vials of 3% sodium nitrite (300 milligrams), and 50-mL vials of 25% sodium thiosulfate (12.5 grams) (**Table 204-7**).

The decision to administer the cyanide antidote kit is straightforward when faced with a comatose, bradycardic patient with a clear history of cyanide exposure. More difficult management decisions arise in patients with smoke inhalation who have or may have carbon monoxide exposure as well as suspected cyanide exposure, and patients who are critically ill and acidotic without any known history of cyanide exposure. Consultation with a toxicologist or the regional poison control center is advised.

Nitrites The rationale for using nitrites is based on their ability to form methemoglobin, which binds cyanide more avidly than the ferric iron of cytochrome oxidase. This process removes cyanide from the cytochrome and enables the mitochondria to reactivate electron transport and oxidative metabolism.[65] Although this is believed to be the main mechanism of action of nitrites in cyanide poisoning, the vasodilatory effects may contribute to its effects.[66,67] **Inhaled amyl nitrite is a temporizing measure when an IV line is not available, but amyl nitrite is not needed when sodium nitrite can be given IV.** Inhalation of the amyl nitrite ampule generates approximately 5% methemoglobin, while sodium nitrite IV generates approximately 8% to 20%.[68] Nitrites do have significant side effects, including hypotension and the development of excessive methemoglobinemia.[58,62,69] **However, hypotension is not a contraindication to nitrite therapy in severe cyanide poisoning.**

In children, the sodium nitrite dose is adjusted according to the hemoglobin level to keep the methemoglobin level less than 30% (**Table 204-8**).[51,69] Aggressive sodium nitrite treatment has resulted in the death of a child from methemoglobinemia after a nonlethal ingestion of cyanide.[51,69] If hemoglobin values are not available, the empiric dose of sodium nitrite for a child less than 25 kg is based on the 10-gram hemoglobin concentration.[69]

Theoretically, nitrites are relatively contraindicated in victims of smoke inhalation who have or are thought to have concomitant carbon monoxide poisoning because the induction of methemoglobinemia will further decrease oxygen delivery. In cases such as these where increased methemoglobinemia would be potentially harmful, consider withholding the nitrites and giving only the sodium thiosulfate or using hydroxocobalamin.[70]

TABLE 204-7 Treatment of Cyanide Poisoning in Adults

100% oxygen	
IV crystalloids and vasopressors for hypotension	
Sodium bicarbonate for acidemia	
AND	
Cyanide antidote kit	Amyl nitrite inhaler; crack vial and inhale over 30 s.* Sodium nitrite 3% solution: 10 mL (300 milligrams) IV given over no less than 5 min.† Sodium thiosulfate 25% solution: 50 mL (12.5 grams) IV. Repeat sodium thiosulfate once at half dose (25 mL) if symptoms persist.
OR	
Hydroxocobalamin	5 grams IV over 15 min. If needed, may repeat 5 grams for a total of 10 grams.

*Not necessary if IV is in place.

†Avoid nitrites in the presence of severe hypotension if diagnosis is unclear; consider sodium thiosulfate or hydroxocobalamin.

TABLE 204-8 Treatment of Cyanide Poisoning in Children

100% oxygen	
IV crystalloids and vasopressors for hypotension	
Sodium bicarbonate for acidemia	
AND	
Cyanide antidote kit	Amyl nitrite inhaler; crack vial and hold in front of nose for 15–30 s.*† Sodium nitrite 3% solution: adjusted according to hemoglobin level, given IV over no less than 5 min†‡ (monitor methemoglobin level <30%).

Hemoglobin (grams/100 mL)	Sodium Nitrite 3% Solution (mL/kg)
7	0.19
8	0.22
9	0.25
10	0.27
11	0.30
12	0.33
13	0.36
14	0.39

Sodium thiosulfate 25% solution: 1.65 mL/kg IV.

Repeat sodium thiosulfate once at half dose (0.825 mL/kg) if symptoms persist.

*Not necessary if IV is in place.

†Consider withholding nitrites if suspected concomitant carbon monoxide poisoning.

‡Avoid nitrites in the presence of severe hypotension if diagnosis is unclear.

Sodium Thiosulfate After the administration of sodium nitrite, infuse sodium thiosulfate. Sodium thiosulfate enhances the activity of the enzyme rhodanese, a mammalian enzyme that likely evolved in response to the ubiquitous presence of cyanide in nature. Rhodanese catalyzes the transfer of sulfate from sodium thiosulfate to cyanide to form thiocyanate, a less toxic form that is excreted by the kidneys.[58,62,63] Animal studies using lethal doses of cyanide demonstrate that the therapeutic effects of sodium nitrite and sodium thiosulfate are synergistic.[62-64]

Sodium thiosulfate has very limited toxicity in comparison with nitrites and is a safer empirical therapy when the diagnosis is not clear. It may also be useful as a sole therapy for victims of inhalation injury where there is concern that the induction of methemoglobinemia in the setting of carbon monoxide exposure may further reduce oxygen carrying capacity.[71] However, sodium thiosulfate alone was not effective in an animal model of cyanide-induced shock, suggesting that such isolated therapy is not useful for serious human toxicity.[72]

Hydroxocobalamin Because of the side effects of nitrites, an effort has been made to develop equally efficacious but less toxic therapies.[58-60] **Hydroxocobalamin (vitamin B_{12a})**, was approved in 2006 by the U.S. Food and Drug Administration. Hydroxocobalamin is a metalloprotein with a cobalt center that binds cyanide, removing it from cytochrome oxidase and forming cyanocobalamin, which is then eliminated via the kidneys. Because of its low toxicity and its efficacy, **it is thought to be ideal in cases where the diagnosis of cyanide poisoning is uncertain or in cases where the induction of methemoglobinemia (i.e., concomitant exposure to carbon monoxide) may be detrimental.**[73-75]

The dose of hydroxocobalamin in an adult patient is 5 grams IV over 15 minutes. A second dose of 5 grams IV may be repeated once (for a total of 10 grams) if the patient's condition warrants.[76] Side effects associated with hydroxocobalamin include transient hypertension, a reddish discoloration of the skin and mucous membranes, and rare anaphylactic reactions. Due to the discoloration of body fluids caused by hydroxocobalamin,[77] interference with chemistry and co-oximetry tests[78,79] and with hemodialysis machines has been reported.[80]

The combination of hydroxocobalamin followed by sodium thiosulfate led to a faster return to baseline of the mean arterial pressure in animal models when compared to sodium nitrate and sodium thiosulfate; however, there was no difference in mortality.[81] A follow-up study in the same animal model found that reversing cyanide-induced shock resided with the hydroxocobalamin alone.[72]

Other Antidotes **Dimethylaminophenol** is a rapid methemoglobin inducer developed in Germany for the treatment of cyanide poisoning.[58-60,62] Clinical efficacy is similar to sodium nitrite. The adult dose is 250 milligrams (5 mL of 5% solution) IV over 1 minute, used in combination with sodium thiosulfate.

Dicobalt edetate is a cobalt compound with a high affinity for cyanide. Although highly effective as a cyanide antidote, the toxicity of dicobalt edetate is greater when cyanide is not present, limiting its use to cases where the presence of cyanide is unequivocal.[42,43,58-60,62] The adult dose for dicobalt edetate is 300 milligrams IV over approximately 1 minute. If there is inadequate clinical response after 5 minutes, a second dose of 300 milligrams IV may be given.

Cobinamide, a precursor to cobalamine, is highly effective in a mouse model of cyanide poisoning.[82] A potential advantage is that cobinamide sulfite can be administered as an IM injection and could be useful in the prehospital setting.

Hyperbaric Oxygen The data on hyperbaric oxygen for cyanide poisoning are conflicting.[83-85] Although there are reports in the literature that support its use, studied patients had received multiple therapies, so improvement cannot be contributed solely to hyperbaric oxygen. In addition, animal studies of cyanide poisoning show no benefit of hyperbaric oxygen over 100% oxygen.[62] The timing, lack of science, and impracticality make hyperbaric oxygen therapy an unproven endeavor in acute cyanide toxicity.

Gastric Decontamination Patients with a history of ingestion may benefit from activated charcoal, which should be considered only in patients who are alert, have a patent airway, and present within 1 hour of ingestion.

DISPOSITION AND FOLLOW-UP

All patients who receive cyanide antidotal therapy should be admitted for observation. Patients who have ingested a substance that may result in delayed toxicity (up to 6 hours) should also be admitted. Full recovery is anticipated in many cases of severe poisoning in which treatment is initiated rapidly and cardiac arrest has not yet occurred. Recovery despite cardiac arrest also has been reported, but anoxic encephalopathy may ensue. Successful organ transplant has been reported after death secondary to cyanide poisoning.[86]

HYDROGEN SULFIDE

Hydrogen sulfide is a colorless, flammable gas that may be encountered in industries such as oil and gas or as a natural product of organic decomposition, such as sewer or manure gas.[87,88] Hydrogen sulfide can be made by mixing common household products, and in Japan, this method was associated with a rash of attempted suicides in 2008.[89] Regardless of its source, it is among the most common causes of fatal gas inhalation exposures. Fatal exposures usually occur in enclosed spaces that may claim additional victims as would-be rescuers are poisoned upon entering. Large industrial or natural releases of hydrogen sulfide may produce fatalities in unconfined spaces.[90]

The mechanism of toxicity is similar to that of cyanide, with disruption of oxidative phosphorylation through inhibition of cytochrome oxidase a_3, except this impairment reverses rapidly when hydrogen sulfide exposure ceases.[91] Cellular asphyxia and impaired ATP production promote anaerobic metabolism with lactate accumulation and metabolic acidosis.

Hydrogen sulfide is one of the few chemical asphyxiants that also possesses irritative properties, such that respiratory and ocular irritation are common following exposure.[88,92] The characteristic odor of "rotten eggs" may not be noticed due to olfactory fatigue from persistent low-level exposures or from olfactory paralysis seen at high hydrogen sulfide levels. In high concentrations, rapid loss of consciousness, seizures, and death occur after only a few breaths.[93] Delayed pulmonary edema and corneal injury should be anticipated with massive exposures.

Treatment begins with removal from the source, administration of high-flow oxygen, and decontamination of the skin and eyes, as appropriate.[94] For patients still conscious, symptoms resolve with this treatment alone. For patients with altered sensorium or impaired cardiovascular function after hydrogen sulfide exposure, administration of **sodium nitrite** 300 milligrams IV can produce rapid improvement.[88,94] The concept is that low-level methemoglobin formation may enhance conversion of sulfide to the less toxic sulfmethemoglobin. An animal model of lethal hydrogen sulfide toxicity found benefit with hydroxocobalamin, but human treatment experience is needed before this agent can be recommended.[95,96] Hyperbaric oxygen therapy for hydrogen sulfide toxicity has been described in multiple published case reports, but there is no evidence that it is superior to standard oxygen therapy.[84,97]

CHAPTER 205

Vitamins and Herbals

Rick Tovar

INTRODUCTION

Vitamins and herbal preparations, particularly those sold in health food stores, are considered by many to be innocuous but may have potential toxicity when taken in excessive amounts over a period of time. Also, herbal preparations may contain toxic contaminants that can cause acute poisoning.

Hypervitaminosis from the fat-soluble vitamins A, D, and E can produce chronic toxicity (after weeks to months of excessive ingestion) or subacute toxicity (after days to a few weeks). Of the water-soluble vitamins, niacin, pyridoxine, and ascorbate are associated with toxicity (**Table 205-1**).

VITAMIN A

Dietary vitamin A is usually found in two forms: retinyl palmitate (an ester) from animal sources or carotenoids found in plants. After ingestion, the ester form is hydrolyzed in the gastrointestinal tract to retinol. Retinol is then absorbed into intestinal mucosal cells, where it then combines with a fatty acid to again become a retinyl ester. Carotenoids are dark-colored compounds found in plants. Plants containing the carotenoids have β-carotene, which is the vegetable compound most efficiently converted to retinol. The liver contains approximately 95% of body vitamin A stores.

Vitamin A forms part of the visual pigments of the retina (rhodopsin and iodopsin), is important for the formation of mucus-secreting cells in the columnar epithelium, maintains bone growth, and maintains cellular membrane stability. The recommended dietary allowance ranges from 4000 international units (IU) for women to 5000 IU for men.

Hypervitaminosis A generally occurs in either the supplement or dietary forms.[1] The chronic form of vitamin A toxicity is usually due to excessive supplement use, although there have been case reports of acute toxicity due to ingestion of mammal organs (e.g., fish liver).[2] When the total dose is similar, water-miscible preparations are more toxic than oily preparations because of better absorption.[3] There is variability among patients in the amounts necessary to develop hypervitaminosis; hemodialysis patients can develop hypercalcemia with lower doses of vitamin A supplementation due to decreased renal clearance of retinol.[4] Thus the minimum dose that may cause toxicity in humans is not established.

TABLE 205-1 Symptoms of Hypervitaminosis

Vitamin	Symptoms
Vitamin A	Subacute toxicity: red peeling rash, headache, vomiting Chronic toxicity: blurred vision, appetite loss, abnormal skin pigmentation, hair loss, dry skin, pruritus, long-bone pain, bone fractures, rare cases of pseudotumor cerebri, hypercalcemia, and hepatic failure
Vitamin D	Subacute toxicity: hypercalcemia, anorexia, nausea, abdominal pain, lethargy, weight loss, polyuria, constipation, confusion, and coma
Vitamin E	Chronic toxicity: coagulopathy in patients on warfarin, nausea, fatigue, headache, weakness, and blurred vision
Vitamin K	Acute toxicity: anaphylactoid reactions if given in parenteral form (rare)
Vitamin B_1 (thiamine)	No toxicity observed with ingestion of large doses
Vitamin B_2 (riboflavin)	No toxicity observed with ingestion of large doses
Vitamin B_3 (niacin)	Acute toxicity: niacin flush, dose >100 milligrams, redness, burning, and itching of the face, neck, and chest; rarely hypotension Chronic toxicity: doses >2000 milligrams/d, abnormalities of liver function, impaired glucose tolerance, hyperuricemia, skin dryness and discoloration
Vitamin B_6 (pyridoxine)	Subacute and chronic toxicity: doses >1–3 grams/d orally or more over several weeks, peripheral neuropathy with unstable gait, numbness of the feet, similar symptoms in the hands and arms, marked loss of position and vibration senses
Vitamin B_{12}	No toxicity observed with ingestion of large doses. With large IV doses: erythema of skin, mucous membranes, serum, and urine. Rare anaphylactoid reactions. Possible interference with serum colorimetric lab studies.
Folate	No toxicity observed with ingestion of large doses. Masking of macrocytic anemia from vitamin B_{12} deficiency with large doses of folate.
Vitamin C (ascorbate)	Chronic toxicity: nephrolithiasis (controversial), intrarenal deposition of oxalate crystals with renal failure; large doses can produce diarrhea and abdominal cramps.

Symptoms of hypervitaminosis A include blurred vision, appetite loss, abnormal skin pigmentation, loss of hair, dry skin, pruritus, long-bone pain, and an increased incidence of bone fractures. **Massive doses can additionally cause pseudotumor cerebri, hypercalcemia, and hepatic failure.**[5]

The treatment of hypervitaminosis A includes discontinuation of the vitamin and supportive care. Acute ingestions may be treated with oral activated charcoal.

β-Carotene, a precursor of vitamin A, may be rarely associated with toxicity but does not generally cause hypervitaminosis A. In diabetic patients and patients with hypothyroidism, however, large doses of β-carotene can cause a yellowish discoloration of the skin, which fades once β-carotene is stopped. This phenomenon is occasionally seen in infants and toddlers who consume large amounts of carrots and other pigmented vegetables.

VITAMIN D

Dietary vitamin D is ingested as a provitamin, either ergocalciferol (vitamin D_2) or cholecalciferol (vitamin D_3). Both forms are essentially bioequivalent. These provitamins are then converted to calcitriol (1, 25-dihydroxycholecalciferol), the physiologically active form of vitamin D. The major function of calcitriol is to elevate plasma calcium and phosphorus levels, enabling normal bone mineralization.

The recommended dietary allowance for vitamin D is approximately 400 IU, and therapeutic doses sometimes exceed 5000 IU. Infants may develop hypercalcemia from doses as low as 2000 IU, but adults require much higher doses before toxicity develops.[6,7] **The main toxicity from hypervitaminosis D is hypercalcemia,** and clinical findings include anorexia, nausea, abdominal pain, lethargy, weight loss, polyuria, constipation, confusion, and coma. Symptoms from massive doses of 1000 to 3000 IU/kg per day can develop in 2 to 8 days.

Treatment of hypervitaminosis D includes discontinuation of vitamin D, reduction of the calcium intake, and reduction of serum calcium levels. Pamidronate disodium, a bisphosphonate, inhibits osteoclastic bone resorption and can be used to treat the hypercalcemia.[10,11]

VITAMIN E

Vitamin E activity is not limited to one compound; eight different fat-soluble, naturally occurring alcohols (called tocopherols and tocotrienols) have vitamin E activity, but α-tocopherol is the most active form. Because it is rapidly oxidized, α-tocopherol protects other molecules from being oxidized and thus is termed an *antioxidant*.[10] Foods high in vitamin E include wheat germ, corn, soybean, sunflower seed, cod liver, and others.

Vitamin E is absorbed and distributed through the body similarly to other fat-soluble vitamins: from the intestines and then through lymphatic chylomicrons. The recommended dietary allowance is about 15 milligrams (or 22.4 IU) of α-tocopherol in adults with an increase to 19 milligrams per day during lactation.

Vitamin E is thought to be nontoxic at daily doses of up to 600 IU. The most significant clinical effect of vitamin E at doses higher than 1000 IU per day taken on a long-term basis is the ability to antagonize the effects of vitamin K.[11] Specifically, vitamin E acts as a competitive inhibitor of vitamin K–dependent γ-carboxylation. This effect is only clinically significant in those patients taking warfarin.[12] Additionally, through the production of thromboxane, high levels of vitamin E inhibit platelet aggregation. **Patients being treated with warfarin should be cautioned about ingesting large amounts of vitamin E.** Patients not undergoing treatment with warfarin may rarely have bleeding from large amounts of vitamin E. Other effects in adults who take large doses for a long period of time include nausea, fatigue, headache, weakness, and blurred vision.[13] These symptoms resolve weeks after discontinuation of the vitamin.

VITAMIN K

Vitamin K activity is found in several compounds of varied origin: phylloquinone or vitamin K_1, which is naturally produced by plant sources; menaquinone or vitamin K_2, which is produced by bacterial sources; and menadione or vitamin K_3, a synthetic chemical that is a vitamin precursor of vitamin K_2. Because large doses of menadione are toxic, the use of menadione supplements is banned in the United States for human use but can still be found in animal feed. The gastrointestinal absorption of vitamin K requires the presence of bile and pancreatic juice. Between 10% and 80% of ingested vitamin K is absorbed. It is thought that most of the vitamin K stores in the body are derived from plant sources (K_1). Furthermore, if one has an adequate dietary intake of vitamin K_1, eradication of the gut bacteria will not lead to a deficiency of vitamin K.[14] The recommended dietary allowance of vitamin K is small, about 1 microgram/kg per day. Because most adults consume a diet that contains 300 to 500 micrograms, vitamin K deficiency states are uncommon. In contrast to the other fat-soluble vitamins, vitamin K is not stored in the body to any significant extent.

Vitamin K is required for the production of several factors involved in the coagulation cascade: factor II (prothrombin), factor VII (proconvertin), factor IX (Christmas factor), and factor X (Stuart-Prower factor), and proteins C, S, and Z. Warfarin compounds inhibit vitamin K activity, thereby producing a coagulopathy.

The main concern about vitamin K toxicity is the adverse reactions seen with the IV form. The only recommended form of vitamin K for both oral and parenteral use is K_1. Because vitamin K is fat soluble, it

must be given parenterally in a lipid-soluble form. Toxicity from IV vitamin K_1 injection is due to the aqueous colloidal suspension formulation[15] producing rare anaphylactoid reactions and reported deaths.[16]

The absorption of IM vitamin K_1 is erratic and therefore not recommended. PO vitamin K is equal in efficacy to the SC route. Therefore, SC injection of vitamin K is recommended only when the patient is hemodynamically stable and unable to take the oral form. The IV form is usually reserved for serious or life-threatening bleeding due to warfarin.[17]

Toxicity from oral vitamin K is rare, although doses exceeding 500 micrograms per day are associated with skin rashes. Treatment from excessive vitamin K includes stopping the drug and monitoring prothrombin times for patients on warfarin.

VITAMIN B_1 (THIAMINE)

Vitamin B_1, or thiamine, is converted by the body to thiamine pyrophosphate, which acts as a cofactor for several metabolic reactions, including transketolations. Food sources of thiamine include fruits, grain, meats, fish, and milk, among others. The recommended dietary allowance for thiamine is 1.5 milligrams.[18]

Intestinal absorption of thiamine is greatest in the jejunum. Thiamine is not stored in the body to any significant extent. Because of renal excretion (water solubility), there is no toxicity to the ingestion of large doses of thiamine over prolonged periods.

The two main clinical concerns with thiamine include the precipitation of Wernicke's encephalopathy and anaphylactoid reactions. Older literature observed the "precipitation" of Wernicke's encephalopathy in patients with thiamine deficiency with prolonged (not acute) treatment with hypertonic IV glucose.[19] However, there was no observed precipitation of Wernicke's encephalopathy from a single or repeated bolus of IV glucose, even in patients with an altered mental status.[20] Furthermore, thiamine uptake into nerve cells is slower than that of glucose uptake, making pretreatment with thiamine low in efficacy in the prevention of a Wernicke's encephalopathy.[21] **In summary, IV glucose is unlikely to precipitate Wernicke's encephalopathy in patients with altered mental status.**

The issue of IV thiamine toxicity is based on older literature that noted anaphylactoid reactions, likely due to the diluent and contaminants.[22] The current pure aqueous forms of thiamine for IV use very rarely result in anaphylactoid adverse reactions.[23] Therefore, IV use of thiamine is both safe and clinically efficacious. Conversely, PO and IM thiamine is absorbed unpredictably in the emergency setting.

VITAMIN B_2 (RIBOFLAVIN)

Riboflavin is excreted through the urine, and toxicity has not been reported regardless of the amount ingested.[24]

VITAMIN B_3 (NIACIN)

There are two active forms of niacin—nicotinic acid and nicotinamide—which, in conjunction with thiamine and riboflavin, have antipellagra activity. Niacin, thiamine, and riboflavin all function as coenzymes in energy metabolism. Niacin becomes part of the coenzymes nicotinamide-adenine dinucleotide and nicotinamide-adenine dinucleotide phosphate; both are required in all major metabolic pathways in which there is oxidative breakdown of amino acids, fatty acids, and other compounds, including the oxidation of ethanol.

Niacin is found primarily in poultry, meat, and fish, with lesser amounts in plants. Niacin deficiency causes changes first in cells of the skin, followed by impairment of nervous system and GI function. Deficiency states create symptoms such as anorexia, anxiety, depression, irritability, and weakness.

Nicotinic acid in the range of 100 to 200 times the recommended dietary allowance of 20 milligrams lowers serum cholesterol and β-lipoprotein, but nicotinamide does not. Large niacin doses can also deplete cardiac muscle glycogen and can cause liver toxicity. Some patients experience a frightening "niacin flush" when taking a dose of >100 milligrams. **The niacin flush, caused by prostaglandin D_2 and E_2 release with subsequent vasodilation, is characterized by face, neck, and chest burning, itching, and erythema.**[25] **Rarely, hypotension may occur.**[26] An adult-strength aspirin may decrease the prostaglandin surge caused by niacin.[27]

Higher niacin doses may additionally cause nausea, abdominal cramping, diarrhea, and headache. Even higher doses >2000 milligrams per day over a prolonged period can produce abnormalities of liver function, impaired glucose tolerance, hyperuricemia, and skin changes such as dryness and discoloration. These subacute and chronic symptoms resolve within days to weeks after stopping treatment.

VITAMIN B_6 (PYRIDOXINE)

Vitamin B_6 is a necessary cofactor for many enzymatic processes. The active form of pyridoxine is pyridoxal-5-phosphate. Dietary deficiency of pyridoxine is classically characterized by cheilosis, glossitis, seborrheic dermatitis, and stomatitis. Severe dietary deficiency can lead to altered mental status and seizures.[27] Dietary deficiency in infants can result in seizures (as a consequence of a reduced synthesis of γ-aminobutyric acid), anemia (caused by impaired synthesis of heme), xanthurenic aciduria (because of reduced formation of hydroxyanthranilic acid), cystathioninuria (because of decreased cleavage of cystathionine to cysteine and homoserine), and homocystinuria (because of impaired formation of cystathionine). Deficiency states can be induced through ingestion of antagonists to vitamin B_6 such as isoniazid, hydrazines (rocket fuels and the toxic mushroom *Gyromitra esculenta*), cycloserine, and penicillamine.

Vitamin B_6 in high doses >1 gram/d over more than several weeks will cause nerve damage.[28-30] Initial symptoms are an unstable gait and numbness of the feet. This is followed by similar symptoms in the hands and arms. There may be a marked loss of position and vibration senses. After withdrawal of the vitamin, recovery occurs within several months, although some patients may have residual neurologic impairment. **There is no evidence that a single 5-gram IV dose of pyridoxine (the usual dose given for hydrazine exposure) will cause any type of nerve damage.**[31]

Vitamin B_6 also can cause intestinal inactivation of levodopa in patients receiving that medication for Parkinson's disease. Patients should be instructed not to take this vitamin at the same time as the medication.

VITAMIN B_{12} (CYANOCOBALAMIN)

Vitamin B_{12} deficiency can result in hematologic, neurologic, and psychiatric effects.[32] The common hematologic disorders include megaloblastic anemia and pancytopenia. The neurologic disorders commonly observed include paresthesias, peripheral neuropathies, and dorsal spinal cord column demyelination. Psychiatric symptoms include depression, dementia, and psychosis.

Partially because of the size and complexity of the vitamin B_{12} molecules, deficiencies of this water-soluble vitamin result more from absorption problems than from dietary insufficiencies.[32] Absorption depends on the production of intrinsic factor by the parietal cells of the stomach. Vitamin B_{12}–intrinsic factor complexes are initially formed in the stomach. The complexes pass to the ileum, where the intrinsic factor attaches to the intestinal epithelium, facilitating the absorption of the vitamin B_{12}. Vitamin B_{12} is stored in the liver in such quantities that it takes several years for pernicious anemia to develop in an individual who is a strict vegetarian and ingests little B_{12} or in someone unable to produce intrinsic factor.[32]

Until recently, it was believed that vitamin B_{12} had a wide therapeutic index for harm. **With the advent of the use of vitamin B_{12} as an antidote for cyanide poisoning, there have been a few case reports of direct vitamin B_{12} toxicity given in the recommended dose of 5 grams IV to adults, producing erythema of the skin, mucous membranes, urine, and serum.**[33] Rare cases of anaphylactoid reactions have also been reported. Hydroxocobalamin can also interfere with colorimetric lab tests, including those that test for carbon monoxide.[34]

BIOTIN

Biotin is required by all organisms but can be synthesized only by bacteria, yeasts, molds, algae, and some plant species. Those taking chronic antibiotics and those on extremely low-calorie diets are at risk of developing a biotin deficiency. For such individuals, 100 to 300 micrograms of biotin per day is recommended. There is no known toxicity to biotin overdosage.[35]

FOLATE

Folate or folic acid is essential for the production of DNA, RNA, and proteins. Folate is found in fresh leafy green vegetables, yeasts, and liver. Recommended daily allowance for folate in nonpregnant adults is 0.4 milligram. After ingestion, folate is actively absorbed in the small and large intestine. Both deficiencies of vitamin B_{12} and folate can result in megaloblastic (macrocytic) anemia. Large doses of folic acid given to an individual with an undiagnosed vitamin B_{12} deficiency could correct megaloblastic anemia but leave the individual at risk of developing irreversible neurologic damage. Such cases of neurologic progression in vitamin B_{12} deficiency have been mostly seen at folate doses of 5 milligrams and above.[36]

VITAMIN C (ASCORBATE)

The major form of vitamin C, ascorbate or ascorbic acid, is a strong reducing agent that participates in hydroxylation reactions such as those necessary for the formation of collagen. **Scurvy** is due to vitamin C deficiency and results in collagen, protein, and lipid metabolism abnormalities. Additionally, the presence of vitamin C in the intestines increases the absorption rate of iron, so those with a vitamin C deficiency will also be iron depleted.

Vitamin C, which is found primarily in fruits and vegetables, is absorbed through the jejunum and ileum. Large doses of vitamin C can lower the frequency of gout attacks.[37] It is controversial whether high-dose vitamin C is responsible for an increased risk of oxylate renal kidney stones.[38] Intrarenal deposition of oxalate crystals has been reported to cause renal failure in patients with chronic high-dose ascorbate ingestion.[39] Large doses of vitamin C may produce diarrhea and abdominal cramps, which subside with discontinuation. **Megadoses of vitamin C may result in false-negative guaiac testing of feces and may give falsely elevated glucose levels on dipstick testing.**

HERBAL AGENTS

Herbal preparations have long been used by traditional cultures, and their use appears to be increasing in developed countries.[40] In developed countries, herbal preparations have been looked upon as a natural and inexpensive alternative to common Western pharmaceuticals. Unfortunately, many studies funded by the National Center for Complementary and Alternative Medicine have not supported the use of herbal medications for treatment of depression (St. John's wort),[41] dementia (Ginkgo biloba),[42] prostatic hypertrophy (saw palmetto),[43] osteoarthritis (glucosamine and chondroitin),[44] and the common cold (Echinacea).[45] In addition, no herbal is completely free of adverse side effects or the potential for herb–drug interactions.[46] This can be a problem because many patients are reluctant to divulge that they are taking herbal preparations to medical providers.[47]

Although the U.S. Food and Drug Administration (FDA) has some regulatory oversight of herbal preparations, regulation is not as strict as that for drugs. Instead, herbs are classified as dietary supplements by the Dietary Supplemental Health and Education Act of 1994.[48] Unlike drugs, where the manufacturer must prove safety before marketing, the FDA needs to show that a dietary supplement is unsafe before it may take steps to restrict its sale or remove it from the market. Herbal agents can be classified as generally safe, potentially toxic, and toxic (**Table 205-2**).[49-52] Many herbal agents have specific liver, eye, and cardiovascular toxicities.[53–58]

TABLE 205-2 Some Generally Safe Herbal Agents

Agent	General Use	Rare Adverse Effect
Chamomile	Antispasmodic	Anaphylaxis if patient allergic to ragweed
Chondroitin	To treat arthritis	May cause GI upset
Echinacea	To treat or prevent upper respiratory or urinary tract infections	Anaphylaxis if patient allergic to daisies May deplete vitamin stores
Feverfew	To prevent migraines	Suddenly discontinuing may precipitate migraine If chewed, may cause mouth sores If applied to skin, may cause dermatitis
Garlic	To treat hypertension, colic, and hyperlipidemia	Hypotension, rash, nausea, vomiting, diarrhea; death has been reported in massive doses in children
Ginkgo	To treat dementia, vertigo, and Raynaud's disease	May inhibit platelet aggregation and interact with warfarin May cause GI upset
Ginseng	To treat impotence, fatigue, ulcers, and stress	May interact with warfarin Lowers blood glucose May cause insomnia, nervousness
Glucosamine	To treat arthritis	Allergic reaction
Kava	Used for sedation and to relieve sore throat pain	Hepatotoxicity
St. John's wort	To treat depression	Phototoxicity May interact with serotonin reuptake inhibitors; avoid tyramine-containing foods
Valerian	Used for sedation	Interacts with other sedating drugs May have paradoxical stimulant effect

TABLE 205-3 Some Potentially Toxic Herbal Agents

Agent	General Use	Adverse Effect
Black cohosh	To delay or treat menopause	Nausea, vomiting, dizziness, weakness
Chaparral (creosote bush)	Antioxidant effects, analgesia	Potentially hepatotoxic and nephrotoxic
Comfrey	Bone and teeth building, variety of other uses	Potentially hepatotoxic
Ephedra	Weight loss	Hypertension; contraindicated for patients with hypertension, diabetes, or glaucoma
Hawthorn	Congestive heart failure	Additive toxicity with prescribed cardioactive steroids
Juniper	Diuretic	Hallucinogenic; may also cause renal toxicity, nausea, and vomiting
Lobelia	As an expectorant or for treatment of asthma	Anticholinergic syndrome
Nutmeg	Dyspepsia, muscle aches, and arthritis	Hallucinations, GI upset, agitation, coma, miosis, and hypertension
Pennyroyal	Rubefacient, delaying menses, abortifacient	Hepatotoxicity
Pyrrolizidine alkaloids	Pulmonary ailments	Hepatic veno-occlusive disease
Sabah	Weight loss	Pulmonary toxicity
Wormwood	Dyspepsia	Absinthism: restlessness, vertigo, tremor, paresthesias, delirium
Yohimbe	Aphrodisiac	Hallucinations, weakness, hypertension, and paralysis

TABLE 205-4 Some Likely Herb–Drug Interactions

Herb	Herb Used for	Drug	Effect of Interaction
Cayenne (Capsicum)	Arthritis, neuralgia, analgesic	Angiotensin-converting enzyme inhibitors	Increased cough
		Theophylline sustained-release	Increased absorption
Dan shen (salvia)	Reduction of lactation	Warfarin	Decreased warfarin metabolism
Ephedra	Energizer, weight loss, asthma, sinus congestion	Monoamine oxidase inhibitors	Increased toxicity
		Sympathomimetics	Additive effect
Ginkgo	Dementia, peripheral arterial disease, tinnitus	Aspirin	Increased risk of bleeding
		Warfarin	
Grapefruit juice	For vitamin C activity	Amiodarone	Increased drug availability of any one of these drugs because of inhibition of intestinal CYP3A4
		Benzodiazepines	
		Calcium channel blockers	
		Carbamazepine	
		Clomipramine	
		Cyclosporine	
		Dextromethorphan	
		Ethinyl estradiol	
		3-hydroxy-3-methyl-glutaryl-CoA reductase inhibitors ("statins")	
		Phosphodiesterase type 5 inhibitors (erectile dysfunction drugs)	
		Quinidine	
		Sertraline	
Kava	Sedative/anxiolytic	Caffeine	Increased levels from inhibition of CYP1A2
		Fluvoxamine	
		Theophylline	
Licorice in chronic, high doses	Respiratory disorders, hepatitis, inflammatory diseases, infections	Antihypertensives	Decreased effect (can cause pseudohyperaldosteronism by inhibiting 11-β-dehydrogenase)
		Diuretics	Increased potassium loss, myopathy
		Prednisolone	Increased drug levels
St. John's wort	Depression	Cyclosporine	Decreased serum levels; transplant rejection
		Digoxin	Decreased serum level
		Indinavir	Decreased serum level
Yohimbine	Erectile dysfunction, sexual potency	Clonidine	Decreased effect
		Cyclic antidepressants	Enhanced autonomic and central effects of yohimbe

Abbreviation: CYP = cytochrome P-450.

Although herbal preparations can cause direct toxicity from the herb itself, it is much more common that the patient becomes ill from the contamination, misuse, overuse, or misidentification of the herbal preparation.[59] Herbal preparations can cause either direct toxicity (**Table 205-3**) or indirect toxicity from herb–drug interactions (**Table 205-4**).[52] Reported contaminants in herbal preparations include lead, selenium, and cyanide.[62-66]

Much of the available literature on herb–drug interactions is anecdotal and nonreproducible, but there are some herb–drug interactions that, because of numerous clinical reports, animal studies, and/or controlled clinical studies, can be deemed to be "likely" (**Table 205-4**).[61] Although not usually of clinical relevance, certain herbals may also interfere with assays for therapeutic drugs.[67-69]

CHAPTER 206

Antimicrobials

Joseph G. Rella
Wallace A. Carter

INTRODUCTION

Adverse effects associated with antimicrobials occur primarily in three circumstances: side effects with therapeutic dosing, acute toxicity resulting from excessive dosing, and subacute to chronic effects from sustained therapeutic use. Side effects can be immunologic (allergic) or nonimmunologic (pharmacologic or idiosyncratic) in nature. Antibiotics cause more reported allergic reactions than other drugs, possibly due to their high frequency of use that is often in a repeated and interrupted fashion. Sometimes a diluent or other chemical constituent in the formulation of a drug causes the adverse effect.

Most patients who sustain an acute antimicrobial overdose remain asymptomatic, and observation is generally all that is required. Measurement of drug levels is not helpful for management but may be

TABLE 206-1 Select Antimicrobial Toxicities and Their Specific Treatments

Drug	Acute Toxicity	Special Therapy for Symptomatic Overdose
Antibacterials		
Penicillin	Seizures (50 million units or more IV)	Benzodiazepines
Amoxicillin	Crystalluria, hematuria, acute renal failure	IV fluid
Cephalosporins	Encephalopathy, seizures	Benzodiazepines
Chloramphenicol	Cardiovascular collapse	Hemodialysis
Fluoroquinolones	Seizures	Benzodiazepines
Macrolides	Prolonged QT interval, torsades de pointes arrhythmia	Magnesium sulfate
Sulfonamides	Methemoglobinemia	Methylene blue
Vancomycin	"Red man syndrome" (anaphylactoid response)	Slow or stop infusion, antihistamines
Antimalarials		
Chloroquine	Seizures, QRS-complex and QT-interval prolongation, hypotension, hypokalemia	Epinephrine, diazepam
Quinine (quinidine)	Sodium-potassium channel blockade, α-adrenergic antagonism, hypoglycemia, ototoxicity, ophthalmic toxicity	Multidose activated charcoal, sodium bicarbonate, dextrose, octreotide
Primaquine	Methemoglobinemia, hemolysis	Methylene blue
Antituberculous medications		
Isoniazid	Inhibition of γ-aminobutyric acid synthesis and functional deficiency pyridoxine, seizures	Benzodiazepines, high-dose pyridoxine

confirmatory. Levels are available for several antibiotics such as chloroquine, isoniazid, and quinine. Ancillary testing should be based on the substance ingested and the clinical condition of the patient, such as methemoglobin concentrations for patients with dapsone or chloroquine toxicity.[1] Some antimicrobials are associated with specific, significant toxicities following an acute ingestion and may require particular therapy (**Table 206-1**).

Consider GI decontamination for patients suspected of ingesting a toxic amount of a potentially dangerous antimicrobial agent. Single-dose activated charcoal without sorbitol given orally or via nasogastric tube is most beneficial within 1 hour of the ingestion.[2,3] Multidose activated charcoal is indicated in symptomatic patients who have ingested dapsone or quinine.[4] Hemodialysis or hemoperfusion is effective at reducing concentrations of dapsone,[5,6] chloramphenicol, cefepime,[7,8] and possibly pentamidine.[9]

ANTIBACTERIALS

PENICILLINS, CEPHALOSPORINS, AND OTHER β-LACTAM AGENTS

Acute overdoses of penicillins and cephalosporins mainly produce nausea, vomiting, and diarrhea but are rarely life threatening. Large doses of penicillins or cephalosporins may produce seizures through γ-aminobutyric acid inhibition, and seizures are managed by administration of benzodiazepines or barbiturates. Seizures resulting from intrathecal doses of penicillins or cephalosporins may require cerebral spinal fluid exchange for treatment. Imipenem may cause seizures in overdose or at therapeutic doses, and these are treated in the same manner. Agitation, encephalopathy, absence seizures, and nonconvulsive status epilepticus have been reported with cefazolin, ceftazidime, cefuroxime, and cefepime.[8,10,11] Patients most at risk for adverse neurologic effects from β-lactams are those with renal failure, those with underlying CNS abnormalities, and those receiving high-dose therapy.[11,12] Amoxicillin overdose may produce crystal-induced interstitial nephritis, hematuria, and renal failure; treatment is supportive with IV fluids.[13-16]

Amoxicillin-clavulanate can cause rare cases of cholestatic hepatitis (1 to 6 weeks following initiation) and pancreatitis.[17] Treat with supportive care and withdrawal of the drug. Penicillins are associated with bone marrow suppression, hemolysis, interstitial nephritis, and vasculitis.[18] Cephalosporins, particularly cefaclor, are associated with serum sickness and can cause acute hemolytic crisis. Cephalosporins with the *N*-methylthiotetrazole side chain, such as cefazolin and cefotetan, can produce a disulfiram-like reaction as the side chain is released.

Two particular acute adverse reactions to procaine penicillin G are the Jarisch-Herxheimer reaction and Hoigne's syndrome. The Jarisch-Herxheimer reaction can begin within a few hours following antibiotic treatment of Lyme disease or early syphilis. This reaction is characterized by headache, fever, myalgias, and rash; is usually limited to 24 hours; and results from antigen released from lysed bacteria.[19] Hoigne's syndrome begins within minutes after an intramuscular or intravascular injection of procaine penicillin G. This syndrome is characterized by extreme apprehension, fear, hallucinations, illusions, hypertension and tachycardia, and seizures. The cause of this reaction is unclear, but the effects occur in the absence of other signs of anaphylaxis. Amoxicillin and ceftriaxone has been reported to produce a similar reaction.

CLINDAMYCIN

The lincosamide class includes clindamycin and lincomycin, and its main acute toxicities are nausea, vomiting, and diarrhea. Although all antibiotics have been associated with depletion of normal gut flora that allows for proliferation of *Clostridium difficile*, clindamycin is among those antibiotics that carry a higher risk for this infection, along with potential complications of pseudomembranous colitis and toxic megacolon.[20] Clindamycin is also associated with two forms of liver injury: (1) transient elevations of serum aminotransferases and (2) acute idiosyncratic liver injury characterized by jaundice, alanine transaminase levels 2 to 12 times over baseline, fever, and rash. This latter form of injury usually shows minimal cell injury on liver biopsy and is not associated with liver failure.[21]

FLUOROQUINOLONES

Acute overdose of fluoroquinolones rarely produces life-threatening effects. Seizures are a rare consequence of fluoroquinolone use, possibly due to γ-aminobutyric acid inhibition or through sequestration of magnesium, which may also result in prolongation of the QT interval and cause torsades de pointes. Fluoroquinolones are associated with acute renal failure, possibly through a hypersensitivity reaction where risk factors include concomitant use of renin-angiotensin–blocking agents.[22] Crystal-induced nephropathy has been reported with therapeutic doses of ciprofloxacin.[23] Caution is advised when using in children due to potential problems with developing cartilage and bone. In adults, tendon rupture has been attributed to fluoroquinolone use for up to 120 days following start of treatment. Discontinue the antibiotic in those who complain of painful or swollen tendons. Fluoroquinolones are also associated with dysglycemia, rash, serum sickness, and tinnitus.[11]

LINEZOLID

The first member of a new class of antibiotic, synthetic oxazolidinones, linezolid inhibits monoamine oxidase and can lead to serotonin syndrome when used concurrently with other serotonergic medications such as selective serotonin reuptake inhibitors.[24]

Chronic therapy longer than 28 days is associated with peripheral neuropathy and optic neuropathy with loss of central vision and loss of color and visual acuity. Lactic acidosis can occur, especially in patients with numerous comorbidities including sepsis and cirrhosis. Linezolid is also associated with anemia, thrombocytopenia and pancytopenia, and cholestatic hepatitis.[25]

MACROLIDES AND KETOLIDES

Although the most common adverse reaction to macrolide use is GI distress, QT-interval prolongation with potential for torsades de pointes

is the most important.[26,27] The mechanism for this effect is blockade of the delayed rectifier potassium currents and has resulted from use of erythromycin, clarithromycin, telithromycin, and, to a lesser extent, azithromycin. Erythromycin and clarithromycin, but not azithromycin, also inhibit the cytochrome P-450 3A4 enzyme, which can result in severe drug interactions. Additionally, macrolides are associated with high-frequency sensorineural hearing loss, cholestatic hepatitis, and rarely pancreatitis.[28]

TRIMETHOPRIM-SULFAMETHOXAZOLE

These two antimicrobials work together for their antibiotic effect and are associated with many commonly reported adverse effects. Among them are allergic reactions, hematologic disorders, hypoglycemia, methemoglobinemia, rhabdomyolysis, and psychosis. Trimethoprim-sulfamethoxazole is also associated with idiosyncratic acute liver injury with a clinical pattern suggestive of a drug allergy or hypersensitivity mechanism and is particularly common among HIV-infected patients.[29]

VANCOMYCIN

Red man syndrome is an anaphylactoid response related to rate of intravenous vancomycin infusion that can include angioedema, chest pain, dyspnea, flushing, pruritus, and urticaria. Rarely, this syndrome can also cause seizures and cardiovascular collapse. Most symptoms resolve within 15 minutes when the infusion is stopped. Continuing the infusion at a slower rate or with increased dilution can help decrease recurrence. Pretreatment with diphenhydramine is also helpful.[30]

ANTIFUNGALS

TRIAZOLES

Antifungal agents such as fluconazole, clotrimazole, and miconazole are not expected to produce severe toxicity in acute overdose settings. Uncommon adverse reactions such as hepatotoxicity can occur, rarely leading to liver failure and death. Liver injury is hepatocellular and can be accompanied by eosinophilia, fever, and rash. Recovery begins with stopping the drug and may take as long as 3 to 4 months. These antifungals are also associated with neutropenia and thrombocytopenia, and they inhibit cytochrome P-450 3A4, potentiating toxicity from other pharmaceuticals.

AMPHOTERICIN B

Amphotericin B is used for progressive, life-threatening fungal infections and is rarely encountered in the ED. Acute overdoses are associated with fever, headache, nausea, vomiting, rigors, hypotension and tachycardia, anemias, dysrhythmias, electrolyte wasting, nephrotoxicity, neuropathy, and cardiac arrest.[31]

ANTIMALARIALS

CHLOROQUINE AND HYDROXYCHLOROQUINE

Chloroquine toxicity usually begins within 3 hours of ingestion with nausea, vomiting, and diarrhea.[32] Cardiovascular collapse may be precipitous, with QRS-complex prolongation and atrioventricular nodal blockade. Hypotension may be more severe than that seen with quinine overdose and is accompanied by respiratory depression and hypokalemia. Neurologic toxicity may include headache, obtundation, and seizures.

Aggressive supportive care is needed. A decreased mortality rate has been demonstrated in chloroquine overdose treated with early intubation, gastric lavage, deep sedation with benzodiazepines, and vasoactive pressor support with epinephrine to maintain a systolic blood pressure of 100 mm Hg (13.3 kPa).[33-35]

MEFLOQUINE

Mefloquine is used for prophylaxis or treatment of drug-resistant malaria and is associated with a variety of complications. In addition to GI distress, mefloquine is a rare cause for cardiac depression and severe CNS events, including seizures, hallucinations, and psychosis. Milder CNS effects, such as headache, insomnia, and vivid dreams, occur in up to 25% of patients. Mefloquine is not recommended as first-line therapy and is contraindicated in patients with seizures or psychiatric disorders.[36]

PRIMAQUINE

Primaquine is associated with GI distress and may cause hemolytic anemia and methemoglobinemia, especially in a glucose-6-phosphate dehydrogenase–deficient population. Granulocytosis, granulocytopenia, hypertension, dysrhythmia, and neurologic depression are rare complications associated with overdose.[37,38]

QUININE

The cardiac toxicity of quinine includes both sodium and potassium channel antagonism, which may result in widened QRS-complex intervals, torsades de pointes, hypotension, syncope, and sudden death.[39] Quinine also has significant ocular toxicity in acute overdose and blindness may result from serum levels >10 to 15 micrograms/mL (31 to 46 micromol/L).[40,41] Ototoxicity from quinine can produce symptoms that range from tinnitus to deafness.[42] Hypoglycemia may also result from hyperinsulinemia.

Sodium bicarbonate to maintain a serum pH of 7.55 is the mainstay of treatment for quinine-induced cardiac toxicity while avoiding class IA, IC, and III antidysrhythmic agents. **Quinine overdose is one of the few drugs for which multiple-dose activated charcoal is truly indicated.**[4]

ATOVAQUONE-PROGUANIL

Atovaquone-proguanil (Malarone) is most often associated with GI distress and headache. It is quite well tolerated and is considered safe during pregnancy and breastfeeding.

ANTIPARASITICS

Most antiparasitics, such as albendazole, mebendazole, and thiabendazole, have minimal toxicity following an acute overdose, usually only producing abdominal pain, nausea, and vomiting. Levamisole, an antihelminthic that was discontinued in the United States in 1999 due to agranulocytosis, has been a common adulterant in illicit cocaine. Complications found among cocaine users stemming from the levamisole contaminant include leukocytoclastic vasculitis, cutaneous necrotizing vasculitis, and thrombotic vasculopathy without vasculitis.[43]

ANTITUBERCULOUS MEDICATIONS

ISONIAZID

First-line medications used to treat both latent and active tuberculosis include isoniazid, rifampin, ethambutol, and pyrazinamide. Of these, isoniazid is associated with high morbidity and mortality in overdose.[44,45] At therapeutic doses, adverse effects from isoniazid include neuropathy and hepatic injury.

The clinical symptoms of acute isoniazid overdose typically begin with nausea, mental status changes, and ataxia, which may be seen as early as 30 minutes after ingestion. These symptoms may progress to **the three classic features of acute isoniazid overdose: seizures, metabolic acidosis, and protracted coma**.[46,47] Seizures typically follow acute isoniazid ingestions of greater than 20 to 30 milligrams/kg. Isoniazid-induced seizures are generalized tonic-clonic in nature and are often refractory to standard anticonvulsive therapy with benzodiazepines and barbiturates. The mechanism for isoniazid-induced seizures is a functional deficiency of pyridoxine (vitamin B_6) and inhibition of the synthesis of γ-aminobutyric acid, the primary CNS inhibitory neurotransmitter. Seizures with therapeutic doses of isoniazid have been reported in patients,[48] presumably due to very low vitamin B_6 levels.[49] Although the metabolic acidosis that accompanies isoniazid-induced seizures is likely due to motor activity, the lactic acidemia may not resolve as rapidly as with other more typical epileptic seizures.

Consider isoniazid overdose in patients with refractory seizures.[44] Isoniazid-induced seizures are treated with a combination of benzodiazepines and pyridoxine. The dose of **pyridoxine** is a gram-for-gram equivalent to the amount of isoniazid ingested.[50] For patients who ingest an unknown quantity of isoniazid, the recommended dose of pyridoxine is 5 grams IV in adults and 70 milligrams/kg (maximum 5 grams) in pediatric patients. Pyridoxine may be administered at a rate of approximately 1 gram IV every 2 to 3 minutes until the seizures stop or the maximum dose has been given. After the seizures have ceased, the remainder of the pyridoxine dose should be given over the following 4 to 6 hours to limit recurrent seizures.

Adequate single-dose therapy of pyridoxine should be effective to stop most seizures, but patients who do not receive adequate pyridoxine dosing may have repeat seizures. Pyridoxine may also assist in reversing isoniazid-induced comas. Hospitals where tuberculosis is endemic should ensure that an adequate supply of intravenous pyridoxine is maintained to treat overdoses.[51] If only pyridoxine tablets are available, they may be crushed and administered by nasogastric tube.

Phenytoin has no role in treating seizures originating from isoniazid overdose, and there is little role for sodium bicarbonate treatment of the metabolic acidosis resulting from isoniazid toxicity. Because most isoniazid-induced toxicity occurs within 2 hours of ingestion, patients who remain asymptomatic for 6 hours after ED presentation are safe for medical clearance.

OTHER ANTITUBERCULOSIS AGENTS

Other antituberculous medications are associated with a variety of adverse reactions of a milder nature. **Ethambutol** toxicity is also primarily GI in nature, but additionally may cause unilateral or bilateral ocular toxicity including blurred vision, disruption of color perception, and loss of peripheral vision. **Rifampin** infrequently causes severe toxicity and is most often associated with GI symptoms. Acute toxicity has been associated with flushing, angioedema, and neurologic effects including numbness, extremity pain, ataxia, and weakness. Rifampin has been presumptively implicated in producing acute kidney injury with proteinuria.[52] **Pyrazinamide** is not associated with any toxic effects following an acute overdose.

CHAPTER 207

Dyshemoglobinemias

Brenna M. Farmer
Lewis S. Nelson

INTRODUCTION

Dyshemoglobinemias are disorders in which the hemoglobin molecule is functionally altered and prevented from carrying oxygen. The most clinically relevant dyshemoglobinemias are carboxyhemoglobin, methemoglobin, and sulfhemoglobin.[1] Carboxyhemoglobin is created during carbon monoxide exposure and, because of its unique importance and prevalence, is usually considered an environmental emergency (see chapter 222, "Carbon Monoxide").

METHEMOGLOBINEMIA

PATHOPHYSIOLOGY

The iron moiety within deoxyhemoglobin normally exists in the ferrous (bivalent or Fe^{2+}) state. Ferrous iron avidly interacts with compounds seeking electrons, such as oxygen or other oxidizing agent, and in the process is oxidized to the ferric (trivalent or Fe^{3+}) state. Hemoglobin in the ferric form is unable to bind oxygen for transport and is termed *methemoglobin*. Under normal circumstances, <1% to 2% of circulating hemoglobin exists as methemoglobin; higher concentrations define the condition of *methemoglobinemia*.

Methemoglobin accumulation is enzymatically prevented by the rapid reduction of the ferric iron back to the ferrous form. Cytochrome b_5 reductase is primarily responsible for this reduction, in which reduced nicotinamide adenine dinucleotide donates its electrons to cytochrome b_5, which subsequently reduces methemoglobin to hemoglobin (**Figure 207-1**). This pathway is responsible for reducing nearly 95% of methemoglobin produced under typical circumstances. Methemoglobinemia occurs when this enzymatic reduction is overwhelmed by an exogenous oxidant stress, such as a drug or chemical agent (**Table 207-1**).

Methemoglobin can also be reduced by a second enzymatic pathway using the reduced form of nicotinamide adenine dinucleotide phosphate (or NADPH) and NADPH-methemoglobin reductase.[2] This pathway is normally of minimal importance and is responsible for less than 5% of total reduction under typical circumstances. However, this enzyme and pathway are crucial for the antidotal effect of methylene blue (Figure 207-1).

The limited role for NADPH partially explains why patients with glucose-6-phosphate dehydrogenase deficiency with a resultant deficiency in NADPH are **not** at increased risk of developing methemoglobinemia, although they are at risk of developing hemolysis following exposure to an oxidant stress. To a very limited extent, nonenzymatic reduction systems, such as vitamin C and glutathione, may participate in the reduction of methemoglobin to hemoglobin.

The primary clinical effect of methemoglobin is to reduce the oxygen content of the blood. Because hemoglobin-bound oxygen accounts for the vast majority of an individual's oxygen-carrying capacity, as the methemoglobin concentration rises, oxygen-carrying capacity to the tissues falls. Patients with methemoglobinemia are often more symptomatic than patients who suffer from a simple anemia that produces an equivalent reduction in oxygen-carrying capacity. This is caused by a leftward shift in the oxyhemoglobin dissociation curve, the consequence of which is a reduced release of oxygen from the erythrocyte to the tissue at a given partial pressure of oxygen (**Figure 207-2**).[2]

The oxyhemoglobin dissociation curve of blood with a 50% reduction in erythrocytes (i.e., anemia) follows a curve similar to that of nonanemic blood; although the oxygen content is lower, unbinding of half of the oxygen (50% oxygen saturation) occurs at the same Po_2. With 50% methemoglobin, the leftward shift of the oxyhemoglobin dissociation curve means that hemoglobin is less willing to give up its oxygen, so that tissue hypoxia is more severe than in those with a 50% anemia.

Acquired Methemoglobinemia Drugs in conventional doses rarely produce clinically significant methemoglobinemia, although subclinical methemoglobinemia may go unrecognized (Table 207-1). Benzocaine is the local anesthetic most commonly associated with methemoglobinemia.[3-5] Methemoglobin induction with sodium nitrite is a therapeutic goal in the management of patients suffering from cyanide poisoning (see chapter 204, "Industrial Toxins"). Certain compounds, particularly dapsone,[6] require metabolism to the "active" oxidant, and there may be substantial delay until toxicity is evident. Occupational methemoglobinemia usually involves exposure to aromatic compounds, primarily amino- and nitro-substituted benzenes.[7] Routes of absorption are typically dermal or inhalational due to the high lipophilicity and volatility of these compounds, respectively.

Neonates and infants are more susceptible to methemoglobin accumulation because of undeveloped methemoglobin reduction mechanisms. This accounts for the relatively common development of methemoglobinemia in infants given certain nitrogenous vegetables (e.g., spinach) or well water that contains high nitrate levels (generally from fertilizer use). Bacteria within the GI flora convert nitrate to the nitrite form, which is a more potent oxidant. Another common cause of acquired infantile methemoglobinemia is gastroenteritis, which presumably is caused by an increased oxidant burden originating in the GI tract.[8]

Hereditary Methemoglobinemia Hereditary methemoglobinemia results from either an enzymatic deficiency (i.e., cytochrome b_5 reductase)

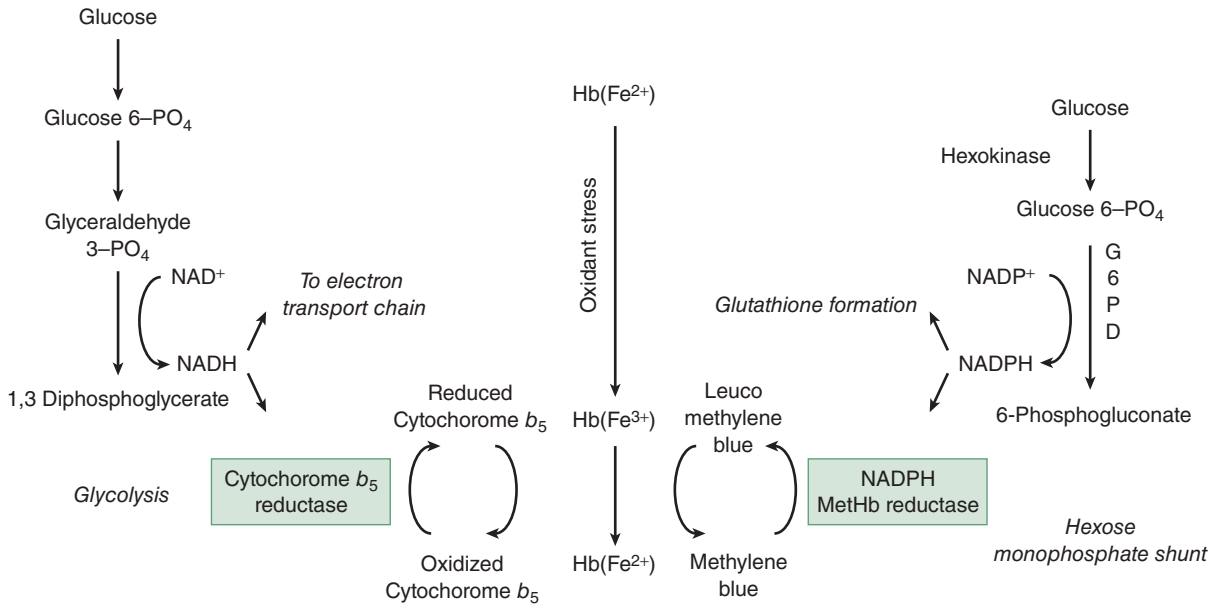

FIGURE 207-1. Methemoglobin formation and mechanism of action of methylene blue. G6PD = glucose-6-phosphate dehydrogenase; Hb(Fe^{2+}) = hemoglobin; Hb(Fe^{3+}) = methemoglobin; NAD^+ = oxidized nicotinamide adenine dinucleotide; NADH = reduced form of nicotinamide adenine dinucleotide; $NADP^+$ = nicotinamide adenine dinucleotide phosphate; NADPH = reduced form of nicotinamide adenine dinucleotide phosphate; PO_4 = phosphate.

or from the presence of an amino acid substitution within the hemoglobin molecule itself, termed *hemoglobin M*.[1] Patients with cytochrome b_5 reductase deficiency develop methemoglobin levels of 20% to 40%. Cyanosis in these individuals begins at birth, but they remain asymptomatic and develop normally.

Hemoglobin M, an abnormal form of hemoglobin, has altered tertiary structure so that the heme iron exists in an environment favoring the ferric form. This disorder only occurs in the heterozygous form, because the homozygous form is incompatible with life. As with cytochrome b_5 reductase deficiency, patients develop profound cyanosis but tolerate the elevated methemoglobin concentrations well due to compensatory mechanisms.

TABLE 207-1 Drugs Causing Methemoglobinemia

Oxidant	Comments
Analgesics	
Phenazopyridine	Commonly reported
Phenacetin	Rarely used
Antimicrobials	
Antimalarials	Common
Dapsone	Hydroxylamine metabolite formation is inhibited by cimetidine
Local anesthetics	
Benzocaine	Most commonly reported of the local anesthetics
Lidocaine	Rare
Prilocaine	Common in topical anesthetics
Dibucaine	Rare
Nitrates/nitrites	
Amyl nitrite	Cyanide antidote kit and used to enhance sexual encounters
Isobutyl nitrite	Used to enhance sexual encounters
Sodium nitrite	Cyanide antidote kit
Ammonium nitrate	Cold packs
Silver nitrate	Excessive topical use
Well water	Problem in infants, due to nitrate fertilizer runoff
Nitroglycerin	Rare
Sulfonamides	
Sulfamethoxazole	Uncommon

CLINICAL FEATURES

Healthy patients who have normal hemoglobin concentrations do not usually develop clinical effects until the methemoglobin level rises above 20% of the total hemoglobin.[9] At methemoglobin levels between 20% and 30%, anxiety, headache, weakness, and light-headedness develop, and patients may exhibit tachypnea and sinus tachycardia. Methemoglobin levels of 50% to 60% impair oxygen delivery to vital tissues, resulting in myocardial ischemia, dysrhythmias, depressed mental status (including coma), seizures, and lactate-associated metabolic acidosis. Levels above 70% are largely incompatible with life.

Cyanosis associated with methemoglobin is often described as a gray discoloration of skin, with a detection threshold for methemoglobin of 1.5 grams/dL, corresponding to methemoglobin levels between 10% and 15% in a nonanemic individual (**Figure 207-3**). Methemoglobin levels above 20% will discolor the blood a chocolate brown.[10]

Anemic patients may not exhibit cyanosis until the methemoglobin level rises well above 10% because cyanosis detection is dependent on the level of methemoglobin, not the percentage. Anemic patients may likewise suffer significant symptoms at lower methemoglobin concentrations because the relative percentage of hemoglobin in the oxidized form is greater. Patients with preexisting cardiopulmonary diseases that impair oxygen delivery will also manifest symptoms with less significant elevations in their methemoglobin levels. Conversely, compensatory mechanisms that shift the oxyhemoglobin dissociation curve to the right, such as acidosis or elevated 2,3-diphosphoglycerate, may result in somewhat better toleration of methemoglobin.

DIAGNOSIS

Consider methemoglobinemia in patients with cyanosis, particularly if cyanosis does not improve with supplemental oxygen (**Figure 207-4**).[4-6,9] A useful clue is that patients with methemoglobin-associated cyanosis generally are less symptomatic than equivalently appearing patients with hypoxemia-induced cyanosis. This is due to the more deeply pigmented color of methemoglobin compared with deoxyhemoglobin; it takes about 5 grams/dL of deoxyhemoglobin to cause cyanosis, which

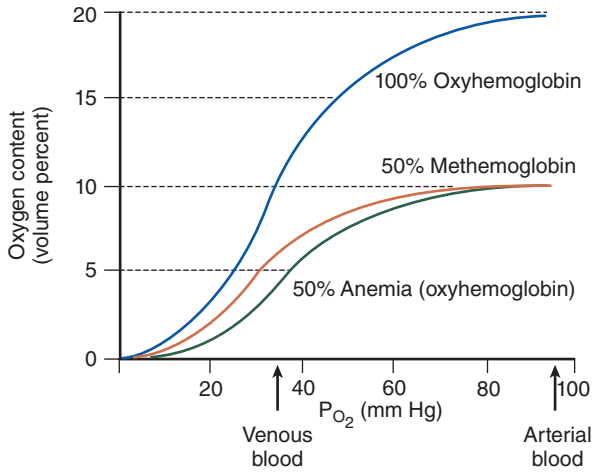

FIGURE 207-2. Oxyhemoglobin dissociation curve.

equates to an oxygen-carrying capacity of approximately 67% of normal, compared with the cyanosis visible with a methemoglobin concentration of 1.5 grams/dL, which equates to an oxygen-carrying capacity of 90% of normal. Blood containing methemoglobin has a characteristic "chocolate brown" color when phlebotomized. Detection of this discoloration is improved when compared directly with normal blood.[10]

Pulse oximetry results are not accurate in patients with methemoglobinemia.[11] The standard pulse oximeter uses two wavelengths of light, 660 nm and 940 nm, to calculate the percentage of oxyhemoglobin. Methemoglobin is also detected by these wavelengths, and light absorption by methemoglobin confounds the calculation for the oxyhemoglobin percentage. **In patients with methemoglobinemia, the pulse oximeter will report a falsely elevated value for arterial oxygen saturation percentage.** The specific values vary by oximeter,[3,11] but typically trend to approximately 85%.[11]

Pulse co-oximeters are commercially available that use additional wavelengths of light to measure the total hemoglobin concentration and percentages of carboxyhemoglobin and methemoglobin.[11] When first released, accuracy for methemoglobinemia levels was progressively unreliable with increasing hypoxemia,[12] but the new probes[13] appear to have corrected the problem.[11]

FIGURE 207-3. Methemoglobinemia due to dapsone. Gray-blue discoloration of the patient's fingernails compared with that of the physician. With the patient on supplemental oxygen, the pulse oximeter reported an oxygen saturation of 93%. Arterial blood gas measurement reported a Pa_{O_2} of 307 mm Hg, a calculated oxygen saturation of 99.8%, and a measured methemoglobin of 12%. [Photo Contributed by J. S. Stapczynski, MD.]

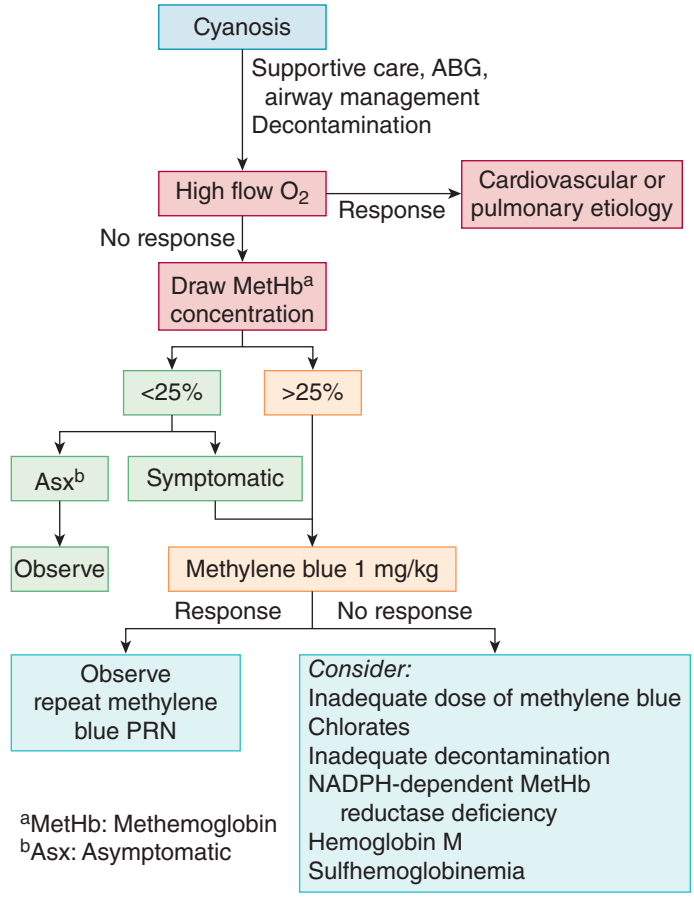

FIGURE 207-4. Toxicologic approach to the cyanotic patient. ABG = arterial blood gas; NADPH = reduced form of nicotinamide adenine dinucleotide phosphate. [Reproduced with permission from Nelson LS, Lewin NA, Howland MA, Hoffman RS, Goldfrank LR, Flomenbaum NE (eds): *Goldfrank's Toxicologic Emergencies*, 9th ed. McGraw-Hill, Inc., 2011; Figure 127-7, p. 1704.]

Definitive identification of dyshemoglobinemias requires co-oximetry, a spectrophotometric method capable of differentiating among oxyhemoglobin, deoxyhemoglobin, carboxyhemoglobin, and methemoglobin species.[9] This widely available test can be performed on a venous or arterial specimen.

Arterial blood gas results may be initially deceptive because the partial pressure of oxygen, a measure of dissolved, not bound, oxygen, is normal. Thus, calculation of oxygen saturation from measured partial pressure by the blood gas analyzer will produce a falsely elevated result.

TREATMENT

Patients with methemoglobinemia require supportive measures to ensure oxygen delivery and the administration of appropriate antidotal therapy, if indicated (**Table 207-2**). Gastric decontamination is of limited value, because there often is a substantial time interval between exposure to the toxic agent and the development of methemoglobin. If a source of continuing GI exposure is suspected, decontamination is indicated, and in most stable patients, a single dose of activated charcoal is likely sufficient. Dermal decontamination should be used as indicated. **Antidotal therapy with methylene blue is reserved for symptomatic patients or for those asymptomatic patients with methemoglobin levels >25%.**

Methylene blue indirectly accelerates the enzymatic reduction of methemoglobin by NADPH-methemoglobin reductase. NADPH-methemoglobin reductase reduces methylene blue to leucomethylene blue, which is then capable of directly reducing the oxidized iron (Fe^{3+}) back to the ferrous state (Fe^{2+}) (Figure 207-1). The initial methylene blue dose is 1 milligram/kg (0.1 mL/kg of the 1% solution or approximately

TABLE 207-2 Management of Methemoglobinemia

Assess airway, breathing, and circulation; exclude other causes of cyanosis
Insert an IV line
Administer oxygen
Attach the patient to a cardiac and pulse oximeter or co-oximeter
Obtain an ECG
Decontaminate the patient as needed
Administer methylene blue: if symptomatic or methemoglobin >25%
Consider: cimetidine for patients taking dapsone

7 mL in an adult) IV over 5 minutes. The infusion should be slow because rapidly administered doses of methylene blue are painful. Clinical improvement should be seen within 20 minutes, and as the methemoglobin level falls, the most severe signs and symptoms will resolve first. Resolution of the cyanosis occurs later only after the methemoglobin concentration falls below 1.5 grams/dL. Repeat dosing of methylene blue is acceptable, if cyanosis has not cleared in 1 hour. Serotonin toxicity (syndrome) is a rare risk when methylene blue is administered to patients on serotonergic drugs such as antidepressants.[14]

Treatment failures may result if the patient has glucose-6-phosphate dehydrogenase deficiency, because this enzyme is critical for the production of NADPH by the hexose monophosphate shunt (Figure 207-1). Hemolysis may impede a response to methylene blue, which requires an intact erythrocyte to be effective. Oxidant drugs with long serum half-lives, such as dapsone with a half-life of approximately 50 hours, produce prolonged oxidant stress to the red blood cell. Therefore, dapsone-exposed patients may require repetitive dosing of methylene blue. Because the hydroxylamine metabolite of dapsone is responsible for the production of methemoglobin, inhibition of its formation by cytochrome P450 with cimetidine,[6] in standard doses, is generally recommended.

In rare instances, patients may be deficient in NADPH-methemoglobin reductase, the required enzyme for methylene blue activation. Lastly, treatment failure may occur in patients with sulfhemoglobinemia, which is clinically indistinguishable from methemoglobinemia, but which is not responsive to methylene blue. Patients who do not respond to methylene blue should be treated supportively. If clinically unstable, the use of packed red cell transfusions or exchange transfusions may be indicated.

SULFHEMOGLOBINEMIA

PATHOPHYSIOLOGY

Sulfhemoglobinemia is a rare condition that occurs when a sulfur atom irreversibly binds to the porphyrin ring of the heme moiety and induces the permanent oxidation of iron to the ferric (Fe^{3+}) state.[1] Many of the agents responsible for sulfhemoglobinemia are identical to those associated with methemoglobin. Because many of these drugs or chemicals do not contain sulfur, the origin of sulfur is speculative; hypotheses include alteration of intestinal flora with production and absorption of hydrogen sulfide and/or glutathione.[15] Historically, sulfhemoglobinemia was most often associated with acetanilide, phenacetin, sulfonamide, and a proprietary mixture that contained sodium bromide. Because these drugs are rarely used and the sodium bromide component in the proprietary mixture was removed in 1975, contemporary cases of drug-induced sulfhemoglobinemia are now most often reported with phenazopyridine, dapsone, metoclopramide, and sumatriptan.[16,17] Sulfhemoglobinemia has been associated with industrial chemicals, such as trinitrotoluene, hydroxylamine sulfate, dimethyl sulfoxide, and hydrogen sulfide.[18]

CLINICAL FEATURES

Patients with sulfhemoglobinemia can have a clinical presentation similar to those with methemoglobinemia. However, the disease process itself is substantially less concerning because, although the reduction in the patient's oxygen-carrying capacity is quantitatively similar, the sulfhemoglobin oxygen dissociation curve is shifted rightward, not leftward as in methemoglobinemia, favoring the release of hemoglobin-bound oxygen to the tissue with sulfhemoglobinemia. Because of the milder symptoms, speculation is that cases of sulfhemoglobinemia are often missed.[19]

DIAGNOSIS

The pigmentation of the blood by sulfhemoglobin is substantially more intense than other colored hemoglobin species; only 0.5 gram/dL of sulfhemoglobin is needed to produce a cyanosis equivalent to that produced by 1.5 grams/dL of methemoglobin or 5 grams/dL of deoxyhemoglobin. The color of blood drawn from a patient with sulfhemoglobinemia has been described as dark greenish-black. **In sulfhemoglobinemia, standard pulse oximetry tends to report a falsely low value for arterial oxygen saturation percentage.**[20] The diagnosis of sulfhemoglobinemia may be difficult to confirm. Standard co-oximetry may not differentiate sulfhemoglobin from methemoglobin because of similar spectral absorbance, and specialized settings are required to reliably measure sulfhemoglobin concentration.[21]

TREATMENT

Sulfhemoglobin persists for the life of the red cell and the level is not reduced by treatment with methylene blue. Most patients require only supportive care, although exchange transfusion or packed red cell transfusion is occasionally recommended for patients with severe toxicity.

CHAPTER 208

Cold Injuries

Michael T. Paddock

INTRODUCTION

The occurrence of cold-related injuries depends on the degree of cold exposure, as well as environmental and individual factors. Frostbite is the prototypical freezing injury and is seen when ambient temperatures are well below freezing. Nonfreezing cold injuries occur as a result of exposure to wet conditions when temperatures are above freezing. The most common nonfreezing cold injuries are trench foot and chilblains. Although frostbite may result in permanent tissue damage, nonfreezing cold injuries are characterized by usually mild but uncomfortable inflammatory lesions of the skin. This chapter describes the occurrence, risk factors, treatment, and prevention of the nonfreezing cold injuries—trench foot and immersion foot, chilblains or pernio, panniculitis, and cold urticaria—and the freezing injury—frostbite.

NONFREEZING COLD INJURIES

TRENCH FOOT

Trench foot and its more severe variant, immersion foot, are rare conditions in civilians but can be a significant problem in military operations. The pathophysiology of trench foot is multifactorial but involves direct injury to soft tissue sustained from prolonged cooling, accelerated by wet conditions. The peripheral nerves seem to be the most sensitive to this form of injury.

Early symptoms progress from tingling to numbness of the affected tissues. On initial examination, the foot is pale, mottled, anesthetic, pulseless, and immobile, with no immediate change after rewarming. A hyperemic phase begins within hours after rewarming and is associated with severe burning pain and reappearance of proximal sensation. As perfusion returns to the foot over 2 to 3 days, edema and possibly bullae form, and hyperemia may worsen. Anesthesia frequently persists for weeks and may be permanent. In more severe cases, tissue sloughing and gangrene may develop. Hyperhidrosis and cold sensitivity are common late features and may persist for months to years. Severe cases may be associated with prolonged convalescence and permanent disability.[1]

Treatment is supportive, but vasodilator drugs may be tried. Oral prostaglandins can increase skin temperatures, which suggests improved circulation.[2] Feet should be kept clean, warm, dryly bandaged, elevated, and closely monitored for early signs of infection. Prophylaxis for trench foot includes keeping warm, ensuring good boot fit, changing out of wet socks several times a day, never sleeping in wet socks and boots, and, once early symptoms are identified, maximizing efforts to warm, dry, and elevate the feet.

CHILBLAINS OR PERNIO

Chilblains, or pernio, are characterized by mild but uncomfortable inflammatory lesions of the skin caused by long-term intermittent exposure to damp, nonfreezing ambient temperatures. Symptoms are precipitated by acute exposure to cold.[3] The most common areas affected are the feet (toes), hands, ears, and lower legs. Chilblains are primarily a disease of women and children, and although rare in the United States, the disease is common in the United Kingdom and other countries with a cold or temperate, damp climate.[3] In addition, young females with Raynaud's phenomenon and other immunologic abnormalities such as lupus erythematosus, as well as those in households with inadequate heating and lack of warm clothing, are at greatest risk. Some studies suggest that a low body mass index may be associated with increased risk.[3,4]

Early symptoms progress from tingling to numbness of the affected tissues. The cutaneous manifestations, which appear up to 12 to 24 hours after acute exposure, include localized edema, erythema, cyanosis, plaques, nodules, and, in rare cases, ulcerations, vesicles, and bullae. Patients may complain of pruritus and burning paresthesias. Rewarming may result in the formation of tender blue nodules, which may persist for several days.

Management is supportive. The affected skin should be rewarmed, gently bandaged, and elevated. Some European studies support the use of nifedipine, 20 milligrams PO three times daily; pentoxifylline, 400 milligrams PO three times daily; or an analog of prostaglandin E_1, limaprost, 20 micrograms PO three times daily, as both prophylactic and therapeutic treatment for local cold injury.[2,5] Topical corticosteroids (0.1% triamcinolone cream) are also effective.[6]

PANNICULITIS

Panniculitis is characterized by mild degrees of necrosis of the subcutaneous fat tissue that develops during prolonged exposure to temperatures just above freezing. It is observed in children (e.g., "popsicle panniculitis" of the cheeks) and on the thighs and buttocks of young women involved in equestrian activities.[7] During resolution of the mild inflammation, adipose fibrosis may result in cosmetic defects, such as unevenness of the skin. There is no effective treatment for the injury.

COLD URTICARIA

Cold urticaria is a distinctive example of hypersensitivity to cold air or water, which in rare cases may lead to fatal anaphylaxis.[8] Most cases are idiopathic,[9] but they can also be associated with increased affinity of immunoglobulin E to mast cells and viral infections.[9] The diagnosis can be confirmed with the cold water test during follow-up. Young adults and children and those with atopy or other forms of inducible urticaria are most commonly affected.[8,10]

Cold urticaria is treated similarly to urticarial lesions from other causes. Antihistamines (H1) are recommended for acute cases, although higher than usual dosing may be required.[11] Other potential therapies include leukotriene receptor antagonists (zafirlukast, montelukast)[12,13] and topical capsaicin. For persistent cold urticaria, ketotifen or doxantrazole may be tried, but oral preparations of these mast cell stabilizers are not available in the United States. Prescribe epinephrine autoinjectors for patients with a history of cold-induced anaphylaxis.

FREEZING INJURIES

EPIDEMIOLOGY

Groups at high risk for frostbite include military personnel, winter sports enthusiasts, outdoor workers, the elderly, the homeless, people who abuse drugs or alcohol, and those with psychiatric disorders. Individual attributes, such as anthropometry, physiology, behavior, and general health, affect an individual's likelihood of developing cold-related injuries[14,15] (**Table 208-1**).

TABLE 208-1 Factors Influencing the Likelihood of Frostbite

Environmental
Temperature
Wind
Wetness
Contact with cold objects or liquids (e.g., metals, petroleum, oil, lubricants)
Duration of cold exposure
Geographical area
Hypoxia
Altitude
Physical/Anthropometric Characteristics
Age
Gender
Race
Behavioral
Cold acclimatization
Alcohol use
Fatigue
Dehydration
Smoking
Use of protective ointments
Inappropriate or wet clothing
Constrictive clothing (e.g., tight boots)
Prolonged stationary posture
Health-Related/Physiologic
Raynaud's phenomenon
Vibration-induced white finger
Cold-induced vasodilation reactivity
Other peripheral vascular diseases
Diabetes
Peripheral neuropathies
Certain medications (e.g., vasoconstrictive drugs)
Previous cold injury
Psychiatric disorders or altered mental status

The areas most commonly affected by frostbite are the head (31% to 39.1% of cases), hands (20% to 27.9%), and feet (15% to 24.9%).[16-18] Studies vary regarding which of these sites is most commonly affected, with military personnel reporting higher incidences of foot and hand involvement than civilians.[18] Although most cases of frostbite are mild (frostnip), 12% of cases are more severe (**Table 208-2**).

RISK FACTORS FOR FROSTBITE

Age and Gender Both age and gender influence the incidence of frostbite. Among Finnish teens, twice as many teenage boys as girls report having had frostbite of at least blister grade during the previous year (4.1% of boys and 2.4% of girls).[19] Young men entering the military service report a cumulative lifetime incidence of 44%.[16] Although frostbite injuries occur more frequently in men as they age, the same is not true of women.[19] In general, the occurrence of frostbite is higher in men than in women,[19,20] which is possibly related to different occupational and leisure time activity patterns. The smaller size of women and their larger surface area–to–mass ratio increase the cooling rate, which makes women more susceptible to cooling and cold injuries.[15,21]

TABLE 208-2 Body Parts Affected by Frostbite (Lifetime Cumulative Incidence)

Degree of Frostbite	Number of Frostbite Episodes			
	All	Head	Hands	Feet
All frostbite cases	2555 (44%)	1668 (31%)	1154 (20%)	810 (15%)
First degree	2333 (41%)	1462 (28%)	1064 (19%)	738 (14%)
Higher than first degree, deep	671 (12%)	459 (9%)	213 (4%)	174 (3%)

Notes: Study population = 5839. Some persons had multiple locations and degrees of frostbite.

Temperature and Windchill The incidence of frostbite among civilians is governed by latitude of residence, the annual number of days on which the ambient temperature is below –15°C (5°F), and the length of daily cold exposure.[19] In the United States, the majority of occupational outdoor cold injuries occur during the few coldest days of winter. Wind strongly increases the injury rate. Rates of injury begin to increase when temperatures fall below –12°C (10.4°F) and wind speeds exceed 4.5 m/s (10 mph).[22] Wind markedly increases the cooling rate by increasing convective heat loss and reducing the insulation value of clothing, thus increasing the risk of frostbite. In addition, the colder temperatures at high altitudes, combined with high wind speeds, increase the risk of frostbite. Frostbite risk is clearly increased above 5182 m (17,000 ft).[23,24]

The National Weather Service windchill temperature index provides the relative risk for frostbite and predicted time for freezing risk at given air temperatures and wind speeds. The risk of frostbite is <5% when the ambient temperature is above –15°C (5°F), but increased surveillance is warranted when the windchill temperature falls below –27°C (–16.6°F).[15]

Frostbite most often occurs at environmental temperatures below –20°C (–4°F). Exposure times for injury vary from hours to several days depending on magnitude of exposure, degree of protective clothing, and physical activity level.

Skin temperature is <0°C (<32°F) when frostbite occurs. Of note, the risk of finger frostbite increases linearly from 5% to 95% when temperature at the skin surface decreases from –4.8°C to –7.8°C (23.4°F to 18.0°F).[25] In addition to ambient temperature and wind, merely touching cold materials (e.g., metal) is a risk factor for frostbite. Contact cooling is dependent on the surface temperature, type of material, duration of contact, and several individual factors. Frostbite can develop within 2 to 3 seconds when metal surfaces that are at or below –15°C (5°F) are touched.[26] Touching surfaces at ambient temperatures of <0°C (<32°F) with bare hands is not recommended. Other factors that increase heat loss and cooling rate and raise the risk of frostbite are wetting of the skin and contact with supercooled liquids (petroleum, oil).

Behavioral and Physiologic Risk Factors for Cold Injuries Multiple behavioral factors influence the risk of cold-related injuries. Alcohol consumption and smoking increase the occurrence of frostbite.[19,23] Inappropriate clothing (e.g., lack of gloves, headgear, or scarf, or wet clothes), constrictive clothing, and prolonged stationary posture increase the incidence of both freezing and nonfreezing injuries. Interestingly, the use of protective ointments is associated with an increased risk of frostbite on the head and face.[17]

Among military personnel, lower level of education or training and lower military rank, as well as situational misjudgments, accidental situations, fatigue, and insufficient nutrition, are all associated with a higher incidence of frostbite.[17] U.S. military studies suggest that black soldiers and those from warmer climatic regions are more susceptible to frostbite.[18]

Certain disease states, such as peripheral vascular disease, atherosclerosis, arteritis, Raynaud's disease, vibration-induced white finger, hypovolemia, diabetes, vascular injury secondary to trauma or infection, and previous cold-related injuries, may predispose to cold-related injury.[16,17,23] In addition, medications that affect the circulation, such as vasoconstrictors, may increase the risk of frostbite[14,19] (Table 208-1).

PATHOPHYSIOLOGY

It is generally agreed that freezing alone is usually not sufficient to cause tissue death, and often the consequences of thawing contribute markedly to the degree of injury. The depth of tissue freezing depends on the temperature, the duration of exposure, and the velocity of freezing.

TABLE 208-3	Classification of Frostbite Injuries
First degree	Numbness, central pallor with surrounding erythema and edema, desquamation, dysesthesia
Second degree	Blisters of the skin with surrounding edema and erythema
Third degree	Tissue loss involving the entire thickness of the skin; hemorrhagic blisters
Fourth degree	Tissue loss involving the entire thickness of the part, including deep structures, resulting in the loss of the part

Endothelial damage, beginning at the point of thaw, is the likely critical event in frostbite. Immediately after freezing and thawing, an arachidonic acid cascade forms and promotes vasoconstriction, platelet aggregation, leukocyte sludging, and erythrostasis, which results in venule and arterial thrombosis and subsequent ischemia, necrosis, and dry gangrene.[27] The necrosis of tissue following frostbite either is due to cellular injury or is secondary to a vascular lesion.[28]

Frostbite injury can be divided into three zones. The *zone of coagulation* is the most severe and is usually distal, and the damage is irreversible. The *zone of hyperemia* is the most superficial, is typically proximal, has the least cellular damage, and generally recovers without treatment in <10 days. The *zone of stasis* is the middle ground and is characterized by severe, but possibly reversible, cell damage. It is this middle zone for which treatment may have benefit if the circulation in the frozen area can be restored.

Tissue susceptibility to frostbite varies. The least to most sensitive tissues are, in order, cartilage, ligament, blood vessel, cutis, epidermis, bone, muscle, nerve, and bone marrow.

CLINICAL FEATURES AND DIAGNOSIS

Frostbite injuries are frequently classified by the depth of injury and amount of tissue damage based on appearance after rewarming (**Table 208-3**). Visual determination of tissue viability is difficult during the first few weeks after the injury, and viable tissue can often be identified only after gangrenous tissue has demarcated and sloughed.

First-degree injury (frostnip) is characterized by partial skin freezing, erythema, mild edema, lack of blisters, and occasional skin desquamation several days later. The patient may complain of stinging and burning, followed by throbbing. Prognosis is excellent. **Second-degree injury** is characterized by full-thickness skin freezing, formation of substantial edema over 3 to 4 hours, erythema, and formation of clear blisters filled with fluid rich in thromboxane and prostaglandins (**Figure 208-1**). The blisters form within 6 to 24 hours, extend to the end of the digit, and usually desquamate and form hard black eschars over several days. The patient complains of numbness, followed later by aching and throbbing. Prognosis is good. **Third-degree injury** is characterized by damage that extends into the subdermal plexus. Hemorrhagic blisters form and are associated with skin necrosis and a blue-gray discoloration of the skin (**Figure 208-2**). The patient may complain that the involved extremity feels like a "block of wood," which is followed later by burning, throbbing, and shooting pains. Prognosis is often poor. **Fourth-degree injury** is characterized by extension into subcutaneous tissues, muscle, bone, and tendon. There is little edema. The skin is mottled, with nonblanching cyanosis, and eventually forms a deep, dry, black, mummified eschar. Vesicles often present late, if at all, and may be small, bloody blebs that do not extend to the digit tips. The patient may complain of a deep, aching joint pain. Prognosis is extremely poor (**Figures 208-3** and **208-4**).

FIGURE 208-2. Second- and third-degree frostbite in the hand with blisters. [Photo contributed by Edward Lew, MD.]

DIAGNOSIS

Frostbite may occur anywhere on the skin but is generally limited to the distal part of the extremities, face, nose, and ears. The injured area looks

pale and waxy and feels hard and cold. Patients frequently complain of stinging and numbness.

Because it is initially difficult to estimate the depth of the cold injury, early injuries are best classified simply as either superficial or deep. Prognostic considerations of ultimate tissue loss should take into account duration of exposure, environmental conditions (temperature, wind, and precipitation), type of clothing worn, level of physical activity, possible contact with metal or moisture, and associated use of recreational drugs, alcohol, or tobacco in addition to physical findings. Patients with frostbite may have concomitant cold-related problems such as hypothermia and dehydration, and patients with hypothermia may also have frostbite.

Although some chemical liquids and burn injuries may cause blister formation, a history of cold exposure differentiates chemically induced blisters from cold-induced injuries.

The diagnosis of frostbite is clinical. **No specific laboratory tests are indicated when treating patients with frostbite**, and specific laboratory evaluation should be guided by the clinical situation including associated trauma or medical illness. Early imaging is rarely helpful, either for diagnostic or prognostic purposes, although the use of technetium-99 scintigraphy may have prognostic value outside of the ED setting.[29]

TREATMENT

Prehospital Care Initial field management of frostbite includes prevention of further cold injury, hypothermia, and dehydration. Remove wet and constrictive clothing, cover with dry clothing, and protect against wind. In mild cases, and if the patient is conscious, warm drinks can be administered. Do not heat the frozen area, because dry heat may cause further injury. Do not attempt rewarming until the risk of refreezing is eliminated.[30,31] Refreezing will cause even more severe damage and is an important concern. Provide analgesia, because the rewarming process is very painful. Immobilize and elevate frozen extremities, and handle gently. Do not ambulate on edematous and blistered feet. Home remedies such as rubbing the affected area or rubbing snow on frostbitten tissue increase tissue damage.[30,31] Locally applied creams should not be used in the field.

ED Management Rapid rewarming is the first definitive step of frostbite therapy and should be initiated as soon as possible.[30,31] Place the injured extremity in gently circulating water heated to a temperature of 37°C to 39°C (98.6°F to 102.2°F), for approximately 20 to 30 minutes, until the distal extremity is pliable and erythematous.[30,31] Frostbitten faces can be thawed using moistened compresses soaked in warm water. Some patients may tolerate immersion of the ears in a bowl or pool of warmed water. **Anticipate severe pain during rewarming and treat with parenteral opiates.**

Local care is directed toward tissue preservation and infection prevention. Management of clear blisters and the use of prophylactic antibiotics are somewhat controversial. The blister fluid is rich in destructive thromboxane and prostaglandins. Although removal theoretically limits damage from these chemicals and enables access to the underlying tissue for topical therapy, not all experts agree that removal is indicated. Hemorrhagic blisters should not be debrided, because this often results in tissue desiccation and worse outcome. However, there is some controversy as to whether aspiration is helpful. Both blister types should be treated with **topical aloe vera cream** every 6 hours, which helps to combat the arachidonic acid cascade.[30,31] Affected digits should be separated with cotton and wrapped with sterile, dry gauze. Other affected areas should be dressed in bulky, loose-fitting dry gauze dressings to allow room for the expected subsequent edema. Elevation of the involved extremities helps decrease edema and pain.

Tetanus immunization status should be assessed and appropriate vaccination administered if needed, because frostbite is a tetanus-prone wound (see chapter 156, "Tetanus").

Because microvascular thrombosis plays a role in tissue injury, thrombolysis has been advocated by some for use in cases at risk for proximal or multiple digit amputations[32,33] and, when given after rapid rewarming, appears to reduce digit amputations.[30,34-36] The evidence in support of IV or intra-arterial tissue plasminogen activator is limited to retrospective studies, and bleeding risks must be weighed against potential benefit.

The role of prophylactic antibiotics is unclear. The edema that is present on the first several days after injury does appear to predispose to infection. *Staphylococcus aureus*, *Staphylococcus epidermidis*, and β-hemolytic streptococci account for nearly half of infections, but anaerobes, *Pseudomonas*, and *Enterococcus* are important pathogens as well. Therapy with penicillin G, 500,000 units IV every 6 hours for 48 to 72 hours, is recommended in several successful protocols and seems to be beneficial. However, infection prophylaxis using topical bacitracin may be as good as or better than IV penicillin. The use of silver sulfadiazine cream also has been advocated by some, but it has not been shown to be consistently beneficial. One disadvantage of using topical antibiotics is that they complicate the concurrent use of aloe vera cream.

Several agents besides aloe vera cream have been recommended to battle the arachidonic acid cascade and thereby limit tissue damage. The most commonly advocated oral medication is ibuprofen, 12 milligrams/kg/d PO in divided doses. Animal studies suggest possible future roles for oral methimazole (a thromboxane synthetase inhibitor) and topical 1% methylprednisolone acetate (a phospholipase A2 inhibitor) in preventing the formation of arachidonic acid.

Another controversial area is the use of sympathetic blockade with either intra-arterial reserpine or surgical sympathectomy to relieve vasospasm and edema. There is no role for early sympathectomy. Prolonged sympathetic blockade using a long-acting anesthetic drug (bupivacaine) may improve blood flow to the hand, relieve pain, and speed recovery.

TABLE 208-4 Treatment of Frostbite

Core Treatment
1. Immersion in or application of water at 37°C to 39°C (98.6°F to 102.2°F) until affected area is pliable and erythematous; do not begin rewarming until risk of refreezing is eliminated
2. Parenteral narcotics for pain management
3. Topical aloe vera cream every 6 h
3. No blister or soft tissue debridement acutely
4. Meticulous local care
5. Tetanus immunization
6. Ibuprofen, 12 milligrams/kg/d PO, in divided doses
Optional Treatment
1. Topical bacitracin ointment for infection prophylaxis
2. Penicillin G, 500,000 units IV every 6 h, for prophylaxis for susceptible organisms
3. Topical silver sulfadiazine cream for prophylaxis (do not use on face)

Continuous epidural anesthesia may relieve peripheral vasospasm and perhaps prevent retrograde arterial and venous thrombosis.

Heparin and hyperbaric oxygen therapy appear to be of little value, although case reports of improvement in isolated cases have been published.[37,38] IV low-molecular-weight dextran has theoretical benefits, but dose and effectiveness have not been validated.[39]

Early surgical intervention is not indicated in the management of frostbite. Premature surgery has been an important contributor to unnecessary tissue loss and poor results in the past. This is due primarily to the inability to assess the depth of frostbite at early stages and the fact that the blackened, mummified carapace protects the underlying regenerating tissue. Limited early escharotomy may be indicated if the eschar is preventing adequate range of motion or circulation. Fasciotomy is rarely, if ever, indicated.

Table 208-4 presents the core treatment of frostbite.

SEQUELAE

Up to 65% of persons with frostbite injuries experience sequelae from their injuries.[1] Sequelae may be seen in patients with mild injuries but are generally more intense with more severe frostbite. The most typical sequelae are hypersensitivity to cold, pain, and ongoing numbness. Neuropathies have also been described. The clinical and functional limitations associated with late sequelae are dependent on the type and severity of the frostbite injury and the related anatomic deformities and amputations.

DISPOSITION AND FOLLOW-UP

Because it is difficult to determine the extent of frostbite on initial examination, it is best to be conservative when contemplating admission. Consider social and medical issues. The homeless or elderly, especially when unable to care for themselves adequately, should never be discharged into subfreezing temperatures. If the frostbite is extensive and the hospital and staff are not equipped to treat injury of that degree of severity, consider transfer to a tertiary hospital after initial rewarming and treatment.

Patients with only superficial local frostbite may be discharged home if social circumstances allow. Patients with deeper frostbite injuries should be hospitalized. At discharge from the ED, patients must be provided with sufficient guidelines for self-care and clear instructions for close short-term and long-term follow-up, preferably with local burn center or plastic surgery providers. They must also be instructed to contact their doctor at an early stage if problems or concerns arise. Patients who are discharged from the ED should be treated with topical aloe vera cream and oral ibuprofen and encouraged not to smoke or drink alcohol. **Table 208-5** lists prevention strategies.

TABLE 208-5 Cold Injury Prevention Strategy

Risk Assessment
Assessment of environmental conditions
Assessment of expected duration of exposure and physical activity level
Risk Management
Raising of awareness
Identification of susceptible population groups, education to recognize personal warning signals of adverse cooling, provision of training and information, distribution of learning and guidance materials
Organizational Preventive Measures
Advance planning; appropriate scheduling of activities; assessment of physical activity level; provision of facilities for warming; establishment of mandatory clothing changes, breaks, etc.
Technical Preventive Measures
Attention to shelters, tools, external heating, work areas, slippery surfaces, lighting, etc.
Protective Clothing
Whole-body protection, hand and footwear, head protection, face and respiratory protection, use of personal protective equipment together with cold protective clothing
Health Care
Individual recommendations based on special needs

CHAPTER 209

Hypothermia

Doug Brown

INTRODUCTION AND EPIDEMIOLOGY

Accidental hypothermia is an involuntary drop in core temperature below 35°C (<95°F) and can often be associated with significant morbidity and mortality.[1] **Therapeutic hypothermia**, also called targeted temperature management, is a purposeful drop in core temperature usually performed with the hope of ameliorating tissue damage associated with an ischemic event.[2,3]

Accidental hypothermia can be subclassified as primary, due to simple environmental exposure, or secondary, due to impaired thermoregulation (**Table 209-1**). Primary accidental hypothermia is commonly seen in cold climates, whereas secondary accidental hypothermia can be seen worldwide. The true incidence of accidental hypothermia and its related morbidity and mortality remain unknown.[4]

HYPOTHERMIA CLASSIFICATION

Historically, hypothermia has been classified as mild, moderate, severe, and profound, based on core temperature, shivering, level of consciousness, and vital signs.[5-7] Unfortunately, there is considerable variation in clinical features at any given temperature, and a reliable core temperature is sometimes unavailable during initial assessment. Shivering is particularly unreliable because it may be present or absent across a wide temperature range. The modified staging system (mild, moderate, severe, hypothermia stage IV) [5-7] described in **Table 209-2** is a hybrid of the Swiss[7] and classical systems[5] that is based primarily on level of consciousness, the presence or absence of vital signs, and core temperature (when available).

TABLE 209-1 Causes of Secondary Hypothermia

Predominantly Increased Heat Loss
Burns
Iatrogenic (i.e., blood transfusions and other cold infusions, cooling blankets, inadequate insulation)
Recent birth
Predominantly Impaired Thermogenesis
Impaired shivering (i.e., advanced or very young age, malnutrition, physical exhaustion, neuromuscular disease)
Multifactorial
Medications and toxins (i.e., alcohol, anesthetic agents, narcotics, sedatives, vasodilators)
Metabolic and endocrine disorders (i.e., alcoholic or diabetic ketoacidosis, hypoadrenalism, hypoglycemia, hypopituitarism, hypothyroid, lactic acidosis, Wernicke's encephalopathy)
Neurologic (i.e., space-occupying lesion, stroke, spinal cord injury)
Sepsis (small subset of sepsis cases, more common in the elderly or cachectic patient)
Shock
Trauma

PATHOPHYSIOLOGY

Body temperature is tightly regulated by a combination of behavioral, neuroendocrinologic, and cardiovascular responses to cold stress. Core temperature will fall when the amount of heat lost to the environment exceeds the amount of heat produced.

HEAT LOSS

Heat is lost from a warm body by conduction, convection, evaporation, and radiation. Conduction occurs when a warm body makes direct contact with a cold object. Conductive heat loss can be minimized by avoiding contact with cold or poorly insulated objects (e.g., metal backboards or stretchers). Convective cooling occurs when a fluid (usually air or water) comes in contact with a warm body. The amount of heat lost via convection can be considerable and is proportional to the amount of fluid that flows around the body, the specific heat capacity of the fluid, and the temperature difference between the fluid and the body. Practically, the emergency physician needs to understand that exposure to cool air or water will result in heat loss, that water can absorb a large amount of heat in a short period of time, and that windy conditions or flowing water can significantly increase the rate of cooling. Evaporative heat loss occurs due to the energy required for water to phase change from a liquid to a gas. The amount of heat lost to evaporation is proportional to the temperature difference between the body and the air and the wind speed over the body and is inversely proportional to the humidity. Therefore, a warm moist body exposed to cold, dry, windy air will lose a significant amount of heat. A vapor barrier (e.g., a plastic bag or sheet), placed around the patient, effectively prevents evaporative cooling but is often not practical when repeated access to the patient's skin is required. Radiant cooling occurs because all warm bodies "radiate" heat, in the form of electromagnetic waves. Increasing the temperature of the room can minimize radiant heat loss, and some losses can be recovered using special reflective fabrics (likely low yield in most clinical situations). In summary, it is important to minimize heat loss in the hypothermic patient, and a basic understanding of the physics of heat transfer can be helpful. Practically, heat loss can be minimized by heating the room, removing wet clothes, drying the patient (or wrapping the patient in a vapor barrier), providing insulation, and protecting the patient from wind.

HEAT CONSERVATION AND PRODUCTION

The most important responses to cold include behavior (e.g., putting on warm clothing, seeking a warm environment), peripheral vasoconstriction, increased metabolic rate, and muscular thermogenesis (voluntary or shivering). Shivering is a remarkably efficient method of heat production, and care is required to preserve this important

TABLE 209-2 Staging and Treatment of Accidental Hypothermia

Stage	Clinical Symptoms	Typical Core Temperature	Treatment
Mild (HT I)	Conscious, shivering	35–32°C	Warm environment and clothing, warm sweet drinks, and active movement (if possible) HT I patients with significant trauma or comorbidities or those suspected of secondary hypothermia should receive HT II treatment
Moderate (HT II)	Impaired consciousness* (may or may not be shivering)	<32–28°C	Active external and minimally invasive rewarming techniques (warm environment; chemical, electrical, or forced air heating packs or blankets; warm parenteral fluids) Cardiac and core temperature monitoring Minimal and cautious movements to avoid arrhythmias Full-body insulation, horizontal position, and immobilization
Severe (HT III)	Unconscious*, vital signs present	<28°C	HT II management plus: Airway management as required Preference to treat in an ECMO/CPB center, if available, due to the high risk of cardiac arrest Consider ECMO/CPB in cases with cardiac instability that is refractory to medical management Consider ECMO/CPB for comorbid patients who are unlikely to tolerate the low cardiac output associated with HT III
HT IV	Vital signs absent	Cardiac arrest is possible below 32°C; the risk increases substantially below 28°C and continues to increase with ongoing cooling	CPR and up to three doses of epinephrine and defibrillation (further dosing guided by clinical response) Airway management Transport to ECMO/CPB† Prevent further heat loss (insulation, warm environment, do not apply heat to head) Active external and minimally invasive rewarming (see HT II) during transport is recommended but controversial; do not apply heat to head

Abbreviations: CPB = cardiopulmonary bypass; ECMO = extracorporeal membrane oxygenation; HT = hypothermia.

*Consciousness may be impaired by comorbid illness (e.g., trauma, CNS pathology, toxic ingestion) independent of core temperature.

†Transfering an HT IV patient to an ECMO/CPB center may reduce mortality by 40% to 90% (number needed to treat, ~2); if ECMO/CPB is not available within a few hours of transport,[6,8] consider on-site rewarming with hot packs or forced air blankets, warm IV fluid, ± warm thoracic lavage, ± warm bladder lavage, and ± warm peritoneal lavage; do not apply heat to the head.

source of heat. Unfortunately, shivering can be suppressed by medications (e.g., analgesics, sedatives), by the application of warming devices (e.g., hot packs, forced air blankets, warm humidified air), if energy stores are exhausted, or if the core temperature drops below a critical level (~31°C).[5] The suppression of shivering by various warming methods is one of the reasons why the rewarming literature is so controversial.

CONTINUED CORE COOLING

Core temperature may continue to drop after a patient is removed from the cold environment,[9,10] a process often referred to as afterdrop. The amount of continued core cooling will depend on the stage of hypothermia, the degree of thermoregulatory dysfunction, the ongoing cold stress (often significant in the prehospital care environment), and the physics of heat transfer (heat from the relatively warmer core will be transferred to the cooler periphery by direct conduction or by convection from blood flow). The relative importance of the various mechanisms and the impact of various rewarming techniques are the source of much debate, due in part to the desire to avoid iatrogenic core cooling. Historically, there was concern that rewarming or active movement could cause convection of cold blood from the periphery to the core with a potential increase in morbidity. Careful experimental studies have demonstrated an ~1°C drop in core temperature during minimally invasive rewarming when shivering is inhibited with narcotics[11] or during exercise,[12] but case series have not demonstrated any clinically significant afterdrop or morbidity when minimally invasive rewarming is used.[6,13] In general, healthy uninjured patients who are able to shiver and have adequate fuel reserves (or can drink warm sweet drinks) will be able to self-rewarm once removed from further cold stress. In contrast, patients who have lost the ability to shiver are at significant risk of further temperature decline unless active rewarming is used.[6,14,15] The use of aggressive immersion rewarming techniques such as hot baths or showers should likely be avoided due to the potential risks of vasodilatory hypotension or convective cooling.[16]

SECONDARY HYPOTHERMIA

Cases of secondary hypothermia can be conveniently organized into those caused predominantly by increased heat loss, those caused predominantly by impaired thermoregulation, and those caused by multiple factors (Table 209-1). This classification is somewhat arbitrary, but in general, the multifactorial cases have a higher risk of missed diagnosis and are less likely to fully resolve with rewarming and supportive care. Iatrogenic causes of hypothermia deserve special attention, particularly in trauma patients, where the loss of just a few degrees of core temperature can create a profound coagulopathy and more than double patient mortality.[17] Massive transfusion and large-volume crystalloid resuscitation are common iatrogenic causes of hypothermia unless proper fluid warmers are used. Inadequate insulation, repeated or prolonged exposure to the cool air of the resuscitation or operating room, and inadequate core temperature monitoring all contribute to iatrogenic heat loss, which may increase morbidity and mortality.

COLD PHYSIOLOGY

The body attempts to preserve normothermia through mechanisms such as increased metabolic rate, peripheral vasoconstriction, increased preshivering muscle tone, or shivering. As the core temperature drops below ~35°C, progressive impairment occurs affecting all of the body's organ systems. CNS impairment can progress from poor judgment, amnesia, and dysarthria, to ataxia and apathy, unconsciousness, areflexia, and eventually electroencephalographic arrest.[5] Paradoxical undressing is a potentially deadly behavior that occurs in up to 30% of fatal hypothermia cases.[18] Below ~29°C, the pupils may become dilated and fixed, and below ~23°C, corneal reflexes may be absent; neither are reliable for neurologic prognosis in hypothermia.[5]

Cardiorespiratory Responses Cardiovascular responses to cold include profound peripheral vasoconstriction and an initial increase in heart rate and blood pressure, usually followed by progressive bradycardia, hypotension, and myocardial irritability. Below ~32°C, the risk of cardiac arrest increases as malignant cardiac arrhythmias become more common, particularly below 28°C.[19] The term *rescue collapse* is used to describe cardiac arrest that can commonly occur during extrication, transport, or treatment of a deeply hypothermic patient. The cause of rescue collapse is multifactorial but ultimately related to the profound irritability of the cold myocardium. Atrial fibrillation and flutter are expected arrhythmias and not necessarily markers of cardiac instability.[6] ECG changes in hypothermia are variable but classically include bradycardia with prolonged PR, then QRS widening, and then prolonged QT_c. ECGs are often complicated by muscle tremors or shivering, and hypothermia can cause almost any heart block or atrial or ventricular arrhythmias. The classic **Osborn J waves (Figure 209-1)** usually occur below 32°C, can be misdiagnosed as ST elevation myocardial infarction, and can also be caused by intracranial pathology or sepsis.[5] Occasionally patients may be in a low-flow state, with a very difficult to detect pulse that may provide some oxygen delivery. Asystole is the common final arrhythmia, but in accidental hypothermia, it does not exclude the possibility of a successful resuscitation.[6]

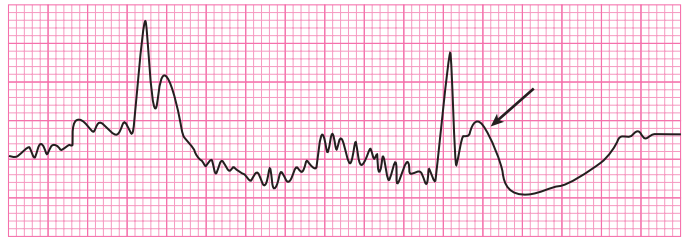

FIGURE 209-1. ECG strip from a patient with a temperature of 25°C (77°F) showing atrial fibrillation with a slow ventricular response, muscle tremor artifact, and Osborn (J) wave (*arrow*).

Respiratory changes include initial tachypnea, followed by a progressive decrease in minute ventilation and eventual respiratory arrest. Pulmonary edema is an inconsistent complication of hypothermia but is common after resuscitation from stage IV hypothermia.

Metabolic Responses The renal response to hypothermia is termed *cold diuresis* and is a response to vasoconstriction-induced hypervolemia. It results in significant fluid losses, which may be further increased in patients with a history of cold water immersion or alcohol intoxication.[5] Rhabdomyolysis is a potential complication of hypothermia[20]; however, the clinician should always exclude a missed compartment syndrome or extensive frostbite when an elevated creatine kinase is detected. Hypothermia can also cause muscle rigidity, termed *pseudorigor mortis*; hence, rigor mortis cannot be used as a reliable marker of death in the cold patient. Hypothermia has a somewhat dramatic impact on coagulation and blood viscosity, and these effects are often underrecognized by clinicians because blood samples are heated to 37°C prior to analysis. Coagulopathy is a concern below 34°C, particularly in trauma patients in whom hypothermia can compromise the chance for a surgical cure and exponentially increase mortality,[17] partly due to poor activity of clotting factors and platelet dysfunction.[21] Hypothermic patients can also be hypercoagulable from a combination of increased viscosity, hemoconcentration, and an inflammatory cascade similar to disseminated intravascular coagulation; these factors can put hypothermic patients at an increased risk for venous thromboembolic disease as well as coronary and cerebral artery occlusion.[5]

Cellular oxygen consumption decreases as core temperature drops and, in an otherwise healthy patient who has adequate oxygen delivery prior to cooling, may provide protection against ischemia. It is estimated that cerebral oxygen requirements are approximately 50% at 28°C, 19% at 18°C, and 11% at 8°C.[5,22] This neuroprotective effect of hypothermia is exploited in certain cardiac surgeries. The most dramatic technique is deep hypothermic circulatory arrest, where patients are cooled to ~18°C and cardiac arrest is induced and maintained for up to ~30 minutes.[23] The combination of the potential to survive prolonged periods of ischemia, with the uncertainty of knowing if a patient has been in a low-flow state (difficult to detect cardiac activity that provides some oxygen delivery) versus cardiac arrest, increases the

complexity of termination of resuscitation decisions for hypothermic patients unless the history clearly indicates death prior to cooling.

CLINICAL FEATURES

Patients with hypothermia will feel cold to touch; they will have a core temperature less than 35°C and may have a history of cold exposure or a history of a condition associated with secondary hypothermia (Table 209-1). Hypothermia can be staged clinically using level of consciousness and vital signs (Table 209-2). Measure the core temperature as soon as possible. If the core temperature deviates significantly from the clinical features of the stage, then consider alternative diagnoses. For example, if a patient has a core temperature of 33°C but is unconscious, hypothermia is unlikely the main cause of coma.

CORE TEMPERATURE MEASUREMENT

Make sure that the device being used to measure core temperature is capable of extreme measurements and is properly calibrated (thermistor devices are usually preferred). Temperature measurement at different body sites will yield different readings depending on local perfusion and environmental conditions. In the intubated patient, the lower third of the esophagus (~24 cm below the larynx in an adult) is the preferred site for core temperature measurement, because it closely mirrors the cardiac temperature.[5] In the absence of an esophageal probe, a rectal probe inserted to a depth of 15 cm or a bladder probe is adequate, but realize that these temperatures often lag behind true core temperature during rewarming and that bladder or peritoneal lavage may falsely elevate the reading. Oral and infrared tympanic temperature measurements do not correlate well with core temperature and should not be used. When an accurate core temperature measurement is not available, management decisions should be made based on clinical staging (Table 209-2). Ongoing core temperature monitoring should be implemented as soon as possible for all moderate through severe hypothermia patients (stages II to IV).

DIAGNOSIS

Hypothermia causes dysfunction of every organ system, so the potential list of differential diagnoses is broad. A practical approach is to focus the differential diagnosis using a combination of history, physical exam, and expected degree of dysfunction for the clinical stage and measured core temperature. For the patient with absent vital signs, if the history indicates normothermic cardiac arrest prior to cooling, then hypothermia can be excluded as the cause of cardiac arrest, regardless of the patient's core temperature (**Figure 209-2**). Similarly, in the patient with absent vital signs, asystole, and an accurate core temperature above 32°C, accidental hypothermia is *not* the cause of cardiac arrest. Classic diagnostic dilemmas in relation to accidental hypothermia often revolve around impaired cognitive function, level of consciousness, or declaration of death. Intoxication, head injury, and CNS infection are three examples of conditions that impair neurologic function directly but can also cause secondary hypothermia and cold-related neurologic dysfunction. Vigilance is required with any decreased level of consciousness, particularly if the degree of neurologic impairment does not match the stage of hypothermia. Areflexia or paralysis should not be attributed to hypothermia until spinal injury has been ruled out.

Carefully consider secondary causes of accidental hypothermia, particularly if the measured core temperature is lower than expected based on the cold exposure history or the patient is slow or fails to rewarm with appropriate therapy. Tachycardia or tachypnea can be a marker of secondary pathology in moderate and severe hypothermia (stages II and III), because bradycardia with or without bradypnea is the normal response to hypothermia below a core temperature of ~32°C. Intoxication and sepsis are two common causes of secondary hypothermia, and depending on the patient presentation, routine screening and, in some cases, empiric therapy may be reasonable. Classic causes such as adrenal failure and myxedema coma are comparatively rare, and empiric testing or therapy is likely unwarranted in the absence of good historical or laboratory evidence. Hyperglycemia that persists after rewarming may indicate secondary pathology such as diabetic ketoacidosis or pancreatitis. The appropriate breadth of workup will vary considerably depending on the particular patient and the degree of clinical uncertainty.

Declaration of Death Declaration of death in the presence of hypothermia is particularly challenging due to the ability of hypothermia to mimic death (can cause fixed and dilated pupils, stiffness resembling rigor mortis, absent reflexes, or respiratory arrest) or cause death that may be reversible. **Figure 209-3** provides a triage tool for stage IV (absent vital signs) patients, to assist with clinical decision making. In general, patients with obvious signs of irreversible death or who are frozen solid, have a history of normothermic arrest with subsequent cooling, or have a potassium level >12 mmol/L are extremely unlikely to benefit from resuscitative efforts, and death can be declared without rewarming.[6] An exception to the above statement is the child with simultaneous normothermic cardiac arrest and very rapid accidental cooling (e.g., a child pinned underwater in an icy creek); in such a case, prolonged resuscitation and expert consultation may be appropriate (see "Special Considerations/Special Populations, Children").[24]

LABORATORY TESTING AND IMAGING

Laboratory testing and imaging studies should be targeted based on history, physical examination, and the differential diagnosis. It seems reasonable that every hospitalized hypothermia patient undergo point-of-care glucose testing, but additional routine tests are not necessarily required. An ECG should be obtained for moderate and severe hypothermia (stages II and III) patients, and a chest x-ray is likely reasonable depending on the suspicion for conditions such as aspiration or pulmonary edema. For cases where secondary hypothermia is suspected, measuring CBC, serum electrolytes, creatinine, glucose, lactate, lipase, thyroid-stimulating hormone, random cortisol level, osmolality, and levels of potential intoxicants (e.g., ethanol, aspirin, acetaminophen) and calculation of the anion and osmolar gap may be reasonable depending on clinical suspicion. Patients with suspected sepsis may benefit from blood culture. For patients with suspected compartment syndrome, frostbite, or prolonged immobility, measure serum creatinine kinase. Severe hypothermia (stages III and IV) patients should be considered critically ill, and therefore, expanded laboratory testing including CBC, electrolytes, pH, lactate, blood gas levels, and creatine kinase may be considered. For patients in cardiac arrest (stage IV), a serum potassium level ≥12 mmol/L is strongly associated with nonsurvival.[6]

HYPOTHERMIA EFFECTS ON LABORATORY VALUES

Laboratory results from hypothermic patients can be difficult to interpret due to the fact that high, low, or "normal" values may be appropriate in different patients. In an otherwise healthy patient with primary hypothermia, most laboratory values will normalize with rewarming; therefore, treat the patient, not the numbers. For complex cases or those that do not respond to usual therapy, it may be helpful to have a sense of the "expected" abnormalities associated with hypothermia. Hematocrit classically increases ~2%/°C, secondary to decreased circulating plasma volume.[5] WBC counts may be normal or decreased due to sequestration or secondary causes such as sepsis. Electrolyte abnormalities are inconsistent, and cold blood may be prone to sampling hemolysis; hence rewarming and ongoing monitoring are often the best strategy. Glucose levels are somewhat unpredictable with an early rise being common secondary to catecholamine-induced gluconeogenesis and hypothermia-induced insulin resistance. This increase is classically followed by a drop with the onset of resource depletion and metabolic failure.[5] Acid-base disturbances in hypothermia are complex; some hypothermic patients will be acidotic, whereas others may be alkylotic, and both conditions may be an appropriate physiologic response to cooling[5] or may be a marker of secondary pathology. Blood gas analyzers rewarm samples to 37°C, and in rewarmed samples, the partial pressure of gases increases and the pH is lower, compared with the cold in vivo sample (correction usually not required, see stage III treatment for details). It is also important to note that the coagulopathy of

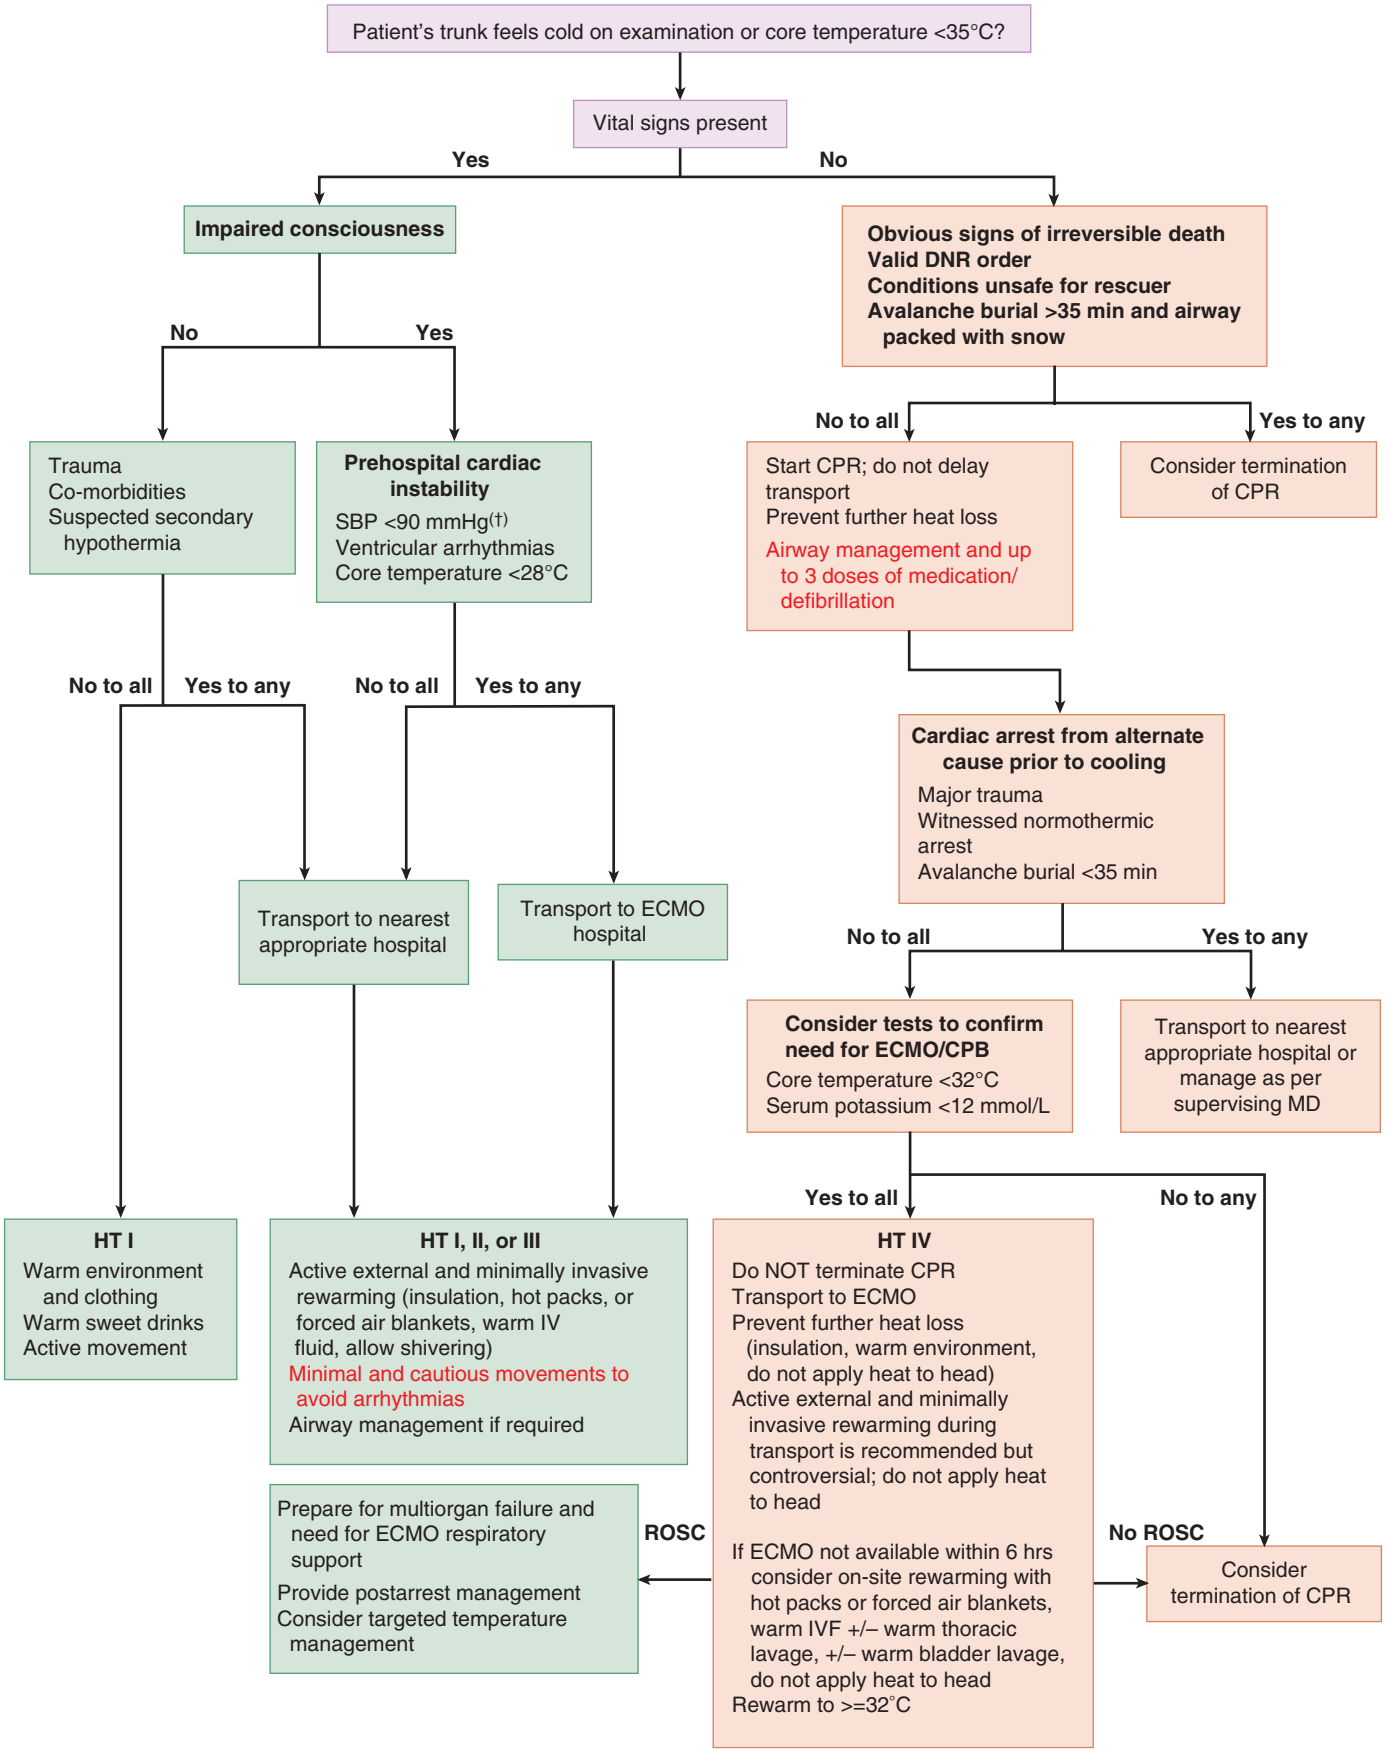

FIGURE 209-2. Transport and management of accidental hypothermia.[6] CPB = cardiopulmonary bypass; DNR = do not resuscitate; ECMO = extracorporeal membrane oxygenation; HT = hypothermia; ROSC = return of spontaneous circulation; SBP = systolic blood pressure. [© Doug Brown, MD, FRCPC.]

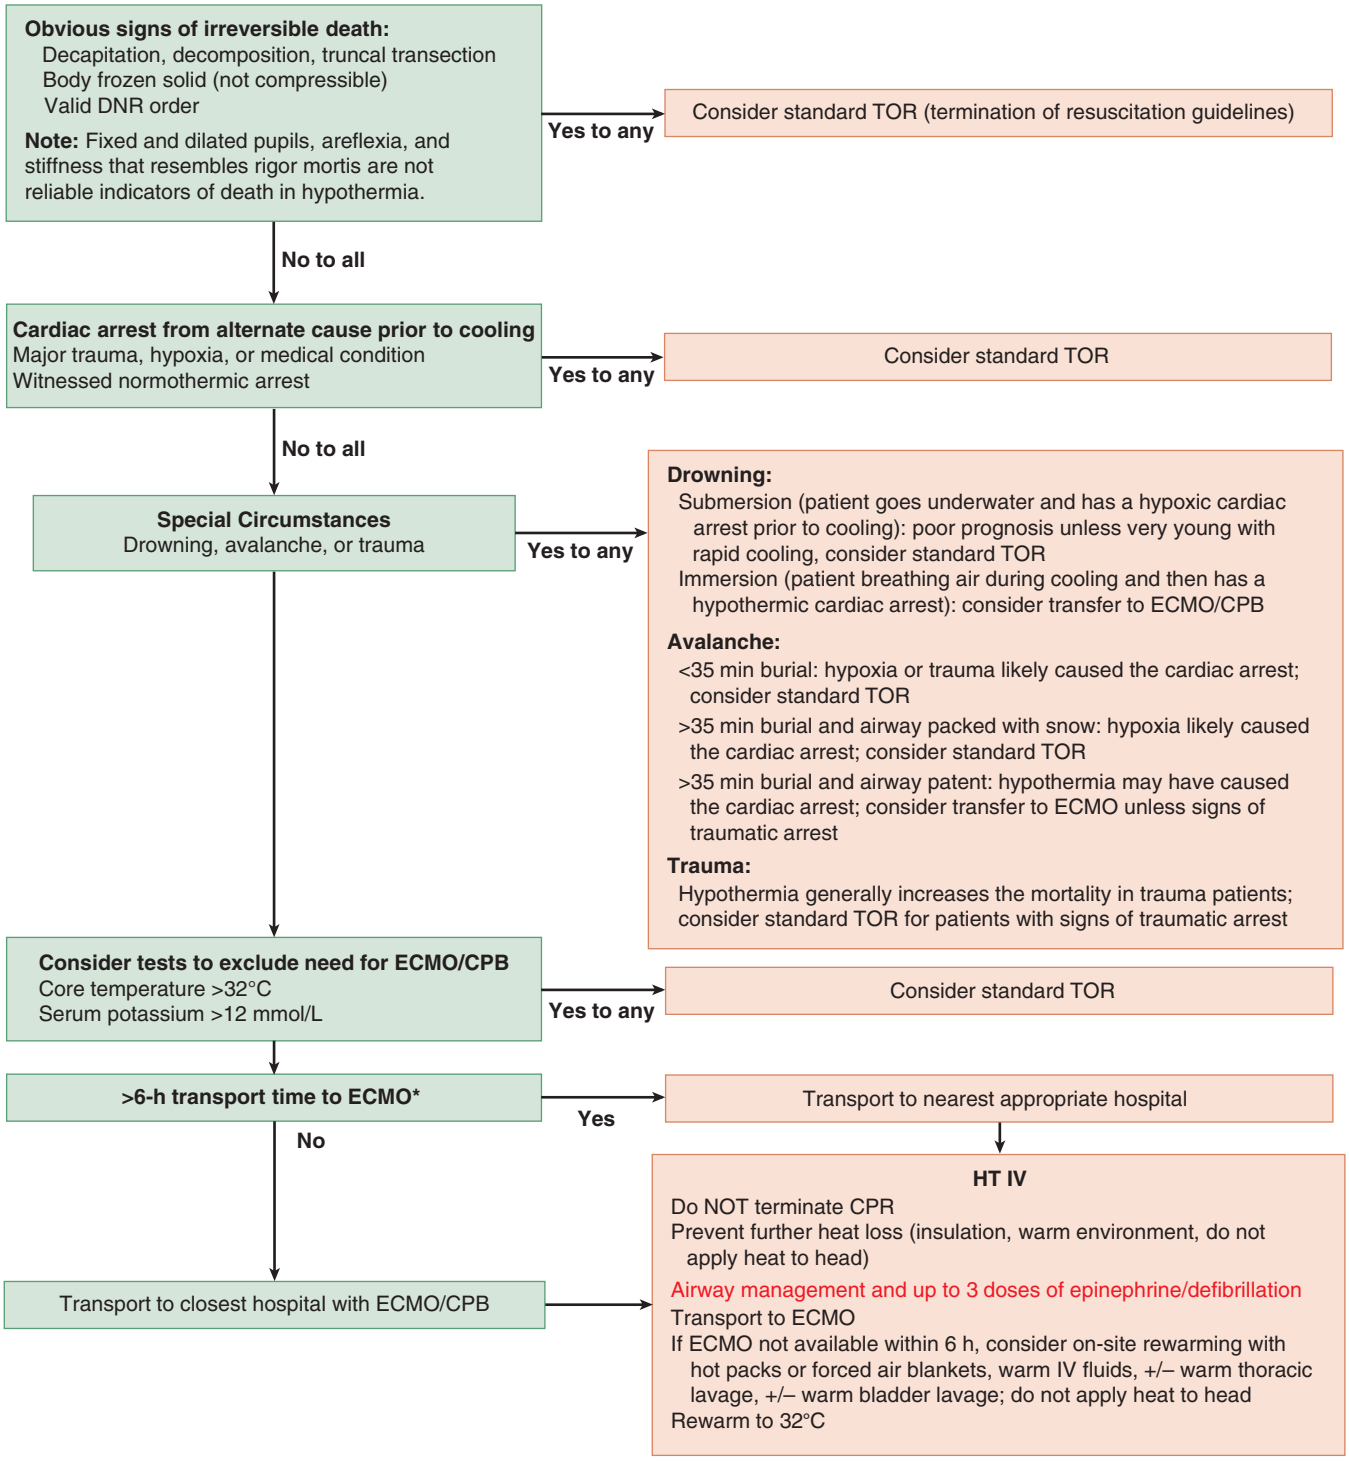

FIGURE 209-3. Triage tool for hypothermia (HT) patients with absent vital signs. CPB = cardiopulmonary bypass; DNR = do not resuscitate; ECMO = extracorporeal membrane oxygenation. [© Doug Brown, MD, FRCPC.]

hypothermia (see earlier section, "Cold Physiology") will not be apparent on laboratory results due to the warming of samples prior to testing.

TREATMENT

Treatment of accidental hypothermia varies depending on the clinical stage, but the general principles include basic or advanced life support, prevention of further heat loss, transport to an appropriate facility if indicated, rewarming (Table 209-2 and Figure 209-2), and in secondary hypothermia, treatment of the underlying cause.

MILD HYPOTHERMIA (STAGE I)

Otherwise healthy stage I patients (conscious, shivering, core temperature ≥32°C) can often be rewarmed locally using a warm environment,

provision of dry clothes, warm sweet drinks, and active movement. Stage I patients with traumatic injuries or significant medical comorbidities or in whom secondary hypothermia is suspected should be transported to the nearest appropriate hospital and managed as per stage II guidelines.

MODERATE HYPOTHERMIA (STAGE II)

Stage II patients (impaired consciousness, may or may not be shivering, core temperature ~28 to 32°C) require careful handling, prevention of further heat loss, active external and minimally invasive rewarming (warm environment; forced air, electrical, or chemical warming blankets; warm parenteral fluids), cardiac monitoring, and core temperature monitoring (**Figure 209-4**). Careful handling to decrease the risk of cardiac arrhythmia becomes important for stage II and III patients, due to the increasing irritability of the cold myocardium. For all stages of hypothermia, warmed crystalloids (38 to 42°C) should be titrated based on clinical volume status. It should be noted that significant volume might be required during rewarming and that warmed IV fluids do not provide significant heat but do prevent iatrogenic cooling. Atrial fibrillation, atrial flutter, and bradycardia are common in accidental

Hospital Resuscitation Checklist:

- ☐ Cardiac monitor & careful handling
- ☐ Core temperature monitoring (esophageal, rectal or bladder)
- ☐ If cardiac arrest, ventricular dysrhythmia, core temp < 28°C or unstable:
  - do not stop resuscitation, seek expert consultation
  - potential for good outcome despite prolonged resuscitation, ideally transfer to ECMO center if indicated
- ☐ Minimally invasive rewarming:
  - ☐ Hypothermia burrito (see below, preference for forced air warming blankets)
  - ☐ +/– Bladder lavage
    (3-way Foley, 40°C saline, 2–4 L/hr by gravity)
    [confirm volume in = volume out, will invalidate bladder and rectal temperature measurements]
- ☐ IV Fluid Resuscitation: (crystaloid, 38–42°C)
  - ☐ Titrate fluids to clinical volume status (avoid over-resuscitation)
  - ☐ 10–20 mL/kg (~1 L) to start (may be reasonable)
  - ☐ Additional 10–20 mL/kg per ~3°C core temp increase (may be required)
- ☐ Hypothermia is NOT a contraindication to airway management
- ☐ Avoid hyperoxia (titrate FiO_2 to 92–98%)
- ☐ If central venous access is required, keep the tip of the catheter (and guidewire) far from the heart (femoral, shallow internal jugular or shallow subclavian)
- ☐ Avoid vasopressors during early resuscitation (relative hypotension may be physiologic depending on core temperature, consider expert consultation)

Minimally Invasive Rewarming: (hypothermia burrito)

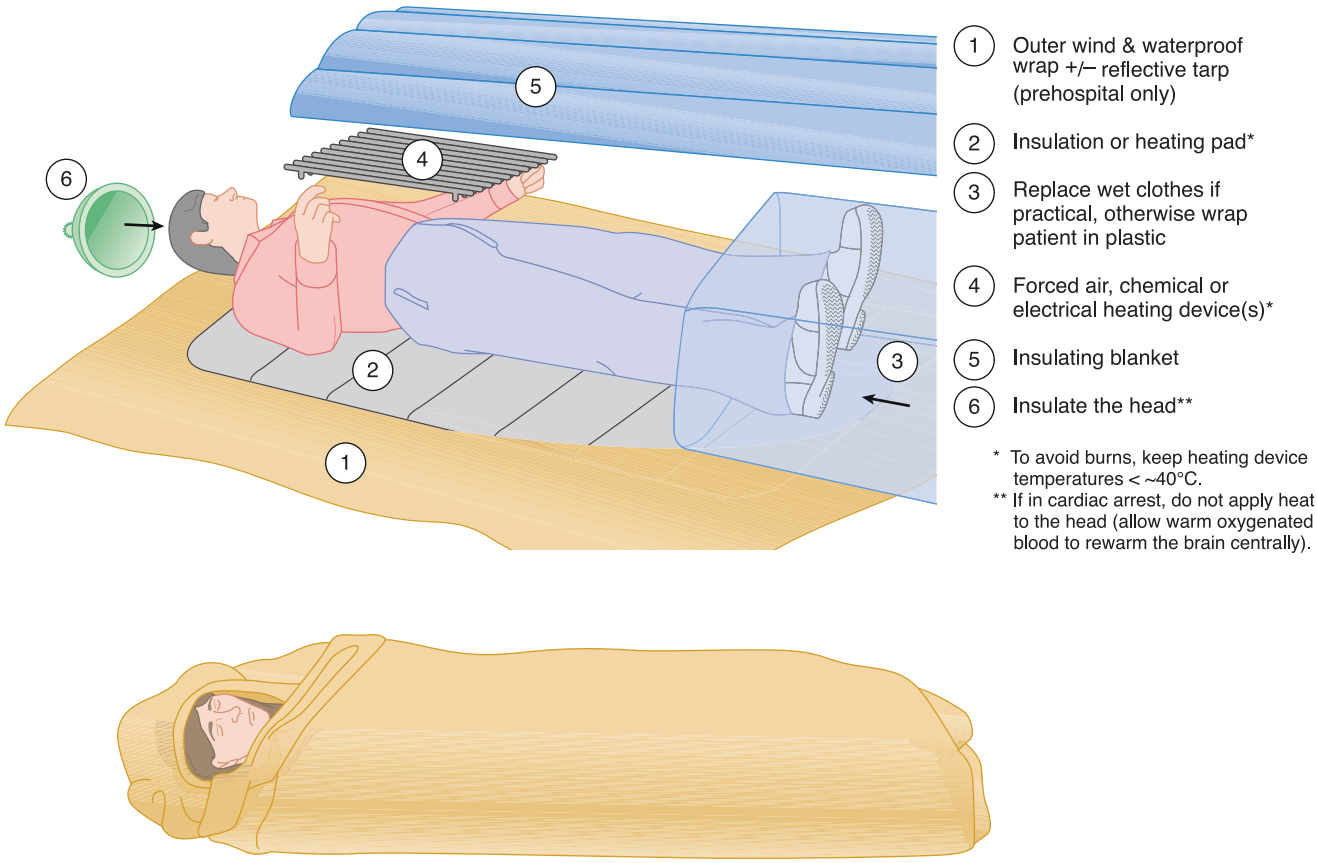

FIGURE 209-4. Practical tips for rewarming patients with moderate and severe hypothermia. ECMO = extracorporeal membrane oxygenation. [© Doug Brown, MD, FRCPC.]

hypothermia, do not usually require specific therapy, and typically resolve with rewarming. Vasopressors are usually not indicated in early resuscitation because hypothermia already provides maximal vasoconstriction and the addition of vasopressors may increase the risk of arrhythmia. Vasopressors may be indicated later in resuscitation, if rewarming-induced vasodilation cannot be managed with fluids and is contributing to significant hypotension. Special care is required when assessing the risk-to-benefit ratio of sedatives and analgesics. Many medications will inhibit shivering, decrease sympathetic tone, and/or cause vasodilatation, all of which can contribute to a further drop in core body temperature.[12,25] Depending on the stage of hypothermia, the degree of thermoregulatory dysfunction, the cold stress, and the physics of heat transfer, continued core cooling is possible despite appropriate treatment, particularly in the prehospital care setting. Such a failure to rewarm should trigger the clinician to reconsider secondary causes of hypothermia and ensure that ongoing heat losses have been ameliorated (uninsulated backboard, wet clothing, cool or windy environment) and that rewarming techniques are actually delivering significant heat.

SEVERE HYPOTHERMIA (STAGE III)

Stage III (unconscious, vital signs present, core temperature <~28°C) patients require the same treatment as stage II patients and will often require intubation for airway protection (Table 209-2). The role of invasive vascular rewarming methods that do not support circulation (dialysis, venovenous extracorporeal membrane oxygenation, and commercial temperature management systems) remains uncertain due to unproven benefits and the potential for procedure- and device-related morbidity.[26] The use of body cavity lavage rewarming has mostly been replaced by minimally invasive rewarming methods for stable patients and by arterial-venous extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass (CPB), where available, for unstable patients or those in cardiac arrest.[6] For stable patients who are slow to rewarm, it is reasonable to use warm saline (38 to 42°C) bladder lavage because the potential for morbidity is very low, particularly when compared with peritoneal, thoracic, gastric, or rectal lavage. The use of warm humidified gases for ventilation is recommended; however, it does not contribute significantly to rewarming.[27,28] Other invasive interventions, such as advanced airway management and central line placement, should be performed if required, despite the slight risk of triggering a malignant arrhythmia (avoid guidewire or catheter tip contact with the heart).[6]

Stage III patients are at high risk for cardiac arrest, so patients with a core temperature <28°C, hypotension out of proportion to the degree of hypothermia, or ventricular arrhythmias should be transferred to an ECMO/CPB center if one is available within a few hours of transport[6,8] unless comorbidities, such as major trauma, necessitate transfer to an alternate center. For stage III patients with vital signs, the minimum sufficient circulation is unknown, and there is no accepted threshold to transition a potentially unstable patient with vital signs onto ECMO. In studies involving mostly healthy young people, patients with stable vital signs do well with minimally invasive rewarming,[29] but in older comorbid populations (who may have poor tolerance for low cardiac output), there is emerging evidence that ECMO may be beneficial for all patients with a core temperature <28°C (see "Special Considerations/Special Populations, ECMO/CPB" below).[30]

Treat acid-base disturbances in hypothermic patients primarily by rewarming and reassessment. For the intubated patient, respiratory parameters should target an uncorrected P_{CO_2} of 40 mm Hg (this is known as an alpha-stat strategy, where correction factors are *not* applied to account for the temperature difference between patient temperature and blood gas analysis temperature).[5,31,32] Do not give bicarbonate to correct pH, unless there is a clear alternate indication, as in certain toxic ingestions.

STAGE IV

Because hypothermia induces a low-flow state, it can be challenging to detect a pulse in a hypothermic patient, so perform a careful check for signs of life. If any breathing, movement, or pulse is detected, watchful waiting and supportive care are recommended; otherwise, start CPR. High-quality CPR, prevention of further heat loss, and transfer to an ECMO/CPB center when possible are the most important priorities for stage IV patients. When transfer to ECMO/CPB is definitely not available and the patient is in cardiac arrest, thoracic lavage with normal saline (38 to 42°C) using a single or dual chest tube method may be the second best rewarming strategy when combined with ongoing CPR.[33]

Controversy exists regarding the use of epinephrine and defibrillation in hypothermic cardiac arrest. The European Resuscitation Council 2010 guidelines recommend up to three defibrillation attempts, to withhold epinephrine until the core temperature exceeds 30°C, and to double the dose frequency until the temperature is above 35°C.[27] In contrast, the American Heart Association 2010 guidelines state that it may be reasonable to use vasopressors during cardiac arrest.[28] Given the conflicting animal and human data that each recommendation is based on, a reasonable approach is to use standard advanced cardiac life support protocols for up to three cycles and, in the absence of clinical response, defer further defibrillation or epinephrine until core temperature increases significantly or the patient's clinical status changes.

One of the major challenges with stage IV hypothermia is to select the patient with cardiac arrest caused by hypothermia for prolonged resuscitation while avoiding futile resuscitation for patients with normothermic cardiac arrest and subsequent cooling. Measuring a serum potassium >12 mmol/L or a core temperature >32°C can help to avoid futile resuscitation, but in their absence, the clinician is dependent on the history and physical to select the patients who may benefit from prolonged resuscitation (Figure 209-3).

Stage IV patients with return of spontaneous circulation should be rewarmed to ≥32°C and get standard postarrest management[28] with consideration given to targeted temperature management[3] or therapeutic hypothermia[2] based on institutional preference. Patients rewarmed to ≥32°C without return of spontaneous circulation who are in asystole can be considered for termination of resuscitation in the absence of other causes of reversible cardiac arrest.

DISEASE COMPLICATIONS

Early complications are those that develop during the rewarming process, whereas late complications occur after rewarming. Most early complications have been described in the previous "Cold Physiology" section and can be minimized by handling patients carefully and using minimally invasive or extracorporeal rewarming techniques. Early ECMO/CPB-related complications are mostly related to cannulation and include bleeding, vessel perforation, dissection, and distal limb ischemia.[30] Possible late complications are numerous and can affect most organ systems. Common respiratory complications include pulmonary edema and infection. Common cardiac complications include prolonged hypotension or arrhythmias. A variety of neurologic injuries, such as seizure disorders, peripheral neuropathy, impaired cognitive function, or persistent vegetative state, are possible in cases of severe or prolonged ischemia. Similar to other critically ill patients, multiorgan failure is possible, including, but not limited to, acute respiratory distress syndrome, renal failure, liver failure, rhabdomyolysis, disseminated intravascular coagulopathy, bowel ischemia, and adrenal insufficiency.[1] With stage IV hypothermia, colder core temperatures and longer durations of CPR generally predict increased complications. Cardiac stunning and respiratory failure requiring ECMO support are two important potential late complications of stage IV hypothermia due to the resource intensity required for management.[25]

DISPOSITION AND FOLLOW-UP

Patients suffering from primary hypothermia who are rewarmed in the ED can be discharged home with routine follow-up by a primary care provider. Patients suffering from secondary hypothermia may require admission or specialized follow-up depending on the nature and severity of the underlying condition. Patients who are unable to be rewarmed within a reasonable period of time will require admission with cardiac and core temperature monitoring (stage III and IV patients require a critical care setting).

SPECIAL CONSIDERATIONS/SPECIAL POPULATIONS

CHILDREN

Pediatric stage IV hypothermia patients require special consideration, and in general, expert consultation is warranted prior to termination of resuscitation. They have a larger surface area–to–body mass ratio, which means they have the potential to cool more rapidly than adults. Additionally, children may have an increased ability to tolerate and recover from hypoxic brain injury. Therefore, prolonged resuscitation may be indicated, even in cases of normothermic hypoxic cardiac arrest, if there is simultaneous very rapid cooling. The classic outlier in the literature is the case of a 2.5-year-old girl who went immediately under the water of a 5°C creek and suffered a normothermic hypoxic cardiac arrest but was rapidly cooled (pinned against a rock under fast-flowing cold water); 66 minutes later, she was removed from the water in cardiac arrest, received 3 hours of CPR, had a core temperature of 19°C, was successfully resuscitated using ECMO/CPB, and had a good neurologic outcome.[24]

ECMO/CPB

The use of ECMO/CPB for the management of stage IV hypothermia can dramatically improve survival for patients, with a number needed to treat of ~2 (absolute risk reduction of death 50% to 90%).[6,8] Well-selected patients treated in an ECMO/CPB center have an ~50% to 100% survival rate, compared with a rate of ~10% to 30% if treated in a center without extracorporeal rewarming.[6,35] Hypothermic patients have tolerated prolonged periods of CPR (≥5 hours) with a good neurologic outcome.[8,36,37] The combination of improved outcomes with extracorporeal rewarming and the prolonged patient tolerance for CPR argue for the early identification of stage III and IV patients and priority transfer to an ECMO/CPB center. Unfortunately, many physicians are not aware of this benefit, and many healthcare systems are not prepared to transfer patients in cardiac arrest. The creation of critical care pathways that outline triage, initial management, transport destinations, and care goals within a given healthcare systems have the potential to improve outcomes, in a similar manner to cardiovascular care pathways.[38] A recent *New England Journal of Medicine* current concepts article[6] provides a preliminary framework, but considerable local and regional work is still required to create a functional system. The Bernese Algorithm,[39] although somewhat dated, is one of the only published hypothermia care pathways. The provincial health authority in British Columbia, Canada, is currently creating a clinical practice guideline and care pathway, which will likely be published and available for download at the authors' Web site in the future.

DROWNING, AVALANCHE, AND TRAUMA

Drowning, avalanche burial, and trauma are three situations that warrant special consideration in the context of hypothermia. Patients removed from cold water should be extracted in a horizontal position in an effort to decrease the risk of orthostatic and hydrostatic changes triggering rescue collapse. The majority of drowning is **submersion**, where the patient immediately goes under the water, suffers a hypoxic cardiac arrest, and then develops hypothermia. With the exception of children, who may undergo simultaneous hypoxic cardiac arrest and rapid cooling,[24] most submersion patients are unlikely to benefit from prolonged resuscitation (normothermic hypoxic cardiac arrest with brain death prior to cooling). The less common **immersion** patient may benefit from prolonged resuscitation; this patient is initially immersed in cold water but able to breathe air, cooling ensues, and the patient eventually suffers a presumed hypothermic cardiac arrest and may or may not become secondarily submerged. An amazing immersion case series took place on a single day in Denmark in 2011. Seven adolescent school children wearing personal floatation devices were found in cardiac arrest, in 2°C water, after a dragon boat accident. All seven were successfully resuscitated using ECMO after prolonged CPR and the neurologic outcome was good in six out of the seven cases.[35] See chapter 215, "Drowning," for detailed discussion of drowning.

With **avalanche** burial, most episodes of cardiac arrest are caused by asphyxia or trauma.[40] Avalanche burial results in much slower cooling than cold water exposure, and it will take from 35 minutes to several hours for the patient's core temperature to drop below 32°C (assuming initial normothermia). Therefore, if the patient is recovered in cardiac after less than 35 minutes of burial, hypothermia is not the cause of cardiac arrest. For patients recovered after 35 minutes of burial, in the absence of obvious traumatic death, an airway packed with snow, or an accurate core temperature >32°C, accidental hypothermia may be the cause of cardiac arrest and prolonged resuscitation may be indicated. Cardiac arrest secondary to blunt trauma has a dismal prognosis (<1% survival),[41] and a core temperature <35°C further increases the odds of death by at least 2.4.[17] Therefore, it is reasonable to apply normothermic termination of resuscitation guidelines to patients suspected of blunt traumatic arrest, even in the presence of hypothermia.

AUSTERE ENVIRONMENTS

In the rare circumstances of stage IV hypothermia in an austere environment, when ongoing CPR during transport is not possible, it may be reasonable to transport without CPR (particularly if the patient has pulseless electrical activity) until such a time as CPR can be maintained or a definitive care center is reached. The decision to not perform CPR in an austere environment may be risky given that prehospital CPR is performed in the vast majority of stage IV hypothermia literature; however, there are two published cases that have shown good outcomes despite CPR interruptions[36,42] and one case where CPR was not performed at all during transport.[43] Interestingly there has been considerable historical and ongoing expert opinion controversy about whether or not to perform CPR for stage IV patients with pulseless electrical activity, even in the nonaustere setting.[44,45] Presumably those who advocate against CPR fear an undetectable perfusing rhythm that could be terminated by starting CPR. Given that a rescuer has carefully checked for a pulse or signs of life for 60 seconds, that starting CPR will generate a palpable pulse and provide ~40% of cerebral blood flow,[46] that CPR has been shown to be safe in normothermic nonarrested patients,[47] that in the absence of adequate cerebral blood flow a deeply hypothermic patient is likely to suffer irreversible hypoxic injury after 30 to 60 minutes,[22] and that CPR is performed in the vast majority of stage IV hypothermia literature, it is this author's opinion that the benefits of CPR far outweigh the risks for the patient with absent vital signs, regardless of the ECG findings.

CHAPTER 210

Heat Emergencies

Frank LoVecchio

INTRODUCTION AND EPIDEMIOLOGY

Heat emergencies represent a continuum of disorders from heat cramps to heat stress that, when severe, culminate in heat stroke. In most circumstances, heat emergencies can be avoided through common sense, public education, and prevention.

The incidence of heat-related emergencies varies with the weather, although this is not an absolute requirement.[1] During heat waves and severe droughts, fatality rates spike.[1] Heat stroke is likely seen less among persons who live in warmer climates than travelers to these areas because of physiologic acclimatization and cultural adaptation of the former to heat.

From 1999 to 2003, an average of 688 heat-related deaths per year from exposure to extreme heat were reported in the United States.[1] The heat wave during the summer of 2003 is estimated to have caused 14,800 deaths in France.[2] In the Russian heat wave in July/August 2010, there were an estimated 15,000 deaths, with additional morbidity from associated forest fires and smoke injury.[3]

PATHOPHYSIOLOGY

MECHANISMS OF HEAT TRANSFER

Body temperature is regulated through the delicate balance of heat production, accumulation, and dissipation. Heat is generated by cellular metabolism and the mechanical work of skeletal muscle. Heat accumulates from radiation from the sun and direct contact with hot objects and is absorbed when the ambient temperature rises above body temperature. As core temperature rises, the autonomic nervous system is stimulated to promote sweating and cutaneous vasodilatation.

The body has several mechanisms for dissipating heat to the environment, including radiation (the transfer of heat by electromagnetic waves from a warmer object to a colder object), conduction (heat exchange between two surfaces in direct contact), convection (heat transfer by air or liquid moving across the surface of an object), and evaporation (heat loss by vaporization of water, or sweat).

Radiation and evaporation dissipate most body heat at lower ambient temperatures (<35°C [<95°F]). Conduction of heat into a layer of ambient air surrounding the skin ends rapidly as soon as that layer acquires similar temperature as the skin surface. This results in creation of an "insulator zone" of warmed air through which little heat may be lost. Removing the warmed air next to the skin and replacing it with cooler air may increase conductive heat loss by convection. When conduction is coupled with convection, rates of heat energy transfer from the body increase. Conduction of heat into water is many times more efficient than conduction into air of the same temperature.

The effect of wind on heat loss depends on wind velocity. Wind moves heat away from the skin by convection, but above 32.2°C (90°F) and 35% humidity, convection does not remove heat well.[4] This is why the use of fans alone is not effective in preventing heat stroke during periods of high environmental temperature and humidity.

When the external temperature rises to >35°C (>95°F), the body can no longer radiate heat to the environment and becomes dependent on evaporation for heat transfer. As humidity increases, the potential for evaporative heat loss decreases. Sweat that drips from the skin does not provide any cooling benefit and only exacerbates dehydration. As a result, the combination of high temperature and high humidity essentially blocks the two main physiologic mechanisms that the body uses to dissipate heat.

RESPONSE TO HEAT STRESS

The body maintains a core temperature between 36°C and 38°C (96.8°F and 100.4°F). Native thermal regulation mechanisms begin to fail at core temperatures of <35°C (<95°F) and >40°C (>104°F).[5] It is possible to maintain core temperatures of 40°C to 42°C (104.0°F to 107.6°F) for short periods without adverse effect.[5]

The physiologic response to heat stress consists of four primary mechanisms: dilatation of blood vessels, particularly in the skin; increased sweat production; decreased heat production; and behavioral heat control. As the core temperature of the body rises, the sympathetic outflow of the posterior hypothalamus is inhibited, which leaves unopposed the sympathetic outflow from the anterior hypothalamus. Sympathetic flow from the anterior hypothalamus results in decreased vascular tone throughout the body, particularly in the cutaneous circulation.

During exercise in conditions of hyperthermia, the heart rate increases to compensate for the decrease in stroke volume from the cutaneous vascular dilation and to maintain cardiac output.[6] Patients with underlying cardiovascular disease or pharmacologic or physiologic impairment of these mechanisms may not be able to elevate cardiac output. Heat stress may also result in arrhythmias, myocardial ischemia, and exacerbation of congestive heart failure.

Elevated cholinergic stimulation to the skin results in increased sweat production. Sharp increases in the rate of sweat production normally occur with core temperature elevations above 37°C (98.6°F). As a general rule, for every pound of weight lost by sweating, 500 mL of fluid should be consumed. Endurance athletes can perspire at a rate of up to 1.5 L/h.[7] Cutaneous vascular dilation and sweating increase as the body temperature rises until a homeostatic stall of heat production and input with heat dissipation is reached and the body's temperature stops rising.[8] Interestingly, sweating activation in older individuals begins at 1.5°C (34.7°F) higher than that in younger individuals.[9]

MEDICATIONS

Medications often interfere with heat-removal mechanisms. Notable drugs are anticholinergic agents, diuretics, phenothiazine, β-blockers, calcium channel blockers, and sympathomimetic agents.[10] Anticholinergic agents impair sweating and the cardiovascular response to heat. Diuretics lead to volume depletion and decreased cardiac output. Phenothiazines have anticholinergic properties and deplete central stores of dopamine, which interfere with the hypothalamic thermoregulatory center. Medications such as β-blockers and calcium channel blockers decrease the cardiovascular response to heat and reduce peripheral blood flow and the ability to sweat. Sympathomimetics cause cutaneous vasoconstriction and inhibit sweating. Alcohol inhibits secretion of antidiuretic hormone, which leads to dehydration, and blunts the psychological heat-avoidance response. Heroin, cocaine, and amphetamines disrupt the function of endogenous endorphins and adrenocorticotropic hormones that are involved in heat adaptation mechanisms. Amphetamines and cocaine increase muscle activity and lead to heat production. Lysergic acid diethylamide and phencyclidine act on the CNS to induce a hypermetabolic state.[10]

ACCLIMATION

Acclimation is the adaptation of the body to environmental changes. It involves a number of physiologic and biochemical adjustments that allow an individual to withstand heat stresses that would otherwise result in substantial morbidity and mortality.

Acclimation lowers the thermal set point in the hypothalamus, which triggers the onset of sweating at lower core temperatures in the acclimated human. In addition, the maximal rate of sweat production is dramatically increased to 1.5 to 3.0 L/h and can be sustained for longer periods.[7] Aldosterone secretion is boosted, and sodium conservation results from more efficient reabsorption from the sweat. Plasma volume expands, heart rate decreases for any given heat load, and exercise tolerance improves. Dilation of cutaneous blood vessels occurs at a lower core temperature to promote earlier cooling.

In most individuals, acclimation can be achieved over 7 days to several weeks.[11-13] Moderate exercise in a hot, dry environment for 60 to 100 minutes each day is probably the optimal approach to achieve acclimation. To maintain heat and exercise-induced adaptive responses, heat exposure needs to continue intermittently at least on 4-day intervals. Simple exposure to a hot environment for 1 to 4 hours a day also may result in acclimation within 2 weeks. Once removed from the hot environment, the body will de-acclimate to the original physiologic parameters within 1 to 2 weeks.[12]

MODELS OF HEAT INJURY

The pathology of heat stroke is not completely understood, and although heat stroke is triggered by hyperthermia, there is evidence that secondary endotoxemia triggers a systemic inflammatory response, coagulopathy, and multiorgan failure.[14,15]

Heat exhaustion and heat stroke occur when the body's thermoregulatory responses are impaired or overwhelmed and are no longer capable of maintaining homeostasis. Excessive heat is directly toxic to cells, causes an acute-phase reaction with release of inflammatory cytokines, and damages vascular endothelium. Nearly all cells respond to sudden heating by producing heat stress proteins, whose mechanism of action is still not completely understood.[14,15]

Escalating cellular temperature results in denaturation of proteins, interruption of cellular processes, and cell death. Temperatures of

>41.6°C (>106.9°F) can produce cellular injury in hours. As temperature rises, cellular damage occurs more quickly and extensively. Temperatures >49°C (>120.2°F) typically result in immediate cell death and tissue necrosis.[15] The enhanced vascular permeability due to damaged vascular endothelium results in activation of the coagulation cascade and disseminated intravascular coagulation.

Classic heat injury occurs during periods of high environmental heat stress. Physical exertion is not required if the heat gain occurs at environmental temperatures and humidity levels that overwhelm the native heat loss mechanisms. The increase in core temperature seen in this setting is often slow, occurring over a period of hours to days. Because of this slow rise in heat burden, volume and electrolyte abnormalities are common. High-risk populations include the elderly, the young, and those with psychological, physiologic, and pharmacologic impairments of heat loss mechanisms (e.g., diabetes; Raynaud's disease; drugs such as anticholinergics, diuretics, antipsychotics, cocaine). Epidemiologic studies of classic heat injury typically identify the elderly, living alone or without social support and without air-conditioning.[16]

Exertional heat injury usually affects individuals who are participating in athletic events or performing jobs under conditions of high heat stress. Risk factors include dehydration, concurrent illness, obesity, wearing too much clothing, and poor cardiovascular fitness. In this setting, heat production and heat gain from the environment exceed the capacity of heat removal processes. Physical exercise is the most common single source of internal heat production. Without an efficient cooling mechanism, progressive dehydration and hyperpyrexia continue to the level of cardiovascular and metabolic failure.

Confinement hyperpyrexia is a special category of nonexertional hyperpyrexia and can occur in several circumstances, such as when children are left inside cars, when stowaways are abandoned inside closed vehicles or railroad cars, and when workers are occupationally exposed to heat inside enclosed spaces. Between July 2000 and June 2001 in the United States, 1960 nonfatal heat injuries and 78 fatalities were reported in children who were left intentionally in motor vehicles during hot days.[17] Nonventilated vehicle compartments in a hot environment may reach temperatures of 54°C to 60°C (129.2°F to 140.0°F) in <10 minutes.[17] Infants have less capacity than adults to deal with heat stress and, if left in motor vehicles for only a matter of minutes, may accumulate a critical heat burden. During 2000, nearly 500 individuals died attempting to cross the Mexico-U.S. border through the desert, locked in closed vehicle compartments and then abandoned by smugglers, with >50% of these deaths due to heat stroke. A particularly dangerous region is southern Arizona, which accounts for 22% of all southwest border deaths of illegal immigrants. In the August 2003 heat wave in France, a risk factor for heat stroke mortality was heat exposure at home or in a non–air-conditioned healthcare facility.[18]

CLINICAL FEATURES AND TREATMENT

Heat emergencies comprise a range of disorders from minor (heat edema, prickly heat, heat cramps, and heat exhaustion) to major (heat stroke).

MINOR HEAT ILLNESSES

Heat Edema **Heat edema** is a self-limited process manifested by mild swelling of the feet, ankles, and hands that appears within the first few days of exposure to a hot environment. Heat edema is due to the cutaneous vasodilatation and orthostatic pooling of interstitial fluid in gravity-dependent extremities. An increase in the secretion of aldosterone and antidiuretic hormone in response to the heat stress contributes to the mild edema. In general, heat edema is found in elderly nonacclimatized individuals who are physically active after a period of sitting while traveling in a vehicle or airplane. Occasionally, heat edema occurs after prolonged standing. It is commonly seen in healthy travelers just arriving from a colder climate. The edema is mild and does not impair or interfere with normal activities. Very rarely, pitting edema of the ankles may develop but does not progress to the pretibial region.

History and physical examination are usually sufficient to exclude systemic causes of edema, and no further testing or treatment except removal from heat source is needed. In the elderly, new pedal edema from heat should be differentiated from early congestive heart failure or deep venous thrombosis. Heat edema usually resolves spontaneously in a few days. No special treatment is necessary, but elevation of the legs and the use of support hose facilitate removal of the interstitial fluid. Diuretics are not effective and can predispose to volume depletion, electrolyte abnormalities, or more serious heat emergencies.[8]

FIGURE 210-1. Miliaria rubra (prickly heat). [Image used with permission of Peter Lio, MD.]

Prickly Heat **Prickly heat** is a pruritic, maculopapular, and erythematous rash over normally clothed areas of the body. Also known as *lichen tropicus*, *miliaria rubra*, or *heat rash*, it is an acute inflammation of the sweat ducts caused by blockage of the sweat pores by macerated stratum corneum (**Figure 210-1**). The sweat ducts become dilated under pressure and ultimately rupture, producing superficial vesicles in the malpighian layer of the skin on a red base. Itching is the predominant clinical feature during this phase and can be treated successfully with antihistamines. Wearing clean, light, and loose-fitting clothing and avoiding sweat-generating situations can prevent prickly heat. Calamine lotion or topical steroids can be of benefit. Chlorhexidine in a light cream or salicylic acid cleaning may provide some relief.[19]

With prolonged or repeated heat exposure, a keratin plug fills the sweat duct, causing obstruction in the stratum malpighian layer. When the duct ruptures a second time, the resultant vesicle will be driven deeper into the dermis. This vesicle simulates the white papules of piloerection and is not pruritic. This is known as the *profunda* stage of prickly heat (miliaria profunda) and can readily advance into a chronic dermatitis. Infection with *Staphylococcus aureus* or methicillin-resistant *S. aureus* is a common complication. The skin can be desquamated by applying 1% salicylic acid to the affected area three times a day.

Heat Cramps **Heat cramps** are painful, involuntary, spasmodic contractions of skeletal muscles, usually those of the calves, although they may involve the thighs and shoulders. These cramps usually occur in individuals who are sweating profusely and replace fluid losses with water or other hypotonic solutions. Heat cramps may occasionally occur during exercise or, more commonly, during a rest period after several hours of vigorous physical activity. Nonacclimated or unconditioned individuals who are just starting manual labor in a hot environment are at risk for heat cramps. Although heat cramps are self-limited and do not cause significant morbidity, the pain associated with them can precipitate an ED visit. In general, heat cramps are short in duration, are limited to a definitive group of muscles, and almost never involve enough muscle mass to cause rhabdomyolysis.

The pathogenesis of heat cramps is believed to involve a relative deficiency of sodium, potassium, or magnesium and fluid at muscle level. The production of large amounts of sweat, which has a high sodium content, coupled with inadequate sodium replacement results in cellular hyponatremia. This in turn produces muscle cramps with calcium-dependent muscle relaxation. Patients with severe heat cramps may have

hyponatremia and hypochloremia.[20] Rhabdomyolysis is rare and occurs secondary to diffuse and protracted muscle spasm.[15]

Treatment consists of fluid and salt replacement (PO or IV) and rest in a cool environment. For mild cases, or if an overwhelming number of patients require treatment, a 0.1% to 0.2% saline solution can be given PO. Two 650 milligram salt tablets dissolved in a quart of water provide a 0.1% saline solution.[13,20] Many electrolyte solution drinks (sports drinks) are commercially available and are much more palatable. Patients with more severe symptoms require IV rehydration with normal saline. Heat cramps can be prevented by maintaining adequate dietary salt intake or by drinking commercial electrolyte beverages. Salt tablets by themselves should not be used, because the tablets are a gastric irritant and cause nausea and vomiting.

Heat Stress Heat stress occurs in two different ways, through water depletion and through sodium depletion, but often is characterized by a combination of both. Water depletion tends to occur in the elderly and in persons working in hot environments with inadequate water replacement. Salt depletion heat exhaustion tends to occur in unacclimatized individuals who replace fluid losses with large amounts of hypotonic solutions.

Heat stress presents with symptoms that include headache, nausea, vomiting, malaise, dizziness, and muscle cramps as well as signs of dehydration, such as tachycardia and orthostatic hypotension or near-syncope. Heat cramps and/or rhabdomyolysis are present on rare occasions. Because of the ill-defined and nonspecific symptoms, heat stress is often a diagnosis of exclusion.

On physical examination, the temperature may be normal or elevated, usually not above 40°C (104°F). Patients with heat exhaustion do not manifest signs of CNS impairment.

Laboratory studies almost universally demonstrate hemoconcentration, although the specific electrolyte abnormalities seen depend on the ratio of fluid and electrolyte losses to intake. Patients who have had no fluid intake of any kind exhibit hypernatremia, whereas those who partly rehydrate with salt-containing fluids develop isotonic hypovolemia with normal sodium and chloride levels. Serum potassium and magnesium levels are variable.

Heat stress is treated with volume and electrolyte replacement and rest. Removal from the heat-stressed environment is essential. Patients with mild heat stress may be treated with oral electrolyte solutions. Rapid infusion of moderate amounts of IV fluids (1 to 2 L of normal saline) may be necessary in patients who demonstrate significant tissue hypoperfusion. Ideally, the choice of IV solution should be guided by laboratory determinations, but isotonic salt solutions may be used until specific electrolyte abnormalities are identified. In general, hospitalization is not required. Patients with congestive heart failure or severe electrolyte disturbances may require admission, because of the time needed to correct their fluid and/or electrolyte deficits.

Heat stress can progress to heat stroke even after the patient is removed from the hot environment. Therefore, patients with heat stress who do not respond to approximately 30 minutes of fluid replacement and removal from the hot environment should be cooled until the core temperature drops to 39°C (102°F).

HEAT STROKE

Heat stroke is an acute life-threatening emergency with high mortality and is fatal if left untreated (**Table 210-1**).

TABLE 210-1 Signs and Symptoms of Heat Emergencies

Heat Cramps	Heat Stress	Heat Stroke
Muscle cramps	Symptoms seen in heat cramps plus:	Symptoms seen in heat stress plus:
Normal to mildly elevated temperature	Normal to elevated temperature (<40°C [<104°F])	Elevated temperature (>40°C [>104°F])
Sweating	Nausea, vomiting, headache, malaise, dizziness	Neurologic abnormalities: inappropriate behavior, confusion, delirium, ataxia, coma, seizures
	Orthostatic hypotension	Anhidrosis or sweating

TABLE 210-2 Differential Diagnosis of Heat Stroke

Infection	*Neurologic*
Sepsis syndrome	Hypothalamic bleeding or infarct
Meningitis	Cerebrovascular accident
Encephalitis	Status epilepticus
Malaria	*Toxicologic*
Typhoid	Anticholinergic toxidrome
Tetanus	Sympathomimetic overdose
Endocrine	Salicylate overdose
Thyroid storm	Serotonin syndrome
Pheochromocytoma	Malignant hyperthermia
Diabetic ketoacidosis	Neuroleptic malignant syndrome
	Withdrawal syndromes—alcohol and benzodiazepine withdrawal

The cardinal features of heat stroke are hyperthermia (>40°C [>104°F]) and altered mental status. Although patients presenting with classic (nonexertional) heat stroke may exhibit anhidrosis, the absence of sweat is not considered a diagnostic criterion because sweat is present in over half of patients with heat stroke.[15]

The CNS is particularly vulnerable in heat stroke. The cerebellum is highly sensitive to heat, and ataxia can be an early neurologic finding. Virtually any neurologic abnormality may be present in heat stroke, including irritability, confusion, bizarre behavior, combativeness, hallucinations, plantar responses, decorticate and decerebrate posturing, hemiplegia, status epilepticus, and coma. Seizures are quite common, especially during cooling. Neurologic injury is a function of the maximum temperature reached and the duration of exposure.[15]

The distinction between exertional and classic (nonexertional) heat stroke is not clinically important, because immediate cooling and support of organ system function is the therapeutic goal for both. A delay in cooling increases the mortality rate.

DIAGNOSIS

There are no diagnostic tests for heat stroke, and the differential diagnosis is extensive. Therefore, the diagnosis of heat stroke is determined by history and clinical presentation, and exclusion of other processes (**Table 210-2**).

LABORATORY EVALUATION

Diagnostic studies are directed toward detecting end-organ damage and excluding other diseases. Helpful studies include a CBC, comprehensive metabolic panel with arterial blood gas analysis, coagulation profile, creatine phosphokinase level, myoglobin level, urinalysis, ECG, and chest radiograph. Lumbar puncture and CT of the head may be indicated to rule out other causes of altered mental status. The partial pressure of arterial carbon dioxide is often <20 mm Hg due to hyperventilation. Patients with exertional heat stroke often have lactic acidosis, and hypoglycemia may occur.

TREATMENT

The goals of therapy are immediate cooling and aggressive support of organ system function.

PREHOSPITAL CARE

Remove the patient from the hot environment immediately, and perform standard resuscitation measures. Check point-of-care glucose if there is altered mental status. Start cooling by removing clothing and implementing one of the following methods: spray the patient with

water and provide airflow over the patient (ideal method but not always practical during transportation); place wet towels or sheets over the patient's body; or place ice on the patient. Administer a bolus of normal saline (1 to 2 L) if hypotension is present.[15] Online medical direction is helpful when transport times are long and when EMS personnel in the given region rarely encounter heat stroke.

ED MANAGEMENT

Initial Resuscitation Continue standard resuscitation measures. Administer IV fluids at a rate that ensures adequate urine output. In elderly patients or patients with cardiovascular disease, consider invasive monitoring. Check glucose levels. Monitor core temperature with an electronic rectal thermometer, temperature probe–equipped urinary drainage catheter, or esophageal thermometer.

Cooling Techniques Currently, only physical methods of cooling are recommended, and there is no evidence to support one particular approach over another. In clinical practice, the primary physical cooling procedure is one that allows easy patient access, is readily available, is tolerated well by the patient, and is effective (**Table 210-3**). With all cooling methods, the goal is to reduce the core temperature to approximately 39°C (102.2°F) and to avoid overshoot hypothermia. If the initial cooling method used does not lower temperature quickly, try another method.[15,21]

Evaporative Cooling **Cooling by evaporation** is practical and comfortable for the patient compared with other methods. Remove patient clothing and spray cool water (~15°C [59°F]) on most of the patient's body surface. Directing a fan over the patient facilitates evaporation. If the skin temperature is reduced below 30°C (86°F), shivering will result in more heat production, and peripheral vasoconstriction will impair evaporation. To prevent hypothermic overshoot, some recommend using either tepid water warmed to 40°C (104°F) or exposing the patient to hot air (45°C [113°F]) with the fan.[21] This method is the foundation of several cooling units such as the **Makkah cooling unit**, which is widely used in the Middle East to treat pilgrims traveling to Mecca who succumb to heat stroke. The Makkah cooling unit is composed of a large hammock with built-in sprinklers that spray cool water (15°C [59°F]) over the patient's body and powerful fans that blow warm air (45°C [113°F]) over the patient. The main problems with the Makkah cooling method are cost, portability, and the fact that evaporation rates are reduced in very humid environments.

The two main difficulties associated with evaporative cooling are shivering and the inability of cardiac electrodes to adhere to the skin. Shivering is treated primarily with short-acting benzodiazepines and secondarily with phenothiazines. Phenothiazines may lower the seizure threshold and cause hypotension, and their anticholinergic properties impair sweating.

Immersion Cooling **Immersion cooling** is performed by placing the undressed patient into a tub of ice water deep enough to cover the trunk and extremities, while keeping the patient's head out of the water. Problems associated with immersion cooling include shivering, displacement of monitoring leads, and inability to perform defibrillation or resuscitative procedures. Also, a tub or receptacle large enough to accommodate the patient may not be readily available. The efficiency of immersion cooling has been documented primarily in young, healthy patients without comorbid diseases. The efficacy and safety of immersion in patients with classic (nonexertional) heat stroke and patients with significant comorbid diseases (e.g., coronary artery disease) have not been established.

Massage with ice water is an alternative for patients who cannot tolerate immersion, although its effectiveness as a single modality for cooling remains unclear.[21]

Invasive Cooling Measures When evaporation or immersion methods are not sufficient, invasive cooling may be considered. The most rapid method of cooling a heat stroke victim is cardiopulmonary bypass, although lack of availability and logistical problems are major disadvantages. Cold water gastric lavage, cold water urinary bladder lavage, and cold water rectal lavage are other adjunctive measures that can be performed in the ED but require patient cooperation, are labor intensive, have the potential for inducing water intoxication, and are of questionable efficacy. Cold water peritoneal lavage is yet another option, but its effectiveness has not been validated.

Other Cooling Measures **Cooling blankets** work slowly and should not be a sole treatment for heat stroke. IV infusion of cold fluids alone is not considered effective treatment. Applying ice packs to the neck, axillae, and groin does not lower temperature quickly enough to be used alone. There are no studies on the effectiveness of antipyretics. Dantrolene is not indicated for treatment of heat stroke.[21]

TABLE 210-3 Summary of Cooling Techniques

Cooling Method	Advantages	Disadvantages	Recommendations
Evaporative cooling	Provides effective cooling	Can cause shivering	Strongly recommended
	Readily available	Less effective in humid environments	
	Practical	Makes it difficult to maintain electrode positions	
	Well tolerated		
Immersion cooling	Provides effective cooling	Can cause shivering	Recommended
		Poorly tolerated	
		Not compatible with resuscitation settings	
Ice packs on neck, axillae, and groin	Practical	Cooling times longer than other modalities	Can be used as adjunct cooling method
	Can be added to other cooling methods	Poorly tolerated	
Cardiopulmonary bypass	Provides fast and effective cooling	Invasive	Recommended in severe or resistant cases when available
		Not readily available	
		Setup is labor intensive	
Cooling blankets	Easy to apply	Have limited cooling efficacy	Not recommended when other methods available
		Impede use of other cooling methods	
Cold water gastric, urinary bladder, rectal, or peritoneal lavage	—	Invasive	Effectiveness and safety not established
		Labor intensive	
		May lead to water intoxication	
		Human experience is limited	

COMPLICATIONS

Heat stroke causes both early and late complications (**Table 210-4**). Hypotension is a common initial finding. Usually the blood pressure will rise in response to fluid bolus and body cooling. The combination of low cardiac output and elevated central venous pressure warrants the use of vasoactive catecholamines such as dopamine or dobutamine if a 20 cc/kg fluid bolus does not result in improvement. Once the central venous pressure reaches 12 to 14 mm Hg and cooling is initiated, dopamine or dobutamine may be used to maintain a normal blood pressure. Inotropes that cause severe vasoconstriction by α-adrenergic stimulation, such as norepinephrine, may impede cooling by redirecting blood flow away from the skin.

Fluid and electrolyte abnormalities vary depending on the type of onset and duration of the disorder, any underlying disease (especially cardiovascular disease), and any prior use of medications, such as diuretics. Hypokalemia due to total-body depletion of potassium may be noted, and hyperkalemia may result from acute renal failure and rhabdomyolysis. Hypernatremia is seen in severely dehydrated patients, whereas hyponatremia occurs in patients who hydrate with oral hypotonic solutions.

Hematologic disorders may be apparent clinically and on laboratory evaluation. Findings of abnormal hemostasis include purpura, petechiae, and conjunctival, GI, renal, or pulmonary hemorrhage. Coagulation studies may show thrombocytopenia, hypoprothrombinemia, and hypofibrinogenemia. Thermal injury to the vascular endothelium can cause increased platelet aggregation, changes in capillary permeability, thermal deactivation of plasma proteins resulting in a decreased level of clotting factors, disseminated intravascular coagulation, and fibrinolysis.[15,22]

Thermal injury to the liver is a common finding in heat stroke, although jaundice does not always develop. Delayed elevation of hepatic enzyme levels, peaking 24 to 72 hours after the thermal insult, is attributed to centrilobular necrosis. Glucose homeostasis is affected. Hepatic damage is almost always reversible, with a full recovery.

Renal failure results from direct thermal injury to the kidney, rhabdomyolysis, or volume depletion. Clinically, this is manifested by oliguria, microscopic hematuria, proteinuria, myoglobinuria, and granular or red cell casts in the urine. Early volume expansion decreases the detrimental renal effects of heat stroke.

Adult respiratory distress syndrome requires ongoing respiratory support until cooling has been accomplished. Cardiac muscle injury may also occur. The presence of hypotension, low cardiac output, and a falling cardiac index is associated with a poor prognosis.

Seizures may occur during cooling and can be controlled with benzodiazepines.

Mortality correlates with the degree of temperature elevation, time to initiation of cooling measures, and the number of organ systems affected. In one prospective cohort study, the risk of death increased substantially in patients who presented with anuria (hazard ratio, 5.24; 95% confidence interval, 2.29-12.03), coma (hazard ratio, 2.95; 95% confidence interval, 1.26-6.91), or cardiovascular failure (hazard ratio, 2.43; 95% confidence interval, 1.14-5.17).[23]

TABLE 210-4 Complications of Heat Stroke

	Early	Late
Vital signs	Hypotension	—
	Hypothermic overshoot	
	Hyperthermic rebound	
Muscular	Rhabdomyolysis	—
Neurologic	Delirium/coma	Cerebral edema
	Seizure	Encephalopathy
		Persistent neurologic deficit
Cardiac	Heart failure	Myocardial injury
Pulmonary	Pulmonary edema	Acute respiratory distress syndrome
Renal	Oliguria	Renal failure, rhabdomyolysis
GI	—	Intestinal ischemia or infarction
		Pancreatic injury
		Hepatic dysfunction
Metabolic	Hypokalemia	Hyperkalemia
	Hypernatremia	Hypocalcemia
	Hyponatremia	Hyperuricemia
Hematologic	—	Thrombocytopenia
		Disseminated intravascular coagulation

DISPOSITION AND FOLLOW-UP

Patients with minor heat emergency syndromes (heat edema, heat cramps, or heat stress) require only ED treatment along with clear discharge instructions and outpatient follow-up. However, patients with underlying diseases, such as congestive heart failure or renal failure, and patients with severe electrolyte imbalance may require hospital admission. No decision rules exist to guide disposition decisions.

Patients with heat stroke require admission to a unit providing care at a level appropriate to the patient's condition. Patients who are intubated, are in hemodynamically labile condition, require invasive hemodynamic monitoring, or need continued cooling should be admitted to the intensive care unit. If the receiving health care facility is unable to provide the services needed for quality care, then transfer the patient to a higher-level facility.

SPECIAL POPULATIONS

Populations at higher risk of developing heat emergencies include the elderly, young children, athletes, persons with limited mobility, alcoholic individuals, and people taking antipsychotics, major tranquilizers, anticholinergics, antiparkinsonian agents, cardiovascular medications (β-blockers, calcium channel blockers, and vasodilators), or over-the-counter sleeping aids or stimulants.[10] Other risk factors for exertional heat emergencies include obesity, dehydration, and vigorous exertion in the heat without proper training and acclimatization.

In addition, individuals with a history of heat stroke are at greater risk for another episode. Patients with congenital absence of sweat glands, progressive systemic scleroderma, hyperthyroidism, and pheochromocytoma are also at increased risk for heat stroke.

Elderly persons who lack mobility, have preexisting medical illness, take medications that may affect thermoregulation or ambulation, live in housing that is without thermal insulation, or sleep on the top floor are particularly susceptible to heat stress.[18]

Young children lack adequate thermoregulatory and sweating capabilities, do not instinctively replace their fluid losses or limit exercise in extreme heat, and may be unable to remove themselves from risky environments such as a closed car in the sun. Teenagers and preadolescents are at risk because they may use poor judgment when exercising in high heat and humidity and may push themselves to the limit. Early season high school heat stroke deaths are most likely to occur during the first 4 days of practice; children require 10 to 14 days to achieve an appropriate acclimatization response.

Athletes should be prescreened about risk factors for heat illness (sickle cell disease, prior heat illness, dehydration) and be acclimated to heat gradually over 1 to 2 weeks. Although there are no standardized guidelines for return to play after heat stroke, depending on the severity of the episode, a rest period of at least 1 week, followed by medical clearance and then gradual progression of activity, is suggested.[13]

PREVENTION

Behavioral control of temperature regulation is important. As individuals begin to feel hot and uncomfortable when exposed to heat stress, they may take actions to find a cool environment. Public education regarding heat-related illness should capitalize on this response mechanism.

Populations with no home air-conditioning have a higher risk for a serious heat illness than populations with air-conditioning. Taking "heat

breaks" in an air-conditioned location for periods as short as 2 hours a day decreases the likelihood of heat stroke among those with no home air-conditioning.

Acclimation protocols to decrease the frequency of heat-related illness have been developed for personnel (e.g., military, firefighters, laborers, and disaster relief workers) who are preparing to deploy to hot environments.

Avoidance of strenuous exercise during periods of high environmental heat stress, as judged by the heat index chart, coupled with acclimation, hydration, breaks from the heat, and education, will prevent exertional heat injury.

Serious heat-related illnesses are preventable. General recommendations for the individual include (1) decreasing or rescheduling strenuous activity for cooler parts of the day; (2) wearing light and loose-fitting clothing; (3) increasing carbohydrate intake and decreasing protein intake to decrease endogenous heat production; (4) drinking plenty of fluids, even when not thirsty; (5) avoiding alcoholic beverages; (6) using salt tablets as well as fluids; (7) avoiding direct sunlight; and (8) taking advantage of the shade. Community health officials and governmental leaders should recognize the need to educate the public, coordinate and plan the implementation of these measures in advance, and avoid resorting to crisis management.

CHAPTER 211

Bites and Stings

Aaron Schneir
Richard F. Clark

INTRODUCTION AND EPIDEMIOLOGY

The phylum Arthropoda is the largest division of the animal kingdom. The phylum includes insects (bees, wasps, hornets, flies, mosquitoes, bedbugs, fire ants, caterpillars, fleas), arachnids (spiders, scorpions, chiggers, ticks), and crustaceans (shrimp, lobsters, crabs). Venomous bites and stings from arthropods are a significant worldwide problem.[1] In the United States, the American Association of Poison Control Centers reported almost 50,000 cases of exposures to arthropods in 2012.[2] Some of these were listed as resulting in major or severe reactions, including severe pain, neurotoxicity, or other signs and symptoms. Fatalities among these exposures are rarely reported to poison centers and usually result from allergic reactions to Hymenoptera stings. Toxic reactions to multiple stings by members of the order Hymenoptera and severe systemic allergic reactions to one or more stings or bites of other insects, such as deerflies, blackflies, horseflies, and kissing bugs, can all present as emergency, life-threatening situations.[3] Other arthropod bites and envenomations merit review either because they cause specific organ system toxicity or because they can result in transmission of infectious disease. This chapter discusses the most common and serious arthropod bites and envenomations. Tick bites are discussed in the "Tickborne Zoonotic Infections" section of chapter 160, "Zoonotic Infections: Tickborne Zoonotic Infections."

HYMENOPTERA (WASPS, BEES, AND ANTS)

More fatalities result from stings by these insects than by stings or bites by any other arthropod. There are three major subgroups or superfamilies of medical importance: (1) Apidae, which includes the honeybee and bumblebee; (2) Vespidae, which includes yellow jackets, hornets, and wasps; and (3) Formicidae, or ants.

BEES AND WASPS (APIDAE AND VESPIDAE)

Apids, such as honeybees and bumblebees, are usually docile, stinging only when provoked. A female honeybee is capable of stinging only once (male bees have no stinger), because its stinger has multiple barbs that cause the sting apparatus to detach from the bee's body, which leads to evisceration and eventual death.

Africanized honeybees, or so-called killer bees, are now found in most of the southern and warmer regions of the United States extending from coast to coast. These bees are hybrids of African bees that escaped from laboratories in Brazil during the 1950s and have successfully spread northward along the coasts and temperate regions of the continent. Their venom is no more toxic than that of their American counterpart, but Africanized hybrid honeybees are more aggressive, and a hive can respond to a perceived threat with >10 times the number of bees that respond from a hive of typical North American bees. An attack from Africanized bees can lead to massive stinging, resulting in multisystem damage and death from severe venom toxicity.[4,5]

Most of the allergic reactions reported each year due to Hymenoptera occur from vespid (wasp, hornet, and yellow jacket) stings. These arthropods nest in the ground, in trees, or in walls; have volatile tempers; and may be disturbed by work taking place around the nest. As with bees, only the females have adapted a stinger from the ovipositor on the posterior aspect of the abdomen. Although vespids also possess barbed stingers, they have the ability to withdraw their stingers from the victim, which permits multiple stings.

Venom Hymenoptera venom contains several components.[6] Although histamine is one of those components, other substances are now recognized as more important. Melittin, a known membrane-active polypeptide that can cause degranulation of basophils and mast cells, constitutes >50% of the dry weight of bee venom. Protein enzymes such as phospholipase and hyaluronidase may account for most systemic reactions.[7,8] Because all Hymenoptera share many of these components, cross-sensitization may occur in individuals allergic to one species. Yellow jacket venom is perhaps the most potent sensitizer.

Clinical Features The most common response to Hymenoptera venom is a local reaction: pain, slight erythema, edema or urticaria, and pruritus at the sting site. A severe local reaction may involve one or more neighboring joints. A local reaction occurring in the mouth or throat can produce airway obstruction. Stings around the eye or on the lid may result in the development of an anterior capsule cataract, atrophy of the iris, lens abscess, perforation of the globe, glaucoma, or refractive changes. When local reactions become increasingly severe, the likelihood of future systemic reactions appears to increase, and if skin test results are positive, immunotherapy may be warranted.

Anaphylaxis Symptoms range on a continuum. Criteria for anaphylaxis are presented in **Table 211-1**, and detailed discussion of anaphylaxis is provided in chapter 14, "Anaphylaxis, Allergies, and Angioedema." Most reactions develop within the first 15 minutes, and nearly all occur within 6 hours. Initial mild symptoms may progress swiftly to shock. There is no correlation between systemic reaction and the number of stings. Symptoms include nausea, vomiting, and diarrhea; light-headedness and syncope; involuntary muscle spasms; edema without urticaria; and, rarely, seizures. Respiratory distress and cardiac arrest can result. Urticaria and bronchospasm do not need to be present. In general, the shorter the interval between the sting and the onset of symptoms, the more severe is the reaction. Fatalities that occur within the first hour after the sting usually result from airway obstruction or hypotension.

Renal and hepatic failure and disseminated intravascular coagulation can result from massive bee stings. Creatine phosphokinase concentrations can reach 100,000 IU/L or more in cases in which rhabdomyolysis occurs from direct venom toxicity.[5] Toxic reactions are believed to occur due to a direct multisystem effect of the venom. Symptoms usually subside within 48 hours but may last for several days in severe cases, and some effects, such as rhabdomyolysis, can be delayed. We recommend **hospital admission or observation for victims with**

TABLE 211-1 Clinical Criteria for Anaphylaxis

1. Acute onset of an illness (minutes to several hours) with involvement of the skin and/or mucosal tissue (e.g., hives/urticaria, pruritus, flushing, swollen lips, tongue, or uvula) associated with at least one of the following:
Respiratory compromise (e.g., dyspnea, wheeze, stridor)
or
Reduced blood pressure
or
Associated symptoms of organ dysfunction (e.g., hypotonia, syncope, incontinence)
2. Two or more of the following that occur rapidly after exposure to a likely allergen for that patient (minutes to several hours):
Involvement of the skin and/or mucosal tissue
Respiratory compromise
Reduced blood pressure or associated symptoms
Persistent GI symptoms (e.g., cramps, vomiting)
3. Anaphylaxis should be suspected when patients are exposed to a known allergen and develop hypotension

>100 stings, for those with substantial comorbidities, and for those at extremes of age.

Delayed Reaction A delayed reaction, appearing 5 to 14 days after a sting, consists of serum sickness–like signs and symptoms of fever, malaise, headache, urticaria, lymphadenopathy, and polyarthritis.[9] Frequently, the patient has forgotten about the encounter and is puzzled by the sudden appearance of symptoms. This reaction is believed to be immune complex mediated.

Unusual Reactions Infrequently, a reaction to Hymenoptera venom produces neurologic, cardiovascular, and urologic symptoms, with signs of encephalopathy, neuritis, vasculitis, and nephrosis. Guillain-Barré syndrome has been reported as a possible consequence of a Hymenoptera sting. Identification of the offending insect can be difficult, except for the honeybee, which predictably leaves its stinger with venom sac attached in the lesion. In general, definitive insect identification is unnecessary, because signs and symptoms of envenomation are similar for all species of Hymenoptera. If edema persists at the sting site, then consider secondary cellulitis. Severe local reactions on the foot or ankle can be misdiagnosed as gout if the insect sting is not visible.

General Treatment If the bee stinger is present in the wound, remove it. Although conventional teaching suggested scraping the stinger out to avoid squeezing remaining venom from the retained venom gland into the tissues, involuntary muscle contraction of the gland continues after evisceration, and the venom contents are quickly exhausted. Immediate removal is the important principle, and the method of removal is irrelevant. Wash the sting site thoroughly with soap and water to minimize infection. For local reactions, intermittent application of ice packs at the site diminishes swelling and delays the absorption of venom while limiting edema. Oral antihistamines and analgesics may limit discomfort and pruritus. Nonsteroidal anti-inflammatory drugs can be effective in relieving pain. Standard doses of opioid analgesics also can be administered. If edema is significant, elevation and rest of the affected limb should limit swelling unless secondary infection develops, in which case antibiotics are necessary. In local tissue reactions, there is often significant inflammatory erythema and swelling, which make it difficult to distinguish from infection. As a general rule, infection is uncommon. We recommend **hospital admission or observation for victims with >100 stings, for those with substantial comorbidities, and for those at extremes of age.**

Anaphylaxis Treatment Although the initial signs and symptoms of a systemic reaction may be mild, the victim's condition can deteriorate rapidly in a matter of minutes. Administer IM epinephrine, 0.3 to 0.5 milligram (0.3 to 0.5 mL of 1:1000 concentration) in adults and 0.01 milligram/kg in children (up to 0.3 milligram). Massage the injection site to hasten absorption. **To avoid mishaps in dosing, many EDs now stock adult and pediatric EpiPens, which provide a standard adult or pediatric dose (EpiPen, 0.3 milligram epinephrine; EpiPen-Jr, 0.15 milligram epinephrine for children <30 kg).** Provide aggressive fluid resuscitation with crystalloids. Antihistamines, histamine-2 receptor antagonists, and steroids are also commonly given. See chapter 14 for detailed discussion. Antivenoms have been studied for the treatment of mass bee attacks but are not yet commercially available.[10]

Long-Term Management and Preventive Care Results of skin tests and radioallergosorbent tests are not fully reliable for determining which patients are at risk for systemic reaction during future encounters with Hymenoptera (**Table 211-2**) but should be coupled with information from the clinical history.[8,11] Patients with negative test results may have been sensitized by the skin tests themselves. Every patient who has had a systemic reaction should be provided with an insect sting kit containing premeasured epinephrine and should be carefully instructed in its use. The physician should stress that the patient must inject the epinephrine at the first sign of a systemic reaction. Physicians should also advise their patients who are allergic to insects to wear identification (e.g., medical alert tags) describing their severe allergy. They should also be advised to follow up with an allergist.

ANTS

There are five known species of fire ants (*Solenopsis*) in the United States: the native species *Solenopsis aurea*, *Solenopsis geminata*, and *Solenopsis xyloni*, and at least two imported species, *Solenopsis invicta* and *Solenopsis*

TABLE 211-2 Long-Term Management for Patients with Reactions to Hymenoptera Stings

Type of Reaction	Risk of Systemic Reaction on Subsequent Stings	Perform Skin Testing?	Results of Skin Testing	Recommended Treatment
Never stung	Minimal	No		None
Local reaction				
Minor local reaction: immediate pain, swelling, and itching at sting site, resolves in 1 d	Minimal	No		None
Extensive local reaction: swelling develops 24–48 h after sting and resolves in 3–7 d	<10%	No		Epinephrine syringe
Systemic reaction				
Adult (urticaria, angioedema, anaphylaxis)	High	Yes	+	Venom immunotherapy plus epinephrine syringe
			–	Epinephrine syringe
Child (urticaria and mild angioedema)	Low	Yes	+	Venom immunotherapy or epinephrine syringe
			–	Epinephrine syringe
Child (anaphylaxis)	Moderate	Yes	+	Venom immunotherapy plus epinephrine syringe
			–	Epinephrine syringe

TABLE 211-3 Medically Important Spider Bites and Treatment

Spider	Bite Features	Complications	Treatment
Loxosceles: brown recluse spider, corner spider (worldwide distribution)	Painless bite, usually firm erythematous lesion that heals with little or no scar over days to weeks	Occasional hemorrhagic blister at 24 h; dermatonecrosis; systemic effects rare, mostly in in children, at 24–72 h	No validated treatments
Widow spider: black widow, redback, button spider (worldwide distribution);	Pinprick bite; pain can spread to entire extremity; target lesion 1–2 cm	Acetylcholine and norepinephrine release; muscle cramps extending to trunk, back, and abdomen; hypertension, tachycardia	*Latrodectus* antivenom, species specific; derived from horse serum; Fab antivenom available in Mexico
Armed spider: banana spider (Central and South America)	Intense pain at bite site	Severe pain, sympathetic and parasympathetic effects; priapism; vertigo, visual disturbances	Antivenom available in Brazil
Funnel-web spider (Australia)	Severe pain, with wheal and erythema at site; very rapid envenomation	Parasympathetic effects, muscle fasciculation; pulmonary edema; cerebral edema; death can occur within minutes	Compressive elastic bandage; funnel-web spider antivenom
Tarantula (worldwide)	Painful bite with local erythema and edema	Barbed hairs can penetrate cornea and conjunctivae; contact dermatitis from hairs	Ophthalmology consult for red eye and pain

richteri. These two imported species entered the United States through Mobile, Alabama, in the 1930s, have now become well established throughout the Gulf Coast states, and are spreading throughout the southwest.[12] Fire ants inhabit loose dirt and breed 9 to 10 months of the year. One mature nest can produce 200,000 ants during a 3-year period, which accounts for rapid spread. The venom of the fire ant is almost entirely an insoluble alkaloid. There is possible cross-reactivity between the venoms of fire ants and those of other Hymenoptera, and individual stings may produce systemic toxicity in sensitized individuals.

Fire ants are characterized by their tendency to swarm when provoked, and they may attack in great numbers. Fire ants in a swarm most often position themselves on their victim and sting simultaneously in response to an alarm pheromone released by one or several individuals. Immobilized or elderly patients can become rapidly covered by swarms, with multiple severe stings or death.[13] Each sting usually results in a papule that becomes a sterile pustule in 6 to 24 hours. Localized necrosis, scarring, and secondary infection can result. Rarely, a systemic reaction manifested by urticaria and angioedema can occur. Fatalities and other severe reactions have been reported to occur rapidly following single stings from ants, but most occur in patients with a history of prior venom allergy and prior cardiopulmonary disease, and injectable epinephrine was not given.[14,15] Rhabdomyolysis and renal failure have also been reported after massive fire ant stings.[16]

Estimated hypersensitivity to fire ant venom occurs in 16% of the general population, with some crossover with those sensitized to the stings of other Hymenoptera. Treatment of fire ant stings consists of local wound care.[13] In systemic reactions, treat for anaphylaxis. Desensitization may be necessary in patients exhibiting potentially life-threatening reactions to these arthropods. The wearing of socks or cotton tights seems to provide more protection from fire ant stings than the use of insect repellants.[17]

SPIDERS (ARANEAE)

Although nearly 40,000 species of spiders have been described worldwide, medically significant envenomations have been described in only a few dozen (**Table 211-3**). Spiders are carnivores, and venom probably evolved for paralyzing prey. The vast majority of spiders pose little harm to humans because their venom-injecting fangs are too small to penetrate human skin, the amount of venom injected is too little to produce toxicity, or the venom itself has little effect on mammalian cells. Even if a reaction is elicited, it is often local, and systemic toxicity is confined to a few specific species (Table 211-3 and **Figure 211-1**).

SPIDERS CAUSING NECROTIC ARACHNIDISM (*LOXOSCELES*)

Loxosceles are brown spiders that have a worldwide distribution. Native species exist in the United States (Figure 211-1), and of these, *Loxosceles reclusa* (the brown recluse spider) occupies the largest geographic area and accounts for the majority of significant envenomations. In South America, particularly Brazil, *Loxosceles laeta* and *Loxosceles intermedia* account for most significant envenomations. Envenomation outside of endemic areas is unusual.[18] *Loxosceles* spiders are nocturnal; are shy; are found both indoors and outdoors in dark, dry areas such as basements, closets, and woodpiles; and may bite when threatened. A pigmented, violin-shaped pattern on the cephalothorax of the brown recluse is often present (**Figure 211-2**). However, this characteristic is considered

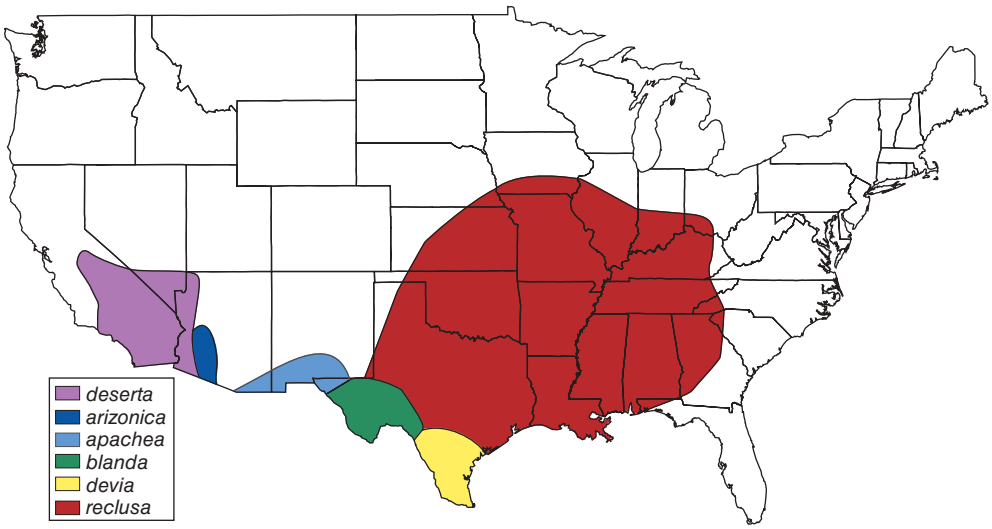

FIGURE 211-1. Range of recluse (genus *Loxosceles*) spiders in the United States.

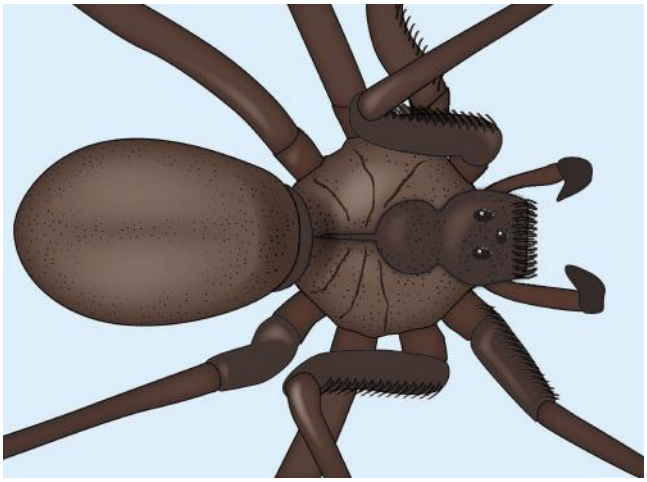

FIGURE 211-2. Close-up look at the characteristic fiddle-shaped back marking on the brown recluse spider (*Loxosceles reclusa*).

unreliable and often misinterpreted. *Loxosceles* species are most accurately identified by their eye pattern, which consists of six paired eyes (one anterior pair and two lateral pairs).[18] Most other U.S. spiders have eight eyes arranged in two rows of four. The venom of the brown recluse contains multiple enzymes, including hyaluronidase and sphingomyelinase D, which is the major enzyme responsible for necrosis. Significant necrotic wounds are rare but possible through neutrophil activation, platelet aggregation, and thrombosis. Although both local and systemic complications of *Loxosceles* envenomation have been well described, the perceived threat of the brown recluse far exceeds its actual danger. For more information about recluse spiders see http://spiders.ucr.edu.

Clinical Features Bites by *Loxosceles* spiders are described as initially painless, which often prohibits possible identification of the spider. The most common manifestation of a bite is a mild erythematous lesion that may become firm and heal with little or no scar within several days or weeks. Occasionally, a more severe local reaction occurs, beginning with mild to severe pain several hours after the bite, accompanied by localized erythema, pruritus, and swelling. A hemorrhagic blister then forms, surrounded by vasoconstriction-induced blanched skin (**Figure 211-3**). By day 3 or 4, the hemorrhagic area may become ecchymotic, which leads to the "red, white, and blue" (erythema, blanching, and ecchymosis) sign. The ecchymotic area may become necrotic, with eschar formation by the end of the first week. The necrotic, slowly healing ulcers may not reach maximum size for many weeks after envenomation and can occasionally result in a significant cosmetic defect requiring skin grafting.

FIGURE 211-3. Early brown recluse spider bite (approximately 8 hours old) with a violaceous center surrounded by a faint spreading erythema. [Photograph by Lawrence B. Stack, MD. Reproduced with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ: *The Atlas of Emergency Medicine*, 3rd ed, © 2009 by McGraw-Hill, Inc., New York.]

Although significant systemic effects are not uncommon after bites of *L. laeta*, the predominant South American species, they rarely occur after bites of the brown recluse, the predominant U.S. species. Systemic effects, the hallmark of which is hemolysis, are seen more often in children and typically occur 24 to 72 hours after the bite. Other effects include nausea, vomiting, fever, chills, arthralgias, thrombocytopenia, rhabdomyolysis, hemoglobinuria, and renal failure. Disseminated intravascular coagulation and death are extremely rare.

Correct diagnosis of a brown recluse envenomation without definitive spider identification is difficult. Although the presence of a consistent clinical picture in an endemic area is suggestive, it is likely that a myriad of infectious and noninfectious conditions are misdiagnosed as brown recluse bites.[18] In patients who are suspected of having been bitten and who exhibit signs and symptoms of envenomation, obtain a CBC, BUN and creatinine, and coagulation profile. Assays to detect envenomation have been used in research, but a commercial test is not currently available.

Treatment Treatment of a possible necrotic spider bite should include the usual supportive measures, including pain medication. Antibiotics are indicated if signs of infection exist. However, secondary infections are uncommon. Arrange follow-up for serial wound evaluation. If ulceration develops, surgical debridement is delayed until clear margins are established, often 2 to 3 weeks after the bite.

Patients with systemic symptoms following a bite warrant hospitalization. Various treatments have been advocated for brown recluse spider bites, including antihistamines, antivenom, colchicine, dapsone, hyperbaric oxygen, surgical excision, steroids, and topical nitroglycerin. None of these therapies have clear benefit, and most wounds from the brown recluse are self-limiting and heal without any medical intervention. Administration of the leukocyte inhibitor dapsone continues to be advocated by some despite lack of supporting research and known adverse effects, including hemolysis and methemoglobinemia. Early antivenom administration after envenomation is efficacious in animal models.[19] However, the delayed time in which patients typically present after envenomation, the current inability to definitively identify an envenomation, and the inability to prognosticate the development of dermatonecrosis, which in itself is rare, greatly limits its potential use.

An equine-derived antivenom is commonly used in Brazil; however, its efficacy is unclear. In the United States, there is no commercially available *Loxosceles* antivenom.

HOBO SPIDER (*ERATIGENA AGRESTIS;* FORMERLY *TEGENARIA AGRESTIS*)

A native of Europe and central Asia, the hobo or northwestern brown spider is now found in the Pacific Northwest of the United States and southern British Columbia. It is not aggressive.[20] Hobo spiders are brown with gray markings and have a 7- to 14-mm body length and a 27- to 45-mm leg span. They live in moist, dark areas such as woodpiles and basements.

Little documentation supports the occurrence of necrosis from hobo spider bites.[18] In its native European habitat, it is not considered poisonous to humans, and venom analysis comparing European to U.S. species has confirmed no unique differences. Confirmed bites have demonstrated localized erythema, itching, pain, and swelling.[20]

There is no diagnostic test for hobo spider envenomation, and there is no proven treatment.

WIDOW SPIDERS (*LATRODECTUS*)

Latrodectus or "widow" spiders have a worldwide distribution. In the United States, the black widow is the most well known, although of the five *Latrodectus* species found commonly in the United States, only three (*Latrodectus mactans*, *Latrodectus variolus*, and *Latrodectus hesperus*) are actually black. Other varieties may be predominantly brown (*Latrodectus geometricus*) or red (*Latrodectus bishopi*). An orange-red hourglass-shaped marking characterizes many of the *Latrodectus* species

FIGURE 211-4. Black widow spider (*Latrodectus mactans*) with offspring. Note characteristic hourglass marking on abdomen. [Photograph by Lawrence B. Stack, MD. Reproduced with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ: *The Atlas of Emergency Medicine*, 3rd ed, © 2009 by McGraw-Hill, Inc., New York.]

(**Figure 211-4**). Female spiders are relatively large, with a body size ranging up to 1.5 cm in length and leg spans of 4 to 5 cm. The male spider is approximately one-third the size of the female and lighter in color, and his bite cannot penetrate human skin. Black widow spiders are found most often in woodpiles, basements, garages, and sheds. *Latrodectus* will aggressively defend her web, particularly when guarding her eggs. Most black widow bites occur between April and October and are usually seen on the hands and forearms.

The black widow spider injures its victim and its prey with highly potent venom. The most active component of the venom is α-latrotoxin, which acts through both calcium-dependent and calcium-independent pathways leading to receptor stimulation, pore formation, and ultimately massive release of neurotransmitters (predominantly acetylcholine and norepinephrine).[21] Acetylcholine release accounts for neuromuscular manifestations, and norepinephrine release accounts for the cardiovascular manifestations.

Clinical Features Most *Latrodectus* bites are felt immediately as a pinprick sensation at the bite site, followed by increasing local pain that may spread quickly to include the entire bitten extremity. Erythema appears approximately 20 to 60 minutes after the bite. In many bites, a small, <5-mm erythematous macule develops that may evolve into a larger target lesion with a blanched center and surrounding erythema (**Figure 211-5**). The clinical syndrome is called *latrodectism*. Victims frequently complain of muscle cramp–like spasms in large muscle groups, although physical examination of the "cramping" extremity rarely reveals rigidity. The pain often increases progressively, becomes generalized, and can involve the trunk, back, and abdomen. Localized diaphoresis near the site of envenomation can be seen. Severe abdominal wall musculature pain and cramping are well described. Hypertension and tachycardia are common, and systemic symptoms include headache, nausea, vomiting, diaphoresis, photophobia, and dyspnea. Rarely reported complications include atrial fibrillation, myocarditis, priapism, and death. The pain with envenomation can be severe and intermittent and, if untreated, often lasts for a day. Occasionally, symptoms may persist for several days.

FIGURE 211-5. Black widow spider bite on the knee. [Photograph by Gerald O'Malley, DO. Reproduced with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ: *The Atlas of Emergency Medicine*, 3rd ed, © 2009 by McGraw-Hill, Inc., New York.]

Because an immediate pinprick sensation is usually reported with *Latrodectus* bites, it is common for the offending spider to be identified. In the absence of a witnessed bite, a clinical diagnosis can be made based on characteristic symptoms and signs. There is no confirmatory laboratory test.

Treatment Cleansing of the bite site is reasonable. Pain and muscle spasms can generally be controlled with liberal doses of opioids and benzodiazepines.[22] Although IV calcium has been advocated to relieve symptoms, a retrospective review of patients with *Latrodectus* envenomation indicated that this treatment is ineffective.[22] For severe envenomations, admission may be required for continued analgesia. The most effective therapies for severe envenomation are parenteral opioids and *Latrodectus* antivenom.

Administration of ***Latrodectus* antivenom** often causes rapid resolution of symptoms and can significantly shorten the course of illness. Even in severely symptomatic cases of *Latrodectus* envenomation, patients can often be discharged from the ED after a short observation period when antivenom is administered. Successful treatment of latrodectism with antivenom has been described even with administration 90 hours after envenomation.[23] Antivenin *Latrodectus mactans* is not contraindicated in pregnancy.[24]

Latrodectus antivenom is produced in at least three countries with specificity for indigenous species: Redback (*Latrodectus hasselti*) Spider Antivenom (CSL Ltd., Melbourne, Australia), Button Spider Antivenom (South African Vaccine Producers Institute, Edenvale, South Africa), and Antivenin *Latrodectus mactans* (Merck & Co., Inc., Whitehouse Station, NJ). It is likely that the antivenom to one species would be clinically effective in treating the bites of the others. Indications, amount, and route of administration vary according to product. Antivenin *Latrodectus mactans* and Button Spider Antivenom are administered IV, and Redback Spider Antivenom is typically administered by IM injection. An Australian-based study using Redback Spider Antivenom found minimal clinical difference between IV and IM routes.[25]

Latrodectus antivenom is derived from horse serum, and hypersensitivity reactions are possible. Redback antivenom is the most frequently used antivenom in Australia, and adverse reactions are rare. Until recently one death from anaphylaxis had been reported after administration of Antivenin *Latrodectus mactans* in the United States. Analysis attributed this to the antivenom being administered undiluted via IV push to an asthmatic patient with known allergies to multiple medications. Slow administration of diluted Antivenin *Latrodectus mactans* has generally been considered safe.[26] However, two additional cases of anaphylaxis to Antivenin *Latrodectus mactans* have been described despite dilution and slow administration.[27,28] In one of these cases, the anaphylaxis resulted in cardiac arrest, and despite successful resuscitation, the patient later died.[27] Such cases should be kept in mind, particularly because *latrodectism* itself is rarely life-threatening. A F(ab)2 antivenom [Antivenin Latrodectus Equine Immune F(ab)2 (Analatro)], expected to be less immunogenic and safer than whole-antibody products, is currently commercially available in Mexico. At the time of writing, it is not approved in the United States.[29]

ARMED SPIDERS (*PHONEUTRIA*)

The armed spiders are found throughout South America and Costa Rica. The majority of clinically important bites have been described in Brazil. The spiders are solitary, nocturnal, do not construct a web, and possess potent neurotoxic venom. They have been reported to hide in banana bunches during shipping and can bite workers handling these bananas at their destination. When threatened, they assume a characteristic aggressive position by raising their four front legs, displaying their fangs, bristling their leg spines, and moving position to continually face

their threat. The best-known armed spider, *Phoneutria nigriventer* (banana spider), is large, with a body size up to 3.5 cm and leg length up to 6 cm. *P. nigriventer* venom contains a mixture of potent neurotoxins that produce CNS, spinal cord, and autonomic effects.

Most *P. nigriventer* bites produce no significant symptoms. Significant envenomation produces local symptoms (severe pain) followed by sympathetic stimulation (tachycardia, hypertension), parasympathetic hyperactivity (nausea, vomiting, diaphoresis, salivation), spinal cord impairment (priapism), and CNS effects (vertigo, visual changes). Children and the elderly are at highest risk for serious envenomation. Pulmonary edema, shock, and death are rare.[30] Most healthy adults recover in 1 to 2 days.

In most cases, supportive care is adequate. Local anesthetic infiltration at the bite site can control pain. A polyvalent antivenom (Instituto Butantan, São Paulo, Brazil) is available for cases of severe envenomation from *P. nigriventer*.

FUNNEL-WEB SPIDERS (*ATRAX/HADRONYCHE*)

Funnel-web spiders are arguably the most deadly spiders in the world. Fortunately, they exist in a localized geographical location in eastern Australia, and no fatalities have been reported since the introduction of antivenom in 1981.[31] The spiders are so named because they construct a cylindrical web that extends into a recess, such as a burrow in the ground or a hole in a tree.

Funnel-web spiders have a shiny black body and long fangs, and females can grow up to 4 cm in body length. Females stay close to their webs, but the smaller and more aggressive males tend to wander, especially during the summer following a rain. *Atrax* venom contains a potent mixture of neurotoxins with neuromotor and autonomic effects.

Clinical Features *Atrax* bites may result in local reaction with immediate pain, followed by wheal formation and surrounding erythema. Later, localized sweating and piloerection may be observed. The vast majority of *Atrax* bites do not result in significant envenomation or systemic toxicity. The onset of severe envenomation is rapid and unlikely to begin after 2 hours.[31] Symptoms and signs of systemic toxicity include perioral paresthesias, parasympathetic hyperactivity (nausea, vomiting, diaphoresis, salivation, lacrimation, bronchorrhea), neuromuscular stimulation (muscle fasciculation, tremors, spasms, weakness), and CNS toxicity (altered level of consciousness). Death after *Atrax robustus* envenomation has been reported as a result of cardiac arrest, hypotension, or pulmonary failure occurring between 15 minutes and 3 days after a bite.

Treatment To reduce venom absorption and systemic toxicity from a bite on an extremity, apply a compressive elastic bandage to the entire length of the limb, and splint the extremity to prevent movement.[32] Immobilize the victim and transport promptly to the hospital.

The specific treatment for systemic toxicity is Funnel-Web Spider Antivenom (CSL Ltd., Melbourne, Australia). If the patient has signs of systemic toxicity upon arrival or develops them after the compressive elastic bandage is carefully removed, antivenom should be administered until symptoms improve. Supportive therapy for hypotension (IV fluid), bronchorrhea (atropine), tremors and agitation (benzodiazepines), and hypertension and tachycardia (β-blockers) may be necessary, but antivenom is the only therapy known to consistently improve survival.

TARANTULAS (THERAPHOSIDAE)

Tarantulas are large, hairy spiders belonging to the family Theraphosidae that are popular as pets. The hairs found on the abdomen of most species of tarantulas in North and South America resemble a velvety covering and are used defensively. When threatened, tarantulas may flick these hairs a short distance with their two back legs. Although North American tarantula hairs rarely penetrate human skin, the hairs can imbed deeply into the conjunctiva and cornea and can cause inflammation in all levels of the eye, from conjunctiva to retina. **Patients who manifest a red eye and pain after handling a tarantula should be examined to determine if offending barbed hairs are present in the cornea or conjunctiva.** Although hairs are sometimes easily seen on slit-lamp examination, they may at times be very difficult to detect. Therapy includes surgical removal of the hairs and topical application of steroids to control inflammation. Ophthalmia nodosa is a granulomatous, nodular reaction that can occur in cases of ocular exposure to tarantula hairs.[33] Patients may also develop a diffuse contact dermatitis from indirect exposure to hair while cleaning a tarantula cage. Bites from tarantulas are typically painful, with local erythema and edema, and some patients describe local joint stiffness following bites on nearby areas. Systemic symptoms other than fever are unusual.

OTHER SPIDERS

Yellow sac spiders (*Cheiracanthium*) are medium-sized, typically yellow spiders that have a worldwide distribution. A few species are commonly found in homes. The most common symptoms of a bite are local sharp pain. Minor erythema, swelling, and pruritus may occur at the bite site. Dermatonecrotic lesions are rare.[34]

Wolf spiders (*Lycosa*) are small- to medium-sized (3- to 5-mm body length) ground-dwelling spiders with a worldwide distribution. The venom produces local pain and occasionally induration and erythema, but no systemic symptoms and no skin necrosis.

Jumping spiders (family Salticidae) are typically small (<15 mm), brightly colored, and very active spiders with a worldwide distribution. A bite may produce pain, swelling, pruritus, and erythema with resolution in 2 days.

Daddy long-legs spiders (family Pholcidae) are common cellar and outbuilding dwellers along the Pacific coast and in southwestern deserts. There are no case reports of human envenomation.

SCORPIONS (SCORPIONIDAE)

Scorpions have a worldwide distribution, and highly toxic species are found in Africa, India, Mexico, North Africa, South America, the Middle East, and the Caribbean island of Trinidad. The toxins of the *Centruroides* and *Parabuthus* scorpions exhibit primarily neuromuscular effects, but toxins of the *Androctonus*, *Buthus*, and *Mesobuthus* scorpions exhibit cardiovascular effects.[35] Several species of scorpions are found in the warmer parts of the southern United States, but most species cause little more than localized pain. In the United States, only *Centruroides sculpturatus* (bark scorpion), found throughout Arizona, New Mexico, and parts of Texas and California, possesses venom potent enough to cause systemic toxicity.

CLINICAL FEATURES

Most stings cause localized pain at the bite site, and systemic toxicity occurs in <10% of stings. Scorpion venom contains many toxins, but the toxins with the most serious medical effects can open neuronal sodium channels and cause prolonged and excessive depolarization. Somatic and autonomic (parasympathetic and sympathetic) systems are affected (**Table 211-4**).[35] **Infants and young children are at highest risk for severe systemic symptoms**, which can be life threatening. Motor hyperactivity is nearly universal when symptoms are systemic and may present as restlessness or uncontrollable jerking of the extremities that appears to be seizure-like activity. Peripheral nervous system toxicity includes abnormal oculomotor function, loss of pharyngeal muscle control, uncoordinated neuromuscular activity with respiratory compromise, and tongue fasciculations. Hypersalivation is common and, combined with cranial nerve dysfunction, can threaten airway integrity. Cardiovascular toxicity from systemic envenomation includes tachycardia, hypertension, pulmonary edema, and cardiogenic shock.

DIAGNOSIS

Diagnosis is clinical. Laboratory studies are needed in severe envenomation to identify organ system involvement.

TREATMENT

Treatment is described in Table 211-4. Administer opioids for pain control and short-acting benzodiazepines for sedation as needed. In Latin

TABLE 211-4 Scorpion Bite Effects and Treatment

Clinical Effect	Pathophysiology	Treatment	Comments
Local effects only	Pain at bite site	Acetaminophen, nonsteroidal anti-inflammatory drug, local lidocaine without epinephrine at sting site	
Dermatonecrosis over hours or days	Local necrosis, in 20% systemic features, myoglobinuria; similar to *Loxosceles* spider envenomation		*Habromys lepturus* of Iran
Tachycardia, hypertension, mydriasis	Excess catecholamines	Antivenom*; prazosin	
Agitation and anxiety	Neuromuscular agitation	Benzodiazepines	
Pulmonary edema	Catecholamine-induced cardiac injury, myocardial depression; cardiogenic shock	Antivenom*; nitroglycerin or prazosin†; dobutamine† for cardiogenic shock	*Androctonus*, *Buthus*, *Mesobuthus*, and *Tityus* scorpions
Hypotension, bradycardia, salivation, sweating, abdominal pain, diarrhea, pancreatitis	Cholinergic effects	Atropine	*Tityus* species
Oculomotor abnormalities, uncoordinated neuromuscular activity, muscle spasms	Neuromuscular excitation	Antivenom*; benzodiazepines	*Centruroides* scorpions, also *Parabuthus* and *Tityus*
Multiorgan failure			Supportive care

*Role of antivenom not clear once systemic toxicity established, as antivenom binds toxin but does not reverse established injury.

†Role of vasodilators not clear; concern if using vasodilators with dobutamine.

America and India, the vasodilator prazosin is used to counteract the adrenergic surge that can lead to hypertension and resultant pulmonary edema. Envenomations in North Africa, on the other hand, are thought to develop pulmonary edema from systolic dysfunction, and the use of dobutamine may be helpful.[36] Scorpion antivenom directed against different species has been produced for research or clinical use in many other countries. Recommendations for use and dosing of these products vary widely. Like all animal-derived antivenom, both immediate and delayed allergic reactions, including serum sickness, are possible. A randomized, double-blind study from Arizona in children suffering from significant neurotoxic effects of *Centruroides* stings demonstrated that an intravenous scorpion-specific antibody resolved the clinical syndrome within 4 hours and significantly reduced the need for concomitant sedation.[37] The antivenom Anascorp® is a F(ab) equine preparation that is approved by the Food and Drug Administration in the United States but currently is quite expensive and should be restricted to patients with severe systemic symptoms.

CHIGGERS (TROMBICULIDAE)

Chigger infestations result from mite larvae feeding on host skin cells. Mites are found in almost every habitat and are 0.3 to 1.0 mm in length, and the larvae attach themselves to host skin with mandibular structures. They tend to attach in areas where an obstacle like tight-fitting clothing is met, such as at the tops of socks, the leg bands of underwear, the waistband, or the edges of a bra. Once attached, the larvae release digestive enzymes to liquefy epidermal cells. The combination of digestive enzymes secreted by the mite and subsequent host immune response produces the "chigger bite."

CLINICAL FEATURES

Although diseases such as rickettsialpox and scruff typhus have been spread by mite vectors, the major clinical manifestation of chigger infestation is most often intense pruritus. The attached chigger may be seen initially as a bright red fleck on the skin, and it, along with the larvae, may be easily scratched off. Lesions are intensely pruritic and often appear as grouped papules or papulovesicles. The localized allergic response may last for weeks, and significant excoriation may occur at the site from intense scratching.

The diagnosis of chigger infestation may be difficult, because many other arthropods cause similar clinical manifestations. The history of outdoor exposure combined with the presence of signs and symptoms localized to areas of snug-fitting clothing may be helpful.

TREATMENT

Treatment is primarily symptomatic to control the itching and consists of oral antihistamines and topical steroids. Oral steroids may be helpful in severe cases. Chiggers themselves may be killed with permethrin and other topical scabicides. If secondary infection occurs, antibiotics are indicated.

MOSQUITOS, FLIES, FLEAS, AND LICE (DIPTERA)

MOSQUITOES

Mosquitoes penetrate skin with the piercing motion of a bayonetlike proboscis. The actual puncturing of the skin surface causes minimal trauma and frequently is not felt by the host. A local anesthetic is injected into the wound that causes local tissue damage and local hypersensitivity. Bites can lead to both immediate and delayed reactions. An immediate skin reaction includes redness, a wheal, and itching. A delayed reaction can occur and usually consists of edema and pruritus. The immediate reaction tends to be of short duration, whereas a delayed reaction may persist for hours, days, and even weeks. Severe local reactions with skin necrosis are possible. Patients can acquire allergy to mosquito saliva constituents and develop symptoms consisting of an escalating reaction to seasonal exposures with increasingly pronounced edematous and pruritic lesions, sometimes accompanied by fever, malaise, generalized edema, severe nausea and vomiting, and necrosis with resulting scarring. Treatment is symptomatic with antihistamines and nonsteroidal anti-inflammatory drugs.

The greatest danger from mosquitoes is the transmission of disease. Even with extensive pest control programs, arbovirus infections and malaria are epidemic in many parts of the world. Chikungunya virus, dengue, Japanese B encephalitis, yellow fever, and various types of equine encephalitis are among the many viruses transmitted by mosquitoes. In addition, West Nile virus has recently spread west across North America. Malaria is also encountered frequently in patients in the United States after travel and in immigrant populations from areas where malaria is endemic. Insect repellents offer some protection from mosquito bites.

FLIES

Bloodsucking flies range in size from the tiny sand fly, approximately 1 to 3 mm in length, to horseflies, which can be >2 cm. All flies stab and pierce the skin, causing some degree of pain and pruritus. Several species, such as deerflies, blackflies, horseflies, and sand flies, can produce allergic reactions, although these are rarely as severe as those produced by Hymenoptera venom. There is also the possibility of myiasis (infestation of

tissue with fly larvae, i.e., botfly) from fly bites, but this condition is rare in the United States.

The diagnosis of fly bite depends chiefly on the patient's history and a knowledge of the arthropods that frequent the area of encounter. Treatment for most local reactions to Diptera bites is symptomatic, and treatment of systemic reactions is the same as for reactions to Hymenoptera venom. Application of cold compresses may alleviate localized edema. Secondary infection of Diptera bites can occur, and antibiotics may be necessary in some cases. Oral antihistamines may be helpful in relieving pruritus from fly bites, but topical steroids can be used when local reactions are severe, and oral steroids are indicated when systemic hypersensitivity symptoms are present.

FLEAS (SIPHONAPTERA)

Bites of fleas, lice, and scabies mites produce lesions so similar that diagnosis is often difficult. Flea bites are frequently found in zigzag lines, especially on the legs and in the waist area. The lesions most often have a hemorrhagic-appearing center surrounded by erythematous and urticarial patches. Flea bites are usually quite pruritic, and red spots can persist at bite sites for some time.

The main concern in the treatment of these bites is the possibility of secondary infection. Children may develop impetigo as a complication. The lesions should be washed thoroughly with soap and water. Children with flea bites should have their fingernails cut short to prevent scratching. To relieve discomfort and itching, local application of calamine, cool soaks, and oral or topical antihistamines may be helpful. For severe discomfort, application of a topical steroid cream or spray may be necessary. If secondary infection develops, topical or oral antibiotics may be needed.

KISSING BUGS AND BED BUGS (HEMIPTERA)

The order Hemiptera includes two blood-sucking families of arthropods with medical importance. These are Reduviidae (reduviids, or "kissing" bugs) and Cimicidae ("bed bugs" and their relatives). Various species of kissing bugs are found predominantly in the southern United States and Central and South America. The common name "kissing bugs" derives from their habit of feeding at night on any exposed surface of a sleeping victim, commonly the face. Bed bugs are also nocturnal feeders, and their distribution is worldwide. Recently, there has been a worldwide major resurgence in bed bug infestations, particularly in developed countries. This has been attributed to immigration, international travel, and insecticide resistance.[38] Both bugs are attracted to warm bodies and hide near beds. Bed bugs are found in nearby cracks and crevices. Kissing bugs of Central and South America are vectors of Chagas' disease (trypanosomiasis). Although transmission of many diseases to humans has been attributed to bed bugs, there is little evidence to support it. The transmission of hepatitis B does appear at least theoretically possible.[38]

Clinical Features Bites from both bugs are typically painless. Erythematous papules, bullae, and wheals may develop. A linear bite pattern on the skin is well described with bed bugs, and telltale brown or black patterns of excrement may be found on bed linen. A thorough search of bedding and nearby cracks and crevices will often reveal the bugs. Bed bugs are notoriously difficult to eradicate. One study demonstrated the potential for ivermectin (oral antiparasitic drug) administration to help eradicate those bed bugs that are feeding on the patient.[39]

Treatment Treatment of both types of bite is symptomatic. Cool compresses, topical steroids, and antihistamines can be used to relieve associated pruritus. Some individuals become highly sensitive to kissing bugs and react with systemic allergic symptoms following a bite. They should be treated as previously outlined for Hymenoptera envenomation.

CATERPILLARS AND MOTHS (LEPIDOPTERA)

Lepidopterism refers to the adverse effects resulting from contact with butterflies, moths, or their caterpillars. Caterpillars, the larval stage of moths and butterflies, are responsible for the vast majority of symptomatic exposures. For protection, they may have either hairs or spines that can be attached to venom glands. The spines and hairs may cause mechanical irritation, whereas the venom can produce additional symptoms. Although isolated exposures are most common, particularly in children who may be attracted to the colored or "furry" appearance of caterpillars, there are multiple species that under the right conditions can cause "epidemics" of cutaneous or systemic exposures. A couple of moth species, most notably the *Hylesia* genus in Venezuela (responsible for the "Caripito itch"), can cause local irritant or allergic reactions.

CLINICAL FEATURES

Most reactions to Lepidoptera are mild and self-limited. The vast majority of caterpillars are harmless to humans. Pruritus from localized "caterpillar dermatitis" and occasional diffuse urticaria are the predominant symptoms of exposures to the hairs and venom. The puss caterpillar (*Megalopyge opercularis*) is found in the southeastern United States and accounts for most of the serious envenomations in that country. After initial contact, intense local burning pain, rather than pruritus, is typical. A gridlike pattern of hemorrhagic papules may be seen within 2 to 3 hours of these exposures and may last for several days. Regional lymphadenopathy is common, and the affected limb can swell considerably. Other potential symptoms include headaches, fever, hypotension, and convulsions. No deaths have been reported. Ingestions of the hickory tussock caterpillar (*Lophocampa caryae*), found in the eastern United States, have been reported, with symptoms ranging from drooling to diffuse urticaria. Spines have been visualized in the oropharynx and even the esophagus in some of these patients, requiring endoscopy to aid in removal.[40] Two species of *Lonomia* caterpillars, found primarily in Brazil and Venezuela, are capable of causing potentially fatal coagulation defects.

TREATMENT

Treatment is symptomatic and supportive. Spines can be removed using adhesive tape. Antipruritic or topical anesthetic preparations, topical steroids, and oral antihistamines are typically used. For symptomatic ocular and oral exposures, removal of hairs may be necessary, and endoscopy has been described. Anaphylaxis is rare but would be treated in the typical manner. An antivenom specifically for *Lonomia obliqua* is available in Brazil to reverse coagulopathy.[41]

BLISTER BEETLES (COLEOPTERA)

Although the order Coleoptera includes a large number and variety of beetles, clinically significant envenomation occurs only from those that contain a vesicant (blister beetles). Blister beetles are found worldwide, including the United States. The most well-known blister beetle is the "Spanish fly" (*Cantharis vesicatoria*), found in Spain.

CLINICAL FEATURES

Blister beetles contain a highly potent vesicant (either cantharidin or pederin) that can be exuded or released if the beetle is brushed against, pressed, or crushed on the skin. **For this reason, a blister beetle should be removed from the skin by blowing or flicking.** Cantharidin-containing preparations are used medicinally in wart removal. Application of these substances in low concentration is without adverse effect.[42] However, higher concentrations or contact with the beetle's venom may cause local inflammation, leading to bullae formation. Severe conjunctivitis may also occur if cantharidin or pederin contacts the eyes from contaminated hands. The majority of described cases of blister beetle dermatosis are from seasonal outbreaks due to pederin-containing beetles.[43] At least one outbreak has been described in the United States. Topical exposure to blister beetles can cause a vesiculobullous eruption typical of a vesicant. Pederin-containing dermal exposures result in a more delayed (up to 36 to 72 hours) but more painful and symptomatic eruption than those from cantharidin-containing beetles. Due to the delay in onset of symptoms and signs, misdiagnosis is common. High concentrations of cantharidin preparations may result in dermal absorption and systemic toxicity. Systemic toxicity is well described following the ingestion, either of the whole beetle or of cantharidin-containing

preparations. Severe vomiting, hematemesis, abdominal pain, and diarrhea may occur, followed by dysuria, hematuria, oliguria, and renal failure. Although the exact mechanism by which cantharidin produces systemic toxicity is unknown, the vesicant action likely explains most of the findings. Direct cardiac toxicity with large ingestions of cantharidin is possible, and deaths have been reported. Fortunately, most preparations sold as "Spanish fly" for their purported aphrodisiac properties have very low concentrations of cantharidin. The local vascular congestion and urethral inflammation that occur following ingestion may be interpreted by some as enhanced sexuality.

TREATMENT

Treatment is supportive. The skin should be irrigated thoroughly after topical exposure to remove any persistent vesicant, followed by local wound care. Patients who are symptomatic after ingestion should be admitted and treated supportively.

CHAPTER 212

Reptile Bites

Richard C. Dart
Julian White

INTRODUCTION AND EPIDEMIOLOGY

An estimated 1.5 to 3 million bites and possibly greater than 100,000 deaths occur each year in the world from venomous snakes.[1] The American Association of Poison Control Centers reports an average of 6000 bites each year, approximately 2000 of them by venomous snakes. Because of underreporting, the true number of snakebites is possibly as high as 45,000 per year in the United States, with 7000 to 8000 by venomous snakes.[2] The major venomous snakes of the world can be divided into three groups: Viperidae (vipers and pit vipers), Elapidae (includes Hydrophiinae, or sea snakes; see chapter 213, titled "Marine Trauma and Envenomation"), and the diverse group of non–front-fanged colubrid snakes (former family Colubridae, now split into several families).

In the United States, most snakebites occur in the warm summer months, when snakes and victims are most active. In the past, it was estimated that mortality from venomous snakebite approached 25%. Because of the availability of antivenom and advances in emergency and critical care, mortality rates today are <0.5%; approximately five deaths occur per year.[3]

Except for bites by imported species, North American venomous snakebites involve the pit vipers (Crotalinae subfamily of Viperidae) or coral snakes (Elapidae family). The crotaline snakes are represented by the rattlesnakes (*Crotalus* species), pygmy rattlesnakes, and massasauga (*Sistrurus* species), as well as the copperheads and water moccasins (*Agkistrodon* species). Venomous snakebites from imported exotic species are infrequent but may occur in zoo personnel as well as in amateur herpetologists. A regional poison control center can provide information on snake identification, expected toxicity, and location of antivenom.

CROTALINAE (PIT VIPER) BITES

The crotaline snakes are called pit vipers because of bilateral depressions or pits located midway between and below the level of the eye and the nostril (**Figure 212-1**). The pit is a heat receptor that guides strikes at warm-blooded prey or predators. Crotaline snakes are also distinguished by the presence of two fangs that fold against the roof of the mouth, in contrast to the coral snakes, which have shorter, fixed, erect fangs. Within the pit viper group, the rattle distinguishes the rattlesnake from other crotaline snakes. The mistaken belief that rattlesnakes always rattle before striking has persisted for centuries. In truth, many strikes occur without a warning rattle.

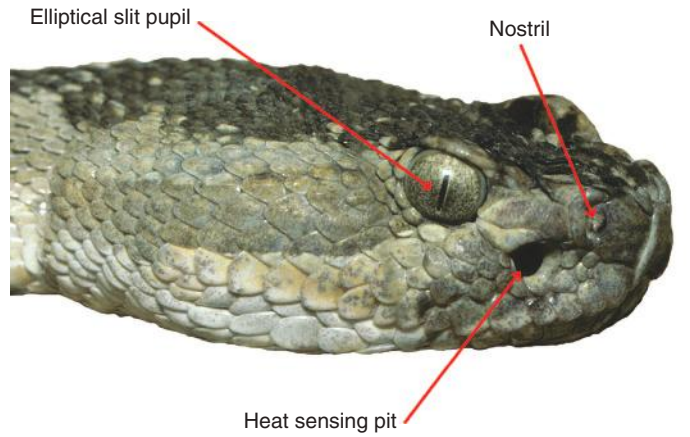

FIGURE 212-1. Pit viper.

PATHOPHYSIOLOGY

Crotaline venom is a complex enzyme mixture that causes local tissue injury, systemic vascular damage, hemolysis, fibrinolysis, and neuromuscular dysfunction, resulting in a combination of local and systemic effects. Crotaline venom quickly alters blood vessel permeability; this leads to loss of plasma and blood into the surrounding tissue, which causes hypovolemia. Crotaline venom activates and consumes fibrinogen and platelets, causing a coagulopathy. In some species, specific venom fractions block neuromuscular transmission, which leads to cranial nerve weakness (e.g., ptosis), respiratory failure, and altered sensorium.

CLINICAL FEATURES

Up to 25% of crotaline snakebites are dry bites: venom effects do not develop. The manifestations of crotaline envenomation involve a complex interaction of the venom and the victim. The species and size of the snake, the age and size of the victim, the time elapsed since the bite, and characteristics of the bite or bites (location, depth, and number; the amount of venom injected) all affect the clinical evolution. The severity of envenomation following a crotaline bite is therefore variable. An initially minimal bite may evolve into a more serious bite and require large amounts of antivenom.

The cardinal manifestations of crotaline envenomation are the presence of one or more fang marks, localized pain, and progressive edema extending from the bite site.[2] Other early symptoms and signs are nausea and vomiting, weakness, oral numbness or tingling of the tongue and mouth, dizziness, and muscle fasciculation. Systemic effects include tachypnea, tachycardia, hypotension, and altered level of consciousness. In general, local swelling at the bite site becomes apparent within 15 to 30 minutes, but in some cases, swelling may not start for several hours. In severe cases, edema can involve an entire limb within an hour. In less severe cases, edema may progress over 1 to 2 days. Edema near an airway or in a muscle compartment may threaten life or limb without causing systemic effects. Rapid onset of angioedema may occur.

Progressive ecchymosis may also develop because of leakage of blood into subcutaneous tissue. Ecchymoses may appear within minutes or hours, and hemorrhagic blebs may be seen within several hours. Hemoconcentration often develops as a result of fluid extravasation into subcutaneous tissue, followed by a decrease in hemoglobin level over several days as intravascular volume is restored.

DIAGNOSIS

The diagnosis of snakebite is based on the presence of fang marks and a history consistent with exposure to a snake (e.g., walking through a field). **Snake envenomation involves the presence of a snakebite plus evidence of tissue injury. Clinically, the injury may be manifest in three ways: local injury (swelling, pain, ecchymosis), hematologic abnormality (thrombocytopenia, elevated prothrombin time, hypofibrinogenemia), or systemic effects (e.g., oral swelling or paresthesias, metallic or rubbery taste in the mouth, hypotension, tachycardia).** Abnormalities in any one of these areas indicate that venom effect is developing. The absence of any of these manifestations for a period of 8 to 12 hours following the bite indicates a dry bite.

TREATMENT

FIRST AID

First aid measures should never substitute for definitive medical care or delay the administration of antivenom (**Table 212-1**). Take all patients bitten by a pit viper to a healthcare facility. **Avoid dangerous first aid treatments such as suction and incision.** Do not use Snake Bite Kit and similar products because they contain cups that produce little suction and seal poorly on digits. The blade in the kit, or any method of incision, can injure digital nerves, arteries, and tendons. The Sawyer Extractor (Sawyer Products, Inc., Safety Harbor, FL) suction pump is said to remove venom without incision, but safety and efficacy of the product are questioned.[4] Electric shock treatment of the bite site is dangerous and ineffective and can cause electrical injuries. Ice water immersion worsens the venom injury.

Do not use tourniquets because they obstruct arterial flow and cause ischemia. Constriction bands may be useful, especially when immediate medical care is not available. A constriction band is an elastic bandage or Penrose drain, thick rope, or piece of clothing wrapped circumferentially above the bite, applied with enough tension to restrict superficial venous and lymphatic flow while maintaining distal pulses and capillary filling. **Apply the band snugly but loose enough to avoid arterial compromise.** A constriction band can delay venom absorption without causing increased swelling.[5]

PREHOSPITAL MANAGEMENT

In the prehospital phase, immobilize the limb, establish IV access in another limb, administer oxygen, and transport the victim to a medical facility. Do not remove tourniquets or constricting bands until antivenom is available.

Institute advanced life support measures as indicated. If the patient is hypotensive, rapidly administer IV isotonic fluids. Continue to immobilize the limb in a neutral position during transport to reduce further venom absorption. Consult with a physician or poison control center familiar with the management of snake envenomation for most cases.

ED MANAGEMENT

Antivenom is the mainstay of therapy for venomous snakebites[2,6] (Table 212-2). Antivenom is composed of heterologous antibodies derived from the serum of animals immunized with the appropriate snake venoms. The antibodies bind and neutralize the venom molecules.

TABLE 212-1 Recommended First Aid Measures for Snakebite

Retreat well beyond striking range. Many victims are bitten again while trying to capture the snake.
Remain calm. Movement will increase venom absorption.
Immobilize the extremity in a neutral position below the level of the heart.
Ensure prompt transport to a medical facility whether or not there are signs of envenomation.
Constriction bands (see text) can be applied if there is no nearby medical facility.

TABLE 212-2 Clinical Features and Treatment of Reptile Envenomation

Reptile	Clinical Findings	Antivenom
Crotaline snake (pit viper)	Fang marks Local tissue injury Fibrinolysis Thrombocytopenia Systemic effects	Crotalidae Polyvalent Immune Fab
Coral snake	Neurologic dysfunction	Antivenom (*Micrurus fulvius*)
Elapid snake	Coagulopathy for some species Systemic effects, primarily neurologic dysfunction Cardiac arrhythmias and dysfunction Local injury for some species	Each species has monovalent or polyvalent antivenoms
Gila monster	Local pain and swelling Infections from retained teeth Systemic effects	No antivenom available

Crotalidae Polyvalent Immune Fab (Ovine) (FabAV) is used in the United States; equine-derived products (Antivenom [Crotalidae] Polyvalent; see below) are no longer available. FabAV is produced by immunizing herds of sheep with one of four crotaline snake venoms: eastern diamondback (*Crotalus adamanteus*), western diamondback (*Crotalus atrox*), Mojave (*Crotalus scutulatus*), or cottonmouth (*Agkistrodon piscivorus*). The immune serum is harvested from each group and then digested with papain to produce antibody fragments (Fab and Fc). The more immunogenic Fc portion of the antibody is eliminated during purification. The four individual monospecific Fab preparations are combined to form the final antivenom product.

Treat all patients with bites who develop progressive signs and symptoms with antivenom promptly. **Progression is defined as worsening of local injury (e.g., pain, ecchymosis, or swelling), abnormal results on laboratory tests (e.g., worsening platelet count, prolonged coagulation times, or decreased fibrinogen level), or systemic manifestations (e.g., unstable vital signs or abnormal mental status) (Table 212-3).**

Administer FabAV IV as a large "initial control" dose followed by three smaller maintenance doses (**Figure 212-2**). **Initial control is cessation of progression of three clinical evaluation parameters: local effects, systemic effects, and hematologic abnormalities.** The initial dose is four to six vials, which may be repeated to establish initial control of the envenomation. After initial control has been established, two-vial maintenance doses are recommended (Figure 212-2). After reconstitution, dilute each

*Should be performed as soon as possible and repeated within 12 h.

†Suggested for patients >50 y of age and patients with a history of heart disease.

‡Should be performed if any signs or symptoms of respiratory compromise are evident.

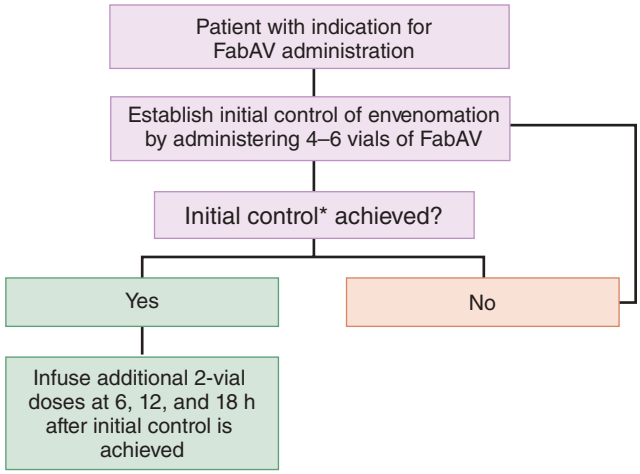

FIGURE 212-2. Administration of Crotalidae Polyvalent Immune Fab (Ovine) (FabAV). *Initial control is cessation of progression of all components of envenomation: local effects, systemic effects, and coagulopathy.

dose of FabAV in 250 mL of crystalloid and infuse over 1 hour. **The total volume, but not the number of vials, may be reduced in small children.**[7] **If IV access is unavailable, consider intraosseous administration.**

Do not inject antivenom directly into a digit, or IM, because venom-induced hypovolemia may retard absorption of antivenom. Hospital pharmacies in those regions of the United States where venomous snakes are prevalent should maintain adequate stocks of antivenom. Unfortunately, many hospitals stock insufficient amounts of antivenom, even in endemic areas.[8]

The package insert is useful as a guide for antivenom preparation. Give antivenom in a critical care facility such as an ED or intensive care unit, under direct physician supervision, and with resuscitative drugs and equipment immediately available (including epinephrine). The incidence of acute reactions to FabAV is <10%.[9] If an acute allergic reaction occurs, stop the infusion immediately and administer antihistamines (both histamine-1 and histamine-2 receptor blockers). Epinephrine should be readily available and administered for anaphylaxis.

Continue to observe for progression of edema and systemic signs of envenomation during and after antivenom infusion. Measure limb circumference at several sites above and below the bite, and outline the advancing border of edema with a pen every 30 minutes. These measures serve as an index of the progression as well as a guide for antivenom administration. Repeat laboratory determinations every 4 hours or after each course of antivenom therapy, whichever is more frequent. Additional doses of FabAV may be warranted if the patient's condition worsens. FabAV has been formally tested only in the treatment of rattlesnake bites. Initial case reports support its efficacy in treatment of copperhead snakebites.[10]

The value of aggressive supportive care cannot be overemphasized. Administer isotonic fluid resuscitation followed by vasopressor agents for hypotension. **Antivenom is the best treatment for hematologic abnormalities, but if active bleeding occurs, blood component replacement may be necessary.** Compartment syndrome is another complication of snakebite: increased compartment pressure may occur when venom is injected or spreads into a compartment. This is often manifested by severe pain, localized to a compartment and usually resistant to opiate analgesia. **Table 212-4** presents the suggested treatment of compartment syndrome.[11] The use of fasciotomy is controversial, and there is no firm evidence supporting its use.

Clean the bite wound and determine the need for tetanus immunization. Obtain wound specimens for culture and administer antibiotics if signs of infection are present. Although antibiotic prophylaxis is recommended by some authors, the data available do not support its use.[12] Steroids are not effective and could be harmful. Steroids should be reserved for the treatment of allergic reactions or serum sickness.

Serum sickness develops in about 5% of patients after FabAV treatment. The symptoms are fever, rash, and arthralgias. Start oral prednisone, 1 milligram/kg/d, and taper over 1 to 2 weeks.

TABLE 212-4 Management of Compartment Syndrome Caused by Crotalinae Snake Envenomation*†

Determine intracompartmental pressure.
If pressure is not elevated, continue standard management.
If signs of compartment syndrome are present and compartment pressure is >30 mm Hg:
Elevate limb.
Administer mannitol, 1–2 grams/kg IV over 30 min.
Simultaneously administer *additional* FabAV, 4–6 vials IV over 60 min.
If elevated compartment pressure persists another 60 min, consider fasciotomy.

Abbreviation: FabAV = Crotalidae Polyvalent Immune Fab (Ovine).

*Elevated compartment pressure is caused by the action of the venom on the tissues, and thus management of compartment syndrome due to snakebite is unique; therefore, the most effective treatment is to neutralize the venom, which may reduce the compartment pressure.

†The mannitol and antivenom deliver a high osmotic load, and fluids and electrolyte levels need careful monitoring. The administration of mannitol and antivenom must be completed promptly so that, if ever needed, fasciotomy may be performed as early as possible.

DISPOSITION AND FOLLOW-UP

It cannot be overemphasized that one can easily be deceived by a bite that initially appears innocuous. Unremarkable physical examination and laboratory test results at presentation do not reliably exclude significant envenomation. **Observe patients for at least 6 to 8 hours in the ED before determining disposition.**

Discharge patients with dry bites who have been observed for 6 to 8 hours with instructions to return if pain, swelling, or bleeding develop. Admit patients with severe or life-threatening bites and patients receiving antivenom to an intensive care unit; the general ward is appropriate for patients with mild or moderate envenomations who have completed or do not require further antivenom therapy.

Patients are ready for discharge from the hospital when swelling begins to resolve, coagulopathy has been reversed, and the patient is ambulatory. Physical therapy for the bitten part (particularly the hand) is recommended after swelling has lessened and coagulopathy has resolved. Outpatient follow-up is necessary to monitor for infection and serum sickness, and as with all antivenoms, the patient should be advised of the symptoms of serum sickness prior to discharge and advised to report if such symptoms develop.

ELAPID SNAKEBITE

U.S. CORAL SNAKEBITES

U.S. coral snakes include the eastern coral snake (*Micrurus fulvius fulvius*), the Texas coral snake (*Micrurus fulvius tenere*), and the Arizona (Sonoran) coral snake (*Micruroides euryxanthus*). The eastern coral snake is found primarily in the southeastern United States. The Texas and Arizona coral snakes are found primarily in the states that bear their names. Coral snakes account for 20 to 25 bites a year.

All coral snakes are brightly colored with black, red, and yellow rings. The red and yellow rings touch in coral snakes, but they are separated by black rings in nonvenomous snakes, which led to the well-known rhyme, **"Red on yellow, kill a fellow; red on black, venom lack." This rule is not always true outside of the United States.**

Coral snake venom is primarily composed of neurotoxic components that do not cause marked local injury (Table 212-2). Admit potential victims of coral snakebite to the hospital for observation, because venom effects may develop hours after a bite and are not easily reversed. Administer three to five vials of Antivenin (*Micrurus fulvius*) to patients who have definitely been bitten, because it may not be possible to prevent further effects or reverse effects once they develop.[13] Additional doses of coral snake antivenom are reserved for cases in which symptoms or signs of coral snake envenomation appear. Because respiratory failure may result from clinical effects of the neurotoxin, baseline and serial measurement of pulmonary function parameters (such as inspiratory pressure and vital

capacity), in addition to intensive care observation, may be useful. Prolonged ventilatory support may be required in severe cases. Observe the patient closely for signs of respiratory muscle weakness and hypoventilation. Bites by the Sonoran coral snake are mild, and antivenom is not usually needed.

ELAPID BITES WORLDWIDE

Elapids are found throughout the world in warm climates. Elapids occur in Australia, New Guinea, Asia, Africa, and the Americas. All sea snakes are elapids (subfamily Hydrophiinae). Medically significant groups include some venomous snakes of Australia (tiger snakes [*Notechis*], brown snakes [*Pseudonaja*], taipans [*Oxyuranus*], death adders [*Acanthophis*], "black" snakes [*Pseudechis*], copperheads [*Austrelaps*], rough scaled snake [*Tropidechis carinatus*], broad headed snakes [*Hoplocephalus*]), cobras (*Naja*), mambas (*Dendroaspis*), kraits (*Bungarus*), coral snakes (*Micrurus*), and a variety of less common genera/species.[14]

Elapid bites produce systemic effects, particularly neurologic effects: tremor, salivation, dysarthria, diplopia, bulbar paralysis with ptosis, fixed and constricted pupils, dysphagia, dyspnea, and seizure.[14] Some groups like the cobra species also produce pain and local injury and necrosis, which may be more clinically prominent than systemic effects.[14] The immediate cause of death is usually paralysis of respiratory muscles. Signs and symptoms may be delayed up to 12 or more hours.

PATHOPHYSIOLOGY

The Elapidae possess nonretractile small- to medium-sized paired fangs that have grooved, often enclosed venom channels rather than hollow venom ducts.[14] It is thought that the Elapidae exert voluntary control over the injection of venom, hence the frequent occurrence of a dry bite.

The venom of the Australian elapids contains several important components.[14,15] Neurotoxins (tiger snake, taipan, and death adder) act at the neuromuscular junction and cause descending symmetric flaccid paralysis. Signs usually develop within 2 to 12 hours after the bite and may include ptosis, partial ophthalmoplegia (diplopia), dysarthria, loss of facial expression, and loss of airway control, as well as respiratory paralysis in severe cases. The procoagulant toxins (brown snake, tiger snake, taipan) act as prothrombin converters, leading to a venom-induced consumptive coagulopathy with fibrinogen depletion and variable thrombocytopenia. Intracranial hemorrhage is a recognized complication.

The brown snake can cause rapid collapse and death.[15,16] Renal impairment or failure may also result from snakebite. The mechanisms are poorly understood and may include hypotension, myoglobinuria, coagulopathy, and direct renal toxicity.[14,15] Myolysins (tiger snake, taipan, mulga snake) are structurally related to the neurotoxins but instead produce rhabdomyolysis, which may result in muscle pain, weakness, myoglobinuria, renal failure, and hyperkalemia.[14,15] Rarely, a venom-induced thrombotic microangiopathy may complicate brown and tiger envenomation.[16-18] Local tissue destruction is uncommon with the bite of any Australian species, although mild to moderate ecchymosis and swelling may occur.[15]

CLINICAL FEATURES

The severity of elapid envenomation cannot be estimated by the clinical appearance of the bite site or initial symptoms.[14-17] Even with severe envenomation patients may initially feel well and manifest few clinical features. Initial symptoms include nausea, vomiting, headache, abdominal pain, diplopia, dysphonia, progressive muscle weakness, discolored urine, and seizures.[15] Young children may not provide a history of snakebite, so a high index of suspicion for elapid snakebite is needed if a child develops symptoms of toxicity in a region populated with elapids.[15]

DIAGNOSIS

The diagnosis requires correlation of history, clinical features of envenomation, and laboratory investigations. Laboratory tests often determine if the patient requires antivenom treatment.[14-17] Key tests include prothrombin time, INR, activated PTT, D-dimer, fibrinogen, fibrin degradation products, hemoglobin, platelet count, electrolytes, renal function test, and creatine kinase and should be performed prior to removal of first aid, 1 hour after removal of first aid, and at 6 hours and 12 hours after bite (earlier if abnormalities or clinical symptoms/signs develop).[15,19] Look for evidence of procoagulant coagulopathy (prolonged prothrombin time and activated PTT, high INR, raised D-dimer/fibrin degradation products, low fibrinogen), anticoagulant coagulopathy (abnormal prothrombin time, activated PTT, and INR, but normal fibrinogen, D-dimer/fibrin degradation products), platelet effects, rhabdomyolysis (grossly elevated creatine kinase, myoglobinuria), renal damage (abnormal renal function tests, reduced urine output), hyponatremia, and hemolytic-uremic syndrome–like syndrome (thrombocytopenia, anemia, intravascular hemolysis).[15] A Snake Venom Detection Kit (bioCSL, Parkville, Victoria, Australia) is available to identify snake venom identified at the bite site or in the urine, correlated to venom immunotype (which corresponds to "monovalent" antivenom type), for use exclusively with Australian and New Guinea snakes.[15] Positive Snake Venom Detection Kit identification of venom at the bite site or in the urine assists in selecting a "monovalent" antivenom, but does not represent an indication for antivenom therapy without other evidence of systemic venom effects.[15] World Health Organization guidelines on treating snakebite in Asia and Africa are a useful resource on diagnosis and treatment for these regions and are available online.[20,21]

TREATMENT

FIRST AID

In Australia and New Guinea, pressure bandaging and immobilization of the involved limb is used. The principle is to contain the venom locally and prevent venom transport by lymphatic vessels. Wrap an elastic bandage firmly over the bite site and then extend it to cover the entire limb (bandage pressure similar to that used for sprains: firm, but not tourniquet tight).[15] Splint the limb to prevent movement, an essential part of the method. Examination of lymphatic flow rates with simulated venom has demonstrated that, even if the upper or lower limb is appropriately bandaged and immobilized, walking will hasten systemic envenoming.[22] **Use of tourniquets is contraindicated.** In the rare circumstance that a bite is inflicted on the trunk, apply firm pressure to the affected area without restricting breathing.

Outside of Australia and New Guinea, the choice of first aid is more nuanced. If the bite is from an elapid that may cause local tissue damage or is from an unidentified snake, then pressure bandaging and immobilization may increase local tissue injury.[14] Omit the pressure bandage but splint the bitten part.

ED MANAGEMENT

Any history suggestive of snakebite should prompt appropriate first aid and transport to a medical facility with appropriate medical expertise, laboratory facilities, and antivenom supplies. Maintain pressure bandage immobilization (or immobilization only) until envenomation is excluded or until the patient can receive antivenom.[15] If the patient's condition deteriorates immediately after removal of first aid measures, reapply and give antivenom. Once antivenom is infusing, remove the pressure bandage so that antivenom can reach the envenomed area. There is no evidence that venom is inactivated by being trapped at the bite site.[15]

Antivenom should be given only in cases in which there is clear clinical or laboratory evidence of systemic envenomation. Clinical indications for immediate antivenom therapy include evidence of neurotoxic effects (ptosis, cranial nerve involvement, progressive muscle weakness, or diaphragmatic involvement), coagulopathy, rhabdomyolysis, renal failure, cardiac collapse, significant local tissue injury, or vomiting unresponsive to antiemetics.[14,15] In the absence of clinical or laboratory evidence of systemic envenomation, remove the first aid measures and observe the patient for at least

12 hours, longer for some species.[15,19] Repeat laboratory tests 1 hour after removing the first aid measures and at intervals thereafter dictated by the patient's condition.

For Australian elapid snakebites, there is only one producer (CSL Ltd, Melbourne, Australia), producing five "monovalent" antivenoms corresponding to the five venom immunotypes, a polyvalent antivenom that covers all of the five venom immunotypes, plus a sea snake antivenom that is effective for all sea snake species globally.[14,15] The initial dose of antivenom is controversial, but simply following the product instructions is prudent. Similarly, the initial dose of antivenom for non-Australian snakes should be based on manufacturer recommendations. For patients presenting with severe envenomation, higher initial doses may be warranted. Always administer antivenom IV. **If IV access is unavailable, consider intraosseous administration.** IM administration is strongly discouraged due to slow absorption and potential complications of anticoagulation. Dilute antivenom about 1:10 in normal saline (lower dilution in small children or cardiac-compromised adults), then commence the infusion slowly, looking for evidence of adverse reaction (rash, wheeze, hypotension, angioedema); gradually increase the rate to give the entire dose over 20 to 30 minutes (longer if high volume antivenom).[14,15] Give the same dose to children as adults. Skin testing before antivenom administration is not recommended,[14,15] and equipment for treatment of anaphylaxis should be at the bedside. Hypersensitivity is an uncommon complication of antivenom therapy in Australia.[23-25] Elsewhere, antivenoms may have high rates of adverse reactions. A 5-day course of prednisolone may be prescribed to reduce the incidence of serum sickness, but clear evidence of efficacy is lacking.[15]

Antivenom cannot reverse some venom effects, such as established presynaptic neurotoxic paralysis, renal failure, and rhabdomyolysis. It is therefore important to give antivenom as soon as indicated. If this is not possible, support respiration and renal function as clinically required. Advanced flaccid paralysis usually requires protection of airway and respiratory support for periods of days to months.

When indicated, give monovalent or polyvalent antivenom immediately in sufficient doses to improve coagulation values. Pregnancy is not a contraindication to antivenom therapy.

GILA MONSTER BITES

Gila monsters are slow-moving lizards that inhabit the desert in the southwestern United States. They possess venom as potent as rattlesnake venom but lack the apparatus to inject it effectively. Instead of fangs, they have short, grooved teeth down which their venom flows. Therefore, envenomation requires a prolonged bite. Gila monsters bite tenaciously and may be difficult to remove from the bitten extremity, so fractures and deep injury are possible.

There are few if any documented deaths from Gila monster bite. Most bites result in local pain and swelling only, which worsens over several hours and then subsides over several more hours. Dislodged teeth often contaminate the wound. Occasionally, a more severe syndrome of systemic toxicity develops, including weakness, light-headedness, paresthesia, and diaphoresis. Severe hypertension may occur, which also resolves over several hours.

First aid involves removal of the reptile from the bite site without sustaining another bite. This may require force. It helps to place the animal on a solid surface, because it often loosens its grip when it is no longer suspended in midair. Once the animal is removed, standard local wound care is sufficient, with care taken to remove any teeth in the wound. Radiographs should be considered if bony injury is possible. Update tetanus immunization status and give antibiotics if infection develops.

CHAPTER 213

Marine Trauma and Envenomation

John J. Devlin
Kevin Knoop

MARINE TRAUMA

Human contact with the marine environment is becoming more frequent as recreational and commercial use of the world's oceans increases. In addition to the hazards of drowning and cold exposure, the marine environment provides the habitat for dangerous marine fauna. Many marine animals have evolved sharp teeth and spines or venom glands for defense and predation. Encounters with marine life may result in traumatic injury or envenomation, requiring emergency medical management. Providing care for these conditions may be further complicated by the marine environment's geographic isolation from locations with definitive health care.

EPIDEMIOLOGY

Epidemiologic information typically is organized by geographic region. The most common reported U.S exposures are to jellyfish (31%), stingrays (16%), venomous fish (including lionfish, catfish, and others) (28%), and gastropods (6%).[1] However, data likely favor the reporting of more severe injuries and the exclusion of common minor injuries. Human impact may be altering the geographic distribution of marine fauna as climate change affects migration patterns and artificial waterways connect previously separated bodies of water and their ecosystems.[2,3]

The International Shark Attack File recorded 2074 unprovoked shark attacks between 1960 and 2013, with the United States reporting the most attacks of any country and Florida reporting the most attacks of any state.[4] Despite the public perception, the risk of shark attack is extremely small compared with almost any other injury. There are probably between 70 and 100 shark attacks worldwide each year, with between 5 and 15 deaths.[4,5] Although the incidence of shark attacks has steadily risen since 1900, the mortality has fallen from 40% in the 30 years following World War II to current rates of approximately 10% to 20%.[6] Death is usually a result of a lack of prehospital resuscitation, hemorrhagic shock, or drowning.

Other marine creatures have been reported to attack humans, typically in defense of territory rather than for feeding. The great barracuda (*Sphyraena barracuda*) is the only barracuda species implicated in human attacks.[6] Moray eels, found in tropical to temperate waters, can inflict severe puncture wounds or lacerations, commonly to the hands of inquisitive divers. Other marine vertebrates known to cause traumatic injuries to humans include giant groupers, sea lions, seals, crocodiles, alligators, and piranhas. Some fish with sharp spines and fins (needlefish, wahoo, and triggerfish) can inadvertently injure humans. Wounds resulting from interactions with such creatures are a combination of crush injury, abrasion, puncture, and/or laceration.

BACTERIOLOGY OF MARINE SOFT TISSUE INFECTIONS

Marine soft tissue infections are often polymicrobial, halophilic gram-negative infections that may be resistant to first- and second-generation penicillins and cephalosporins.[7] Infecting bacteria are numerous and can vary with the environment, type of injury, and marine organism. Bacteria include staphylococci, streptococci, *Aeromonas hydrophilia*, *Escherichia coli*, *Pseudomonas* species, *Erysipelothrix* species, *Chromobacterium*, *Edwardsiella*, *Shewanella*, *Mycobacterium* species, *Mycoplasma* species, and *Vibrio* species.[8-10] Culture results can refine antibiotic treatment. Marine-associated infections are frequently diagnosed late because the history of marine exposure or injury is poorly recalled, and patients are often initially given inappropriate antibiotics, which potentially increases

the morbidity of an already virulent infection. Patients with underlying conditions such as liver disease, immunosuppression, and diabetes are more susceptible to halophilic *Vibrio* infections.[11] *Vibrio* skin infections can progress rapidly from initial contact and local painful inflammation, through subepidermal bullae containing hemorrhagic fluid and vasculitis, to necrosis and small-vessel thrombosis, bacteremia, and septicemia.[8,11]

MAJOR MARINE TRAUMA

Encounters with sharks, skates, stingrays, barracuda, Moray eels, and giant grouper can result in major trauma. Of these animal-related injuries, shark bites are the best characterized.[12,13] Shark attacks can result in neurovascular injury and significant tissue loss. Sharks typically attack the appendages (be they seals or humans), which tend to dangle lower than the head and torso while the victim is swimming on the surface. In 70% of surface swimmers, only the lower limb is involved. The upper limb can be subsequently injured when the victim tries to fend off the attacker. Sharks are unable to chew their prey and so sequentially strip it.[5] In more serious attacks, substantial tissue loss and extremity amputation are common.

Stingrays possess spined tails that reflexively whip upward when stepped on or startled. These encounters typically result in foot and ankle injuries. However, serious thoracoabdominal injuries have been reported, such as the sensationalized 2006 death of naturalist Steve Irwin. Morbidity and mortality result from penetrating trauma to internal organs.[14-16] Rarely, spine tips are retained in stingray wounds.

Victims of marine animal–associated trauma should be removed sufficiently from the water to allow immediate resuscitation. As in military settings, place a tourniquet on limbs with evidence of uncontrolled arterial hemorrhage, because the survival benefit after tourniquet placement outweighs the low risk of neurologic injury from compression.[17] At the hospital, manage injuries according to institutional trauma protocols.[12]

However, there are two caveats for marine injuries. First, teeth and spines may be retained in bone and soft tissue and be a source of infection. Obtain plain radiographs of all injured regions to identify fractures, periosteal stripping, and retained foreign bodies. If radiographs are unremarkable but there is still a high clinical suspicion for a retained foreign body, US may be helpful. US may be particularly helpful in identifying radiolucent fragments of sea urchin spines and stingray barbs.[18,19] Second, the mouths and integument of marine fauna can be heavily colonized with marine bacteria. Wounds should be swabbed and specimens sent for culture. Many marine microorganisms require special selective media for culture and sensitivity testing, so alert the microbiology laboratory that a marine-acquired organism might be present. Infections from marine microorganisms can be more serious than usual soft tissue infections. Irrigate open wounds and debride devitalized tissue. **Do not suture lacerations or puncture wounds sustained in marine environments. Provide early antibiotic treatment** for wounds from major trauma, in those at risk for infection, in the immunocompromised or those with hepatic disease, and for established infection (**Tables 213-1 and 213-2**).[8,9,11,20,21] Provide postexposure tetanus prophylaxis.[22] Obtain early surgical consultation for thorough debridement for suspected *Vibrio vulnificus* infections or any necrotizing infection. Regardless of the antibiotic choice, close clinical follow-up is essential to identify treatment failures early.

MINOR MARINE TRAUMA

Most marine injuries and stings do not cause serious injury. Treatment depends on the agent and the seriousness of injury (Table 213-2). Coral cuts are probably the most common injuries sustained underwater and usually involve the hands, forearms, elbows, and knees (**Figure 213-1**). The initial reaction to a coral cut is stinging pain, erythema, and pruritus. Within minutes, the break in the skin may be surrounded by an erythematous wheal, which fades over 1 to 2 hours. With or without treatment, the local reaction of red, raised welts and local pruritus may progress to cellulitis with ulceration and tissue sloughing. The wounds heal slowly over 3 to 6 weeks.

TABLE 213-1 Recommendations for Antibiotic Treatment of Marine-Associated Wounds

No Antibiotic Indicated	Prophylactic/Outpatient Antibiotics	Hospital Admission for IV Antibiotics
Healthy patient	Late wound care	Predisposing medical conditions
Prompt wound care	Large lacerations or injuries	Long delays before definitive wound care
No foreign body	Early or local inflammation	Deep wounds, significant trauma
No bone or joint involvement		Wounds with retained foreign bodies
Small or superficial injuries		Progressive inflamatory change Penetration of periosteum, joint space, or body cavity Major injuries associated with envenomation Systemic illness

Promptly and vigorously irrigate cuts to remove all foreign matter. Fragments that remain can become embedded and increase the risk of infection or foreign-body granuloma. Clean superficial wounds daily. Give antibiotics if infection develops (Tables 213-1 and 213-2).

MARINE ENVENOMATIONS

Venomous marine animals produce venom in specialized glands. The venom can then be applied to or injected parenterally into other organisms using a specialized venom apparatus. Venom is not a pure substance but a mixture of mainly protein and peptide toxins. The effect of a specific toxin depends on its site of action; it may be neurotoxic, hemotoxic, dermatotoxic, cytotoxic, or myotoxic. Unlike thermostable ingestible seafood poisons, marine venoms are typically high-molecular-weight, heat-labile proteins.[23]

STINGRAYS AND VENOMOUS FISH

STINGRAYS

All stingrays' tails house venomous spines.[15] Inflicted lacerations allow the injection of venom. Stingray injuries cause immediate intense local pain that may radiate and last for many hours. There is often significant bleeding depending on the site of injury, and the wound may be erythematous or dusky. Systemic effects are uncommon but have been reported and relate more to the systemic response to severe pain. Submerging the affected extremity in **hot water between 110°F (43.3°C) and 114°F (45.6°C)** can denature the venom protein and provide pain

TABLE 213-2 Antibiotics for Marine-Associated Wound Infections*

For All: Staphylococci and Streptococci Coverage	Seawater Associated: *Vibrio* Species Coverage	Freshwater Associated: *Aeromonas* Species Coverage
First-generation cephalosporin	Fluoroquinolone	Fluoroquinolone
or	*or*	*or*
Methicillin-resistant *Staphylococcus aureus* coverage depending on prevalence	Third-generation cephalosporin	Trimethoprim-sulfamethoxazole
		or
		Carbapenems

*The choice of antibiotic is not clear-cut, and there are no robust evidence-based treatment guidelines. Antibiotic sensitivities vary, and there is considerable discrepancy between the in vitro antibiotic susceptibility data and clinical outcomes. Antibiotic choices should reflect the frequent polymicrobial nature of marine infections.

FIGURE 213-1. These injuries occurred when the swimmer was thrown up against coral by wave action. Coral wounds should be evaluated for retained foreign body. [Photo contributed by Kaitlin Pala, MD.]

FIGURE 213-2. Significant edema and erythema of the right hand after stonefish sting to the thumb. [Photo contributed by Anthony Morocco, MD.]

relief within 10 to 30 minutes.[24,25] Topical lidocaine can be applied for additional pain relief.

VENOMOUS FISH STINGS

Venomous fish are found in tropical and, less commonly, temperate oceans and private aquariums. The important venomous fish include stonefish, weeverfish, scorpionfish, and lionfish. The effects of the stings range from severe with stonefish to minimal with some types of catfish and other fish with nonvenomous spines.[16,26]

Stonefish (*Synanceia* species) and scorpionfish (Scorpaenidae) occur throughout tropical and warmer temperate oceans from the central Pacific, west through the Indo-Pacific, to the East African coastline. They are a diverse group of fish, with differing habitats, swimming patterns, and ability to camouflage.[16,26] The venom apparatus varies among species but most have 5 to 15 dorsal spines. Stonefish are stationary bottom dwellers usually frequenting shallow water.

Clinical effects are characterized by immediate severe and increasing local pain, which may radiate proximally. Untreated, the pain typically peaks at 30 to 90 minutes and persists for 4 to 6 hours, but this varies considerably for different fish. The wound site usually has significant local edema and erythema (**Figure 213-2**). Nonspecific systemic effects such as sweating, nausea, vomiting, and even syncope may occur. Extensive tissue necrosis is not seen unless a secondary infection develops.

Weeverfish (or weaverfish) are all saltwater fish and are the most venomous fish in the temperate zone. They are found in the Mediterranean and European coastal areas and are bottom dwellers that sting when stepped on. Their five to seven envenoming dorsal spines can penetrate leather boots, producing pain severity similar to stonefish injuries. Wounds may eventually necrose.

TREATMENT OF VENOMOUS FISH AND STINGRAY INJURIES

Irrigate the wound immediately, and remove any visible pieces of the spine or integumentary sheath. Control bleeding and immerse in hot water immersion as soon as possible (**Table 213-3**). During the hot water soak, the wound can be explored and foreign material removed. Provide oral or parenteral analgesics as needed. The wound can also be infiltrated with lidocaine **without epinephrine,** or a regional nerve block can be applied to help control pain.

Once pain is controlled, cleanse the wound using an aseptic technique, reexplore and remove foreign material, and debride necrotic tissue. Obtain soft tissue imaging when possible, to visualize retained foreign material.

The conclusions of the few study series involving venomous fish stings and the experience of aquarium workers are that most injuries are minor and do not require antibiotics.[26] Although some authors routinely recommend antibiotic prophylaxis, the majority do not unless the wound is large or there is considerable foreign material. This situation is more likely with stingray wounds, which have the greatest potential to cause necrosis and infection. Prevention of infection by careful cleaning of the wound and debridement, if required, is more important. An **antivenom exists for stonefish envenomation** (CSL Ltd., Melbourne, Australia) and should be used in cases of severe systemic reactions to stonefish and possibly other venomous fish.[27,28] Although it is registered for IM and IV administration, IV is more likely to be effective, based on experience with other antivenoms. The antivenom is prepared from horse serum, so be prepared to treat anaphylaxis.

SEA SNAKES

There are numerous species of sea snakes that are closely related to terrestrial elapids, all of which are venomous. They occur in the tropical and warm temperate Pacific and Indian Oceans. None are found in the

TABLE 213-3 Early Treatment of Marine Envenomations

Organism	Detoxification	Further Treatment
Penetrating Envenomations		
Catfish, lionfish, scorpionfish, stingray	Hot water immersion*, topical lidocaine	Usual wound care†; irrigate with seawater or normal saline (NS) Observe for development of systemic symptoms **Carefully assess for deep penetration from stingray spines**
Stonefish, weeverfish	Hot water immersion*, topical lidocaine	Usual wound care†; irrigate with seawater or NS **Stonefish antivenom** for severe systemic reaction (CSL Ltd., Melbourne, Australia); be prepared to treat anaphylaxis
Sea snake	—	Pressure immobilization **Polyvalent sea snake antivenom** (CSL Ltd., Melbourne, Australia) for systemic reaction; be prepared to treat anaphylaxis Supportive care; observe for 8 h for myotoxicity and neurotoxicity; may need intensive care unit (ICU) care
Blue-ringed octopus	—	Pressure immobilization; flaccid paralysis and respiratory failure can develop in minutes. Provide respiratory support and ICU care
Cone snail	—	Pressure immobilization; observe for paralysis and respiratory failure; supportive care
Sea urchin and starfish	Hot water immersion*, topical lidocaine	Explore wound and remove any spines, tufts, or pincers
Fireworms	Topical 5% acetic acid (vinegar)	Consider topical corticosteroids Remove bristles
Nonpenetrating Envenomations		
Fire coral, hydroids	Irrigate with seawater or saline	Topical corticosteroids for itching
Portuguese man-of-war, bluebottle jellyfish	Hot water immersion*, seawater irrigation, topical lidocaine Remove tentacles and nematocysts	Topical corticosteroids for itching Observe for development of systemic symptoms Supportive care
Box jellyfish (Indo-Pacific *Chironex* species and Australian *Carukia* species)	Hot water immersion* Irrigate with saline or seawater Topical 5% acetic acid (vinegar)‡ Remove tentacles and nematocysts Topical lidocaine	Topical corticosteroids for itching Observe for development of systemic symptoms Supportive care
Irukandji syndrome (Australian, *Carukia* species)	Irrigate with saline or seawater Hot water immersion* Remove tentacles and nematocysts	Administer ***Chironex* antivenom**; be prepared for anaphylaxis Magnesium for cardiac arrest Parenteral opioids for pain

*Hot water immersion = 111°F (43.3°C) to 114°F (45.6°C) water until pain is relieved.
†Usual wound care = Irrigate, explore, debride, consider antibiotics and analgesics, update tetanus immunization, elevate extremity.
‡Controversial; depends on species.

Atlantic Ocean, the Caribbean, or North American coastal waters, except Hawaii. Probably the most important species medically is the beaked sea snake (*Enhydrina schistosa*), which has caused fatalities in Southeast Asia.

Sea snakes can be distinguished from land snakes by their flat tails and valve-like nostril flaps and from eels by the presence of scales and the absence of gills and fins. The venom apparatus consists of two to four short, hollow maxillary fangs, and a pair of associated venom glands. About 20% of bites cause significant envenomation, and up to 40% of these are potentially fatal without treatment. The venom of sea snakes contains neurotoxins and myotoxins; one tends to dominate the clinical features. However, there are no toxins that affect coagulation.

Bites are typically painless and may go unnoticed. Symptoms typically become apparent 30 minutes to 4 hours after the bite. The first complaint is usually related to myotoxicity, with severe myalgia and nonspecific muscle weakness. Other symptoms include nausea, vomiting, and malaise. The muscle pain may become so severe that movement is limited, which is typified by trismus that develops in the jaw. Immobility secondary to pain should be distinguished from weakness or paralysis caused by neurotoxicity. Rhabdomyolysis and secondary renal failure develop in more severe cases, which may be complicated by hyperkalemia. In some sea snake envenomations, neurotoxicity has been reported without myotoxicity, with ascending flaccid or spastic paralysis accompanied by ophthalmoplegia, ptosis, facial paralysis, and pupillary changes. Death is most commonly a result of respiratory failure.

Diagnosis of a sea snake bite is based on the combination of snake identification and the presence of a puncture bite wound that was initially painless and occurred in or near the water. Suspect envenomation if severe myalgia develops. The presence of myoglobinuria and an elevated creatine kinase level is also typical, indicating rhabdomyolysis. Neurotoxic symptoms are rapid in onset and usually appear within 2 to 3 hours. If no symptoms develop by 6 to 8 hours, envenomation is unlikely to have occurred.

First aid treatment is pressure immobilization of the affected limb.[29] Elastic bandages are preferred.[30] Administer **polyvalent sea snake antivenom (CSL Ltd., Melbourne, Australia)** for systemic envenomation.[28] The antivenom is made from horse serum, so be prepared to treat anaphylaxis. Intensive supportive care and monitoring of renal, metabolic, and respiratory functions are critical.

OCTOPUS INJURIES

Injuries from the octopus or squid are unusual. All octopuses have venom, but the only dangerous octopus is the blue-ringed octopus. The venom tetrodotoxin, introduced by a bite, causes respiratory arrest within minutes. Treatment is supportive. Pressure immobilization at the bite area is the recommended first-aid treatment.

The bite of the Australian blue-ringed octopus (*Hapalochlaena* species) has caused at least two deaths. The saliva of the octopus contains

tetrodotoxin and produces effects clinically identical to those of tetrodotoxin poisoning seen most commonly with puffer fish ingestion.[31,32] Octopus bites typically occur on the upper extremity, almost always when the animal is picked up (**Figure 213-3**). The bite causes small, painless puncture marks and many go unnoticed. In most cases, no symptoms develop or only mild local numbness and paresthesia occur. In more severe envenomations, vomiting and progressive flaccid paralysis with eventual respiratory failure may begin within 10 minutes of envenomation.[33] Wrap the limb with a lymphatic occlusive bandage to provide pressure immobilization until definitive care is reached. Treatment is supportive, with mechanical ventilation as required, and full recovery usual occurs over 1 to 5 days. No antivenom or antidote is available.

CONE SNAIL INJURIES

Cone snails have intricate shell patterns, making them attractive to handle. Cone snails are predators that feed by injecting a potent mixture of neurotoxins using detachable, dart-like radicular teeth. Stings by cone snails are very rare. Most stings occur after prolonged contact with the shell or when breaking the shell. With significant envenomation, local pain is followed immediately by local numbness, which quickly spreads from the extremity to the trunk and then to the head and neck region. Partial paralysis develops within 30 minutes, progressing to complete voluntary muscle paralysis and respiratory failure. Mortality following *Conus geographus* envenomation may be as high as 65%.[34] Less severe envenomations cause muscle pain, partial paralysis, or ataxia, or in mild cases only local effects. Treatment is pressure immobilization with a lymphatic-occlusive bandage until definitive care is reached.

SEA URCHINS AND STARFISH

Sea urchins are found in all oceans, and most sea urchins have solid nontoxic spines. Injury from the spines causes localized pain, which is exacerbated by pressure, even if there are no retained spines in the wound[35] (**Figure 213-4**). If a spine enters a joint, it may cause severe synovitis. Wounds from black sea urchin spines may leave a black discoloration of the skin. Contact with the venomous spines causes immediate, intense burning pain, with erythema, swelling, and often bleeding of the skin surrounding the puncture sites. The acute pain usually subsides over hours. Secondary infection and granuloma formation from remaining spine fragments are well-described delayed effects. Systemic features have been reported rarely, often when multiple spines are involved, but may be due to severe pain.

Some starfish have surface spines, tufts, or pincers. The crown-of-thorns starfish (*Acanthaster planci*) can be found on most reefs in the Indo-Pacific region and has caused outbreaks of envenomation in Japan and Australia.[1] Crown-of-thorn starfish are covered with sharp, rigid spines that can passively deliver a variety of substances when they penetrate skin. This includes venom produced in special glandular tissue, mucus, bacteria, and dermal tissue. Injury by the spines causes severe burning pain, often greater than expected for the mechanical injury, and lasts 1 to 2 hours. Other local effects include bleeding, erythema, and mild edema. In more severe cases, particularly with multiple punctures, the wound may become dusky or discolored. Pruritus and persisting edema can occur, perhaps as a result of allergy. Systemic effects are uncommon but may include paresthesias, nausea, vomiting, lymphadenopathy, and muscular paralysis.[1,6]

Treatment is immediate immersion in hot water to tolerance (45°C [113°F]) for 30 to 90 minutes or until pain is relieved. Topical or locally injected lidocaine can provide additional pain relief. Give analgesics. Remove retained spines or tufts as well as possible, without causing more tissue injury. Soft tissue radiographs, US, or MRI may be helpful in locating retained spines. US may be particularly helpful in identifying radiolucent fragments of sea urchin spines.[19] Arrange follow-up, because further surgical removal of spines may be required if there are ongoing symptoms. Spines in joints require immediate orthopedic consultation.

FIREWORMS OR BRISTLEWORMS

Fireworms, or bristleworms, are segmented worms covered with cactus-like bristles that can penetrate the skin. These bristles easily detach in the skin and can be difficult to remove. Envenomation causes intense inflammation with a burning sensation and erythema. Untreated, the pain generally resolves within a few hours, but erythema may last for 2 to 3 days. Bristles should be removed with forceps or adhesive tape. Vinegar (5%) may be applied topically. The inflammatory response may require a course of corticosteroids.

HYDROIDS AND FIRE CORAL

Hydroids are colonies of tiny jellies attached to a feather-like or seaweed-like base. They are abundant on seaweed, reefs, pilings, floating docks, or lines. Coastal storms can break off feather hydroid branches and cause infestation of a local swimming area. Fire corals look like corals, are often mistaken for seaweed, and are small brush-like growths on rocks and coral itself. Contact with nematocysts or stinging threads results in an immediate sting after even a superficial brush contact, followed by itching pain, associated with the development of painful wheals and urticaria after 30 minutes. The welts may last for up to a week but leave no permanent mark. With more extensive exposure, blistering and a hemorrhagic and zosteriform reaction can occur. Lesions crust over after a few days. Vinegar can inhibit nematocyst discharge. Pain relief can be provided with analgesics. Treat itching with topical steroids.

JELLYFISH

There are many types of jellyfish, but the most important groups affecting humans are the Portuguese man-of-war or bluebottle jellyfish, the box jellyfish, and those jellyfish causing Irukandji syndrome.

Jellyfish are characterized by their unique stinging nematocysts[34] (**Figure 213-5**), which number in the thousands and are found mainly on the tentacles, but also in lesser numbers on the body or bell. The nematocyst contains a minute dose of venom, in some cases highly potent, and a harpoon-like mechanism. A physical or chemical stimulus triggers the rapid release of a hollow, sharply pointed, threadlike tube from the nematocyst, which penetrates the skin and delivers venom subcutaneously. There are a number of genera causing local and systemic reactions, off the coasts of Russia, Japan, Brazil , Uruguay, and Argentina—all with similar toxic effects.

The clinical features of jellyfish envenomation vary in severity. The severity depends on the venom dose, the marine species, and the victim (age and size). Mild envenomation results in bothersome acute skin reactions, with immediate stinging pain and erythema or wheal formation at the site. Lesions usually resolve spontaneously over days to a couple of weeks, with occasional postinflammatory hyperpigmentation.

Treatment of jellyfish stings is not well studied, and results are often conflicting. A treatment helpful for one species may worsen effects from another species. Irrigation with seawater to remove nematocysts and hot water immersion and application of topical lidocaine appear to be the most universally beneficial treatments. Other applications, such as sodium bicarbonate or vinegar, may worsen stinging from some species.

PORTUGUESE MAN-OF-WAR AND BLUEBOTTLE JELLYFISH

This group of jellyfish (*Physalia* species) has a large gas-filled float, which suspends multiple tentacles. The nematocysts are found on the tentacles but not on the float. *Physalia* species are the most widely distributed jellyfish and are responsible for thousands of human envenomations in Florida, parts of Asia and Africa, Australia, and Western Europe.[1,2,36] All species occur in swarms in shallow water and usually cause stings in the surf or are washed up on the shore. Nematocysts from fractured tentacles may remain active for months.

The Portuguese man-of-war is a multitentacled jellyfish common in the Atlantic, with tentacles that can be as long as 30 m. The bluebottle jellyfish is smaller and single-tentacled and found commonly in Australia and Hawaii.

Stings from *Physalia* species cause immediate, intense pain that often fades over an hour but may persist for many hours, particularly with larger specimens. The sting causes a characteristic linear erythematous eruption, classically referred to as a "string of pearls" pattern.[35] Respiratory distress and death have been reported following *Physalia* envenomation, and delayed effects have been reported in rare instances.[36,37]

Treatment is to first wash the area with seawater and then immerse in hot water, as the venom is heat labile. In general, vinegar is not recommended for *Physalia* stings. Remove tentacles and nematocysts by scraping the skin with a sharp object (e.g., razor or credit card) or by applying adhesive tape.[38] If adhesive tape is used, the adherent nematocysts can later be identified.

There is no specific antidote for *Physalia* envenomation, and care is supportive.

BOX JELLYFISH AND IRUKANDJI SYNDROME

The box jellyfish is the most dangerous jellyfish and includes two important members: the Indo-Pacific box jellyfish (*Chironex fleckeri*) and the

FIGURE 213-6. Box jellyfish sting. This 24-year-old woman was snorkeling off of Koh Tao, Thailand, when she was stung by a box jellyfish 15 minutes prior to this photograph being taken. She presented with severe extremity pain and chest tightness. [Photo contributed by Sittidet Toonpirom, MD, and Rittirak Othong, MD.]

Australian jellyfish (*Carukia barnesi)* that causes **Irukandji syndrome**.[39,40] Box jellyfish are also found in the Philippines, Japan, and the U.S. Atlantic coast. The Hawaiian box jellyfish (*Carybdea alata*) causes numerous stings to beachgoers in Hawaii, although no deaths have been confirmed from this organism.[41]

The Indo-Pacific box jellyfish (*Chironex*) has been described as the world's most venomous animal.[42] It has caused over 80 deaths in the past century.[43] The exact mechanism of toxicity and toxins involved in death—which occurs rapidly, often within 20 minutes—remains unclear, but a primary cardiotoxic role is likely.[42] Severe reactions or death can occur following skin contact with tentacles, especially in children.[39,44] However, the vast majority of stings are mild to moderate, consisting of skin welts and immediate, sometimes severe pain.[39] The toxic skin reaction may be quite intense, with rapid formation of wheals, vesicles, and a darkened reddish brown or purple whip-like flare pattern with stripes 8 to 10 mm wide. With more severe stings, blistering occurs, and superficial necrosis develops after 12 to 18 hours. Severe box jellyfish stings cause a pathognomonic crosshatched pattern, classically referred to as a "frosted ladder" pattern (**Figure 213-6**). Following the acute toxic reaction, a delayed hypersensitivity reaction occurs in approximately 60% of cases, with papular urticaria at the sting sites.[39,45]

The Australian jellyfish (*C. barnesi)* causes the **Irukandji syndrome**.[40] The sting initially causes mild local effects with localized pain and erythema. Approximately 20 to 30 minutes later, severe generalized pain in the abdomen, back, chest, head, and limbs develops. The pain is usually associated with systemic signs of catecholamine excess, including tachycardia, hypertension, sweating, piloerection, and agitation. In severe cases, cardiogenic shock with pulmonary edema and serum troponin elevation occur.[40,44]

Treatment **Treatment** consists of deactivation of attached nematocysts, tentacle removal, reversal of venom effects if possible, and symptomatic and pain relief. All victims with systemic signs or symptoms should be observed for ongoing envenomation or delayed reactions (Table 213-3).

Irrigate with seawater or normal saline to deactivate undischarged nematocysts. After deactivation, visible tentacles can be removed. Do not irrigate with freshwater because the hypotonic solution is thought to stimulate nematocyst discharge. Best methods for removal are scraping the skin with a sharp object (e.g., razor or credit card) or application of adhesive tape.[38] If adhesive tape is used, the adherent nematocysts can later be identified. Treat with hot water immersion (111°F [43.3°C] to 114°F [45.6°C]) and apply topical lidocaine.[46]

Effective topical decontaminants appear to be species specific.[46,47] Because the species is often unknown, the geographic location of the envenomation guides decontamination. In Indo-Pacific waters, **particularly those surrounding Australia,** nematocyst deactivation therapy with 5% acetic acid (vinegar) is recommended,[43,48] and 5% acetic acid is the first-line management recommendation by the Australian Resuscitation Council.[43,49]

Treatment for severe *Chironex* envenomation (Irukandji syndrome) consists of standard resuscitative measures and administration of sheep-derived antivenom specific for *C. fleckeri* (CSL Ltd., Melbourne, Australia).[39] Be prepared to treat anaphylaxis. Fatalities despite antivenom administration may be related to the rapidity of onset of cardiovascular collapse after *Chironex* envenomation.[27] Therefore, antivenom should be administered IV as early as possible. The initial dose may be repeated if there is no clinical response, and some clinicians recommend three or more doses in severe envenomations associated with cardiovascular collapse.[44] Magnesium improves outcome in animal studies and should be considered in refractory cases of severe *Chironex* envenomation with cardiac arrest.[40,45]

Severe generalized pain in Irukandji syndrome requires titrated IV opioid analgesia, often with large and repeat doses. Magnesium bolus and infusion have been used for treatment of the pain and hypertension associated with Irukandji syndrome.[45,50] However, adverse effects due to hypermagnesemia have been reported, and the treatment has not been as effective as originally suggested.[50] All patients should have an ECG and troponin testing on admission, and echocardiography is useful in patients with myocardial involvement. Pulmonary edema should be managed with oxygen supplementation, positive-pressure ventilation, and inotropes

In waters surrounding the United States, application of 5% acetic acid solutions to tentacles from *Chrysaora* species appear to increase nematocyst discharge.[51,52] For *Chrysaora* or *Cyanea*, a slurry of baking soda (sodium bicarbonate) is thought to be effective. Traditionally, acetic acid solutions were thought to deactivate North American *Physalia* species nematocysts.[52] However, one review of North American and Hawaiian jellyfish envenomation management has questioned the use of acetic acid, concluding that "vinegar may not be an ideal agent because it causes pain exacerbation," but may be considered in *Physalia* species envenomations, whereas "hot water and lidocaine appear more universally beneficial in improving pain symptoms and are preferentially recommended."[46] The venoms are heat labile, and heat reduces toxicity in most jellyfish envenomations.[36,41,47]

MARINE DERMATITIS

SPONGES

Thousands of sponge species exist, but few are medically important. A number of sponges produce toxic secretions (crinotoxin—slimes or surface liquids), including fire sponges (*Tedania* species) and *Neofibularia* species in Australia, which cause skin irritation and dermatitis referred to as *stinging sponge dermatitis*.[53] Minor effects from sponges are likely due to simple mechanical irritation by the spicules. There is often no initial sensation following contact, but after a few minutes to hours, an itching or burning sensation develops. The stinging or itching sensation usually increases in intensity over 2 to 3 days and may become almost unbearable. The effects are usually confined to the area of contact or just adjacent to it. There may be associated local joint stiffness, and an acute inflammatory reaction with erythema and edema develops when symptoms are severe. Untreated mild reactions subside over 3 to 7 days. Papules, vesicles, and bullae may develop in some cases, followed by desquamation of the area days to weeks later, which is most commonly reported with fire sponges.[53] Treatment is irrigation, analgesia, and topical corticosteroids for itching or inflammation.[53]

SEABATHER'S ERUPTION

Seabather's eruption is a vesicular or morbilliform pruritic allergic dermatitis resulting from contact with larvae of the sea anemone or jellyfish

in Atlantic ocean areas. Dermatitis typically occurs within 24 hours after saltwater exposure, and involves skin surfaces covered by bathing suits, swim caps, or fins. Divers may be affected on the neck when floating in water churned by boat propellers that have ground floating jellyfish into fragments. Dermatitis persists for 2 to 14 days and resolves spontaneously. If contact is suspected, shower after removing the bathing or diving suit.

SEA CUCUMBERS

Direct contact with sea cucumbers may induce a contact dermatitis, which is usually mild. Immerse the extremity in hot water. The greatest risk is to the corneas and conjunctivae, which may become intensely inflamed. For ocular exposure, irrigate copiously with normal saline or fresh water.

CHAPTER 214

Diving Disorders

Brian Snyder
Tom Neuman

INTRODUCTION

Millions of recreational, commercial, and scientific dives are logged annually, and the vast majority of dives are completed without incident. However, there are physiologic effects and injuries relatively unique to the underwater environment. Generally, these effects and injuries are secondary to pressure changes on the submerged human body and the breathing of compressed gas.[1] This chapter outlines the most common diving injuries: barotrauma of descent (otic, sinus, and pulmonary), barotrauma of ascent (pulmonary overinflation syndromes and arterial gas embolism), decompression sickness, immersion pulmonary edema, oxygen toxicity, and nitrogen narcosis.

THE GAS LAWS

Understanding diving injuries requires familiarity with the three relevant gas laws most pertinent to diving: Boyle's law, Dalton's law, and Henry's law.

Boyle's law states that given a constant temperature, the pressure and volume of an ideal gas are inversely related. That is, if pressure is doubled, the volume of gas is halved. This law is stated as: $P_1V_1 = P_2V_2$.

Pressure can be measured in a variety of units. The International System of Units defines pressure using the pascal (Pa). Other commonly used units of pressure include millimeters of mercury (mm Hg), torr, pounds per square inch (psi), bar, or atmosphere (atm): 1 atm = 760 mm Hg = 760 torr = 14.7 psi = 1.013 bar = 101,325 Pa = 101.325 kPa. Additionally, pressure in diving settings is often described using feet of seawater (fsw) or meters of seawater (see below). In this chapter, we use atm, mm Hg, and fsw for pressure units.

Because of the high density of water, a relatively small change in depth causes a great change in pressure. The weight of seawater produces a change of 1 atm for each 33 ft of depth. For freshwater, pressure increases 1 atm for each 34 ft of depth. Therefore, the pressure exerted on a diver at a depth of 33 ft in seawater = 1 atm for the seawater + 1 atm for the atmosphere above the water = 2 atmospheres absolute (ATA). A diver at 165 ft of seawater would experience 6 ATA of pressure (1 atm for each 33 ft of seawater = 5 atm + 1 atm for atmospheric pressure at sea level).

Thus, **Boyle's law** dictates as a diver descends in the water column, the volume of air-containing structures will decrease. For example, if the lungs contain volume V at the surface, a diver who descends to 33 ft of seawater holding his or her breath would have a lung volume of $^1/_2V$. If the diver then breathes compressed air at this depth (from scuba equipment or from a surface-supplied source of gas), lung volume would return to V. If the diver then ascends to the surface without exhaling, lung volume would be $2V$ at the surface. This pressure–volume relationship governed by Boyle's law is important in the etiology of injuries due to barotrauma and produces the volume changes of bubbles in the tissues and circulation that are associated with recompression (hyperbaric) therapy.

Dalton's law states that the total pressure exerted by a mixture of gases is the sum of the partial pressures of each gas. Therefore, the partial pressure of a given component of a gas mixture will increase as the ambient pressure increases, although the proportion of gas in the mixture remains constant. The partial pressure of nitrogen in air at sea level is approximately 600 mm Hg or 0.79 ATA (the fraction of nitrogen in air, 0.79 × 760 mm Hg or 1 ATA). At a depth of 99 fsw, the partial pressure of nitrogen in air would be 4 × 600 = 2400 mm Hg (or 3.16 ATA).

Henry's law, which states that at equilibrium the quantity of a gas in solution in a liquid is proportional to the partial pressure of the gas, along with Dalton's law, explains the uptake of inert gas into tissues when breathing compressed air at depth. It is the uptake of inert gas that is intrinsic to the development of decompression sickness.

BAROTRAUMA OF DESCENT

The clinical conditions resulting from barotrauma of descent are barotitis (ear squeeze), external ear squeeze, sinus barotrauma, inner ear barotrauma, and face, tooth, or dry-suit squeeze (**Table 214-1**).

PATHOPHYSIOLOGY

During descent, the volume of gas in all air-containing body cavities decreases. The air space in the middle ear makes the tympanic membrane the tissue most commonly affected by this phenomenon, if active measures such as "clearing the ears" with a Valsalva or other maneuvers are not successful.[2] As the volume of gas decreases, the tympanic membrane is bent inward, causing a feeling of fullness or pain in the ear. Forcing air through the Eustachian tube with a Valsalva maneuver will equalize the pressure between the middle ear and external ear canal by filling the middle ear with additional gas. Generally, divers who experience pain in an ear during descent will attempt to clear the ear and, if unsuccessful, will ascend to decrease the pressure differential and attempt equalizing again. If the diver is unsuccessful in equalizing and continues the descent, prolonged pain and injury to the tympanic membrane may result, known as barotitis or "ear squeeze."

BAROTITIS (EAR SQUEEZE)

Barotitis can range from symptoms of pain or fullness without otoscopic changes, to hemorrhage within the tympanic membrane or hemorrhage into the middle ear with hemotympanum. Ultimately, the tympanic membrane may rupture, resulting in relief of the pain but also possibly causing an influx of water into the middle ear. This, in turn, might cause calorically induced vertigo and potential panic, drowning, or other injury.

Barotitis is treated conservatively with analgesics and decongestants. If tympanic membrane rupture occurs, antibiotics can be prescribed, especially if the diving occurred in contaminated water. Divers with perforated tympanic membranes should refrain from diving until the perforation heals. Most such perforations heal without difficulty, but referral to an otolaryngologist is appropriate for individuals with larger perforations or when healing does not occur. Divers with barotitis without perforation

TABLE 214-1 Summary of Barotrauma of Descent and Ascent

Barotrauma	Clinical Features	Treatment
Barotrauma of descent		
Otic barotrauma ("ear squeeze")	Pain, fullness, vertigo, conductive hearing loss from inability to equalize middle ear pressure	Decongestants, consider antibiotics
Sinus barotrauma ("sinus squeeze")	Pain over affected sinus, possible bleeding from nares	Decongestants, consider antibiotics
Inner ear barotrauma	Sudden onset of sensorineural hearing loss, tinnitus, severe vertigo after forced Valsalva	Head of bed up, no nose blowing, antivertigo medications, and urgent otolaryngology consultation as some surgeons advocate early exploration
Barotrauma of ascent		
Pulmonary overinflation syndromes (pulmonary barotrauma)	Dyspnea, chest pain, subcutaneous air, extra-alveolar air on radiograph; usually occurring secondary to rapid or uncontrolled ascent	Pneumomediastinum requires only symptomatic care and does not require recompression Pneumothorax requires drainage and does not require recompression (if recompression is instituted for treatment of arterial gas embolism, then the pneumothorax must be drained before recompression)
Arterial gas embolism	Neurologic symptoms occurring immediately after uncontrolled or rapid ascent or neurologic symptoms in the setting of pulmonary barotrauma	Airway, breathing, circulation, high-flow oxygen, IV hydration, immediate recompression (hyperbaric oxygen), consider adjunctive lidocaine Any neurologic symptom in the setting of documented pulmonary barotrauma must be treated as an arterial gas embolism

should refrain from diving until the diver is again able to equalize the pressure in the affected middle ear.

EXTERNAL EAR SQUEEZE

If the external canal is occluded by cerumen or an ear plug, the inability to equalize pressure between the external canal and the tympanic membrane causes the bending of the tympanic membrane outward, producing an injury called "external ear squeeze" that produces pain and tympanic membrane hemorrhage.

SINUS BAROTRAUMA

If the ostia to the sinuses are occluded, air cannot enter the sinuses during descent to equalize the increasing pressure. This causes pain and mucosal edema and can lead to submucosal hemorrhage and stripping of the sinus mucosa from bone, hemorrhage (often causing bleeding from the nose into the mask), and, rarely, paresthesias in the infraorbital nerve distribution. A similar traumatic neuropathy can occur to the facial nerve with middle ear barotrauma. Sinus barotrauma is treated with conservative measures, including decongestants and, possibly, antibiotics.

INNER EAR BAROTRAUMA

The inner ear is also susceptible to barotrauma, occasionally causing significant, long-term damage. If a diver attempts a forceful Valsalva maneuver to equalize the middle ear against an occluded Eustachian tube, the pressure differential between the cerebrospinal fluid, transmitted through the vestibular and cochlear structures and the middle ear air space, can cause rupture of the oval or round window, fistulization of the window, tearing of the vestibular membrane, or a combination of such injuries. Additionally, if the diver is able to open the Eustachian tube in this situation, a rapid increase in middle ear pressure may occur. This pressure wave is transmitted to the inner ear and can also cause a similar injury. Divers with inner ear barotrauma will generally present with unilateral roaring tinnitus, sensorineural hearing loss, and profound vertigo. A "fistula test" may be positive—that is, insufflation of the tympanic membrane on the affected side causes the eyes to deviate to the contralateral side. Because this injury usually occurs on descent and divers will provide a history of difficulty clearing the ears, this condition can usually be easily differentiated from other causes of vertigo, such as inner ear decompression sickness, cerebral arterial gas embolism, or alternobaric vertigo (discussed below).

Immediate complications of inner ear barotrauma are potential panic or disorientation, leading to possible drowning or a rapid ascent that predisposes the diver to pulmonary barotrauma. Divers with barotraumatic injuries to the inner ear require urgent otolaryngologic evaluation. Treatment is controversial, with some authors advocating immediate exploration and others suggesting a trial of bed rest (head upright), medications to control vertigo, and mechanical measures to reduce cerebrospinal fluid pressure spikes (e.g., stool softeners, no nose blowing). These authors reserve exploration for patients whose symptoms do not respond to conservative therapy or patients with severe hearing defects or significant abnormalities on an oculo-nystagmogram. Divers with potential inner ear barotrauma who will be treated with hyperbaric oxygen for decompression sickness or cerebral arterial gas embolism require emergent tympanostomy, because hyperbaric treatment will recreate the same pressure differentials that caused the injury, potentially causing more perilymph leakage and, possibly, worsening the injury.[2]

FACE SQUEEZE, TOOTH SQUEEZE, AND DRY-SUIT SQUEEZE

Other air-containing structures can be compressed during descent, producing "squeeze" symptoms. A face squeeze occurs when air is not added to the facemask during descent, causing the face and eyes to be forced into the collapsing mask. This can produce facial bruising, conjunctival injection or hemorrhage, changes in vision, and, rarely, retrobulbar hemorrhage. The latter could be a true ophthalmologic emergency. A tooth squeeze occurs when air spaces inside a tooth—due to decay, a filling, or an abscess—become compressed during descent. A dry-suit squeeze occurs when suit folds are compressed into the underlying skin, producing local trauma manifested by painful red streaks.

BAROTRAUMA OF ASCENT

The clinical conditions of barotrauma of ascent are alternobaric vertigo, pulmonary barotrauma, arterial gas embolism, and decompression sickness (Table 214-1).

ALTERNOBARIC VERTIGO

During ascent, the physics of gas in air-containing organs is, of course, opposite that of descent—that is, air will expand as the pressure decreases. Air will flow through the ostia of the sinuses, and the expanding air in the middle ear will open the Eustachian tube (much like during takeoff in an airplane). Should air be trapped temporarily in one middle ear cavity, the pressure differential may cause unequal vestibular impulses to the brain, resulting in vertigo (alternobaric vertigo). This is usually transient and generally requires no specific treatment.

PULMONARY BAROTRAUMA

Air also expands within the lungs with ascent. If a diver breathing compressed air ascends with a closed glottis (holds breath, coughs, vomits), most frequently seen in a rapid, panicked, out-of-air ascent, the expanding air may cause parenchymal lung injury. This can occur even in shallow water (e.g., a swimming pool). Pulmonary barotrauma, also called *pulmonary overinflation* or *burst lung syndrome*, can lead to pneumomediastinum. This generally only requires symptomatic treatment and may be subtle on the chest radiograph.[3] Mediastinal air can track superiorly into the neck, resulting in subcutaneous air on physical examination or air on a cervical spine radiograph. Pulmonary overinflation injury can cause pneumothorax, requiring aspiration or air or tube thoracostomy. If air enters the pulmonary venous circulation, embolization of the gas through the arterial system occurs. The most sensitive end-organ to such embolization is the brain, and *cerebral arterial gas embolism* is the term applied to this condition, although the air emboli distribute to other tissues and organs.[4] **Any neurologic symptom or sign referable to the circulation to the CNS in the setting of barotrauma associated with ascent should be considered to be secondary to cerebral arterial gas embolism.** The symptoms, signs, and treatment are discussed below in the section "Arterial Gas Embolism."

Pulmonary barotrauma (**Figure 214-1**) can occur without a rapid ascent or closed glottis in divers with congenital cysts, obstructive pulmonary disease, or other processes that cause air trapping.

OTHER BAROTRAUMAS OF ASCENT

An air pocket underneath a tooth may equilibrate with ambient pressure while diving, only to expand during ascent. This produces severe pain and may dislodge a filling or fracture a tooth. Swallowed air during diving may expand during ascent, rarely producing gastric distention and abdominal cramps.

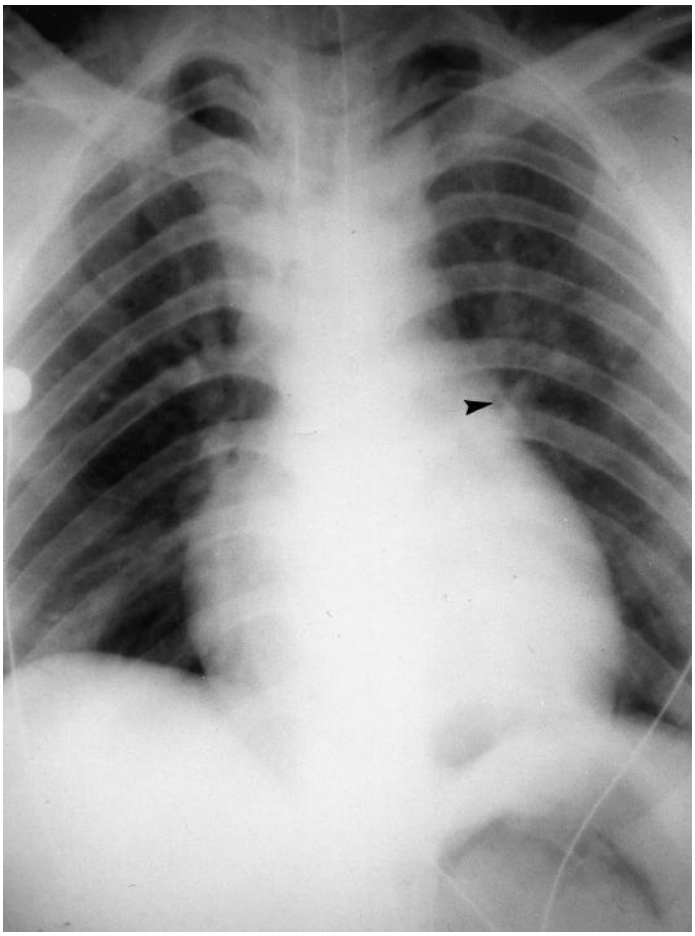

FIGURE 214-1. Pulmonary barotrauma. Note the air in the mediastinum in this radiography (*arrow*). There is also air in the soft tissues of the neck.

DECOMPRESSION SICKNESS

The pathophysiology of decompression sickness is related to the obstructive and inflammatory effects of inert gas bubbles in tissues and the vascular system.[4] Decompression sickness may occur in divers breathing compressed air, caisson workers, high-altitude pilots, or astronauts. Bubbles may form when a body with additional inert gas in solution experiences a decrease in ambient pressure that causes liberation of the gas. Uptake of inert gas occurs at different rates in different tissues.

The U.S. Navy publishes dive tables to provide the limits to a dive (measured by bottom depth and time) that can be undertaken without a decompression stop ("no decompression" or "no stop" dives). Other Navy tables provide a variety of decompression schedules for longer dives. A multitude of dive computers, often using proprietary mathematical models, provide divers with relatively safe diving limits. Decompression sickness is unlikely to occur if the limits of the dive tables or dive computer are followed, but compliance with dive table limits or a dive computer does not completely eliminate risk.

Bubbles are necessary but not sufficient by themselves to cause decompression sickness; bubbling occurs after many dive profiles that do not lead to decompression sickness. Obviously, there must be a threshold at which the bubble load causes symptoms. The exact mechanism of bubble formation is not known, although preexisting gas micronuclei in the circulation likely form a nidus for gas accumulation. This is inferred, because the energy required to form bubbles de novo is much higher than the energy state caused by the saturation of inert gas in tissue.[5] Bubbles may form directly in tissues or the circulation (usually the low-pressure venous circulation). Classically, it is thought that bubbles directly obstruct blood flow, leading to direct ischemia. Also, the air–blood and air–endothelial interfaces initiate a variety of inflammatory and thrombotic processes; activate the endothelium, leading to neutrophil adhesion and activation; and change the permeability of the endothelium, resulting in third spacing of fluid. In addition, decompression stress induces the production of microparticles, which are lipid bilayer–enclosed membranous vesicles extruded from vascular endothelial and other cells. Injection of these microparticles in animal models creates a clinical condition consistent with decompression sickness.[6]

There are no current definitive diagnostic criteria for decompression sickness. The San Diego Diving and Hyperbaric Organizations criteria use a point system to identify dive injuries resulting in decompression sickness with a high degree of specificity.[7] This is helpful to create databases of divers with decompression sickness to study outcomes and allow study of adjunctive therapies. Unfortunately, this system has relatively low sensitivity. Studies of therapies for decompression sickness often lack an acceptable case definition of decompression sickness.

CLINICAL FEATURES

The most commonly used classification divides decompression sickness into two (or sometimes three) main groups (**Table 214-2**). We focus on type I and II for clarity. **Type I** is also called "pain-only" decompression sickness and involves the joints, extremities, and skin ("cutis marmorata"). Lymphatic obstruction can occur in type I, causing lymphedema, which usually takes days to resolve despite recompression therapy. **Type II** involves the CNS (mainly the spinal cord in compressed air divers and the brain in high-altitude decompressions), vestibular symptoms ("staggers"), and cardiopulmonary symptoms ("chokes"). To further complicate the nomenclature and classification of decompression sickness, it can also occur when an arterial gas embolism (see below) causes inert gas to come out of solution after a dive profile that would otherwise not be expected to cause decompression sickness (called type III).[8] Some advocate the use of the alternate term *decompression illness*, instead of differentiating between decompression sickness and cerebral arterial gas embolism, to encompass all pathologic syndromes following a reduction in ambient pressure.[1]

Generally, the symptoms of decompression sickness occur minutes to several hours after surfacing, but in rare cases, symptoms can occur

TABLE 214-2 Classification of Decompression Sickness (DCS)

Classification	Clinical Features	Comments
Type I: "pain-only" DCS	Deep pain in joints and extremities, unrelieved but not worsened with movement	Usually single joint, most commonly knees and shoulders
	Skin changes—mottling, pruritus, and color changes	Lymphatic obstruction can occur and takes days to resolve despite recompression therapy
Type II: "serious" DCS	Pulmonary ("chokes")—cough, hemoptysis, dyspnea, and substernal chest pain	
	Cardiovascular collapse can occur	
	Neurologic—sensation of truncal constriction® ascending paralysis, usually rapid in onset	Has a tendency to affect the lower cervical and thoracic regions may see scattered lesions
		Autonomic dysfunction seen
	Vestibular ("staggers")—vertigo, hearing loss, tinnitus, and disequilibrium	Usually occurs after deep, long dives
Type III: combination of DCS and arterial gas embolism	Symptoms of DCS II noted above plus a variety of stroke syndromes, symptoms, and signs	Symptoms occur on ascent or immediately upon surfacing Symptoms of arterial gas embolism may spontaneously resolve

days after diving. Symptoms occurring between dives may improve during a subsequent dive (as recompression has occurred) but get worse upon resurfacing (as the inert gas load has increased and ambient pressure has decreased). Flying with the resultant decrease in ambient pressure may precipitate or worsen symptoms. For this reason, divers are generally advised to refrain from flying for at least 12 to 24 hours after the last dive depending on the nature of the diving exposure.[9]

Pain Divers with type I decompression sickness typically describe a deep pain, unrelieved but not worsened with movement. This pain can be attributed to or confused with pain caused by injury, potentially making accurate diagnosis difficult. Pain is thought to be due to distention from bubbles in ligaments or fascia, intramedullary bubbles at the ends of long bones, or the activation of stretch receptors caused by bubbles in tendons. The mechanism of simple distention of tissues is supported by the rapid improvement of symptoms with recompression. Common pain locations are knees and shoulders, and most often, only a single joint is involved. Decompression sickness in commercial and military divers, caisson workers, and aviators tends to manifest most often as joint pain. Sport divers, who usually perform multiple dives, often over a period of days, are more prone to spinal cord effects.

Poorly localized and difficult-to-describe back or abdominal pain may herald the more serious signs of spinal cord involvement.

Pulmonary Symptoms Pulmonary symptoms, generally seen usually only after more prolonged exposures, are caused by large numbers of pulmonary artery bubbles and include symptoms of cough, hemoptysis, dyspnea, and substernal chest pain. Cardiovascular collapse can occur.

Neurologic Symptoms The classic description of divers with neurologic decompression sickness (type II) can begin with a sensation of truncal constriction or girdle-like pain. Often a wooly feeling begins in the feet, developing into an ascending paralysis, producing symptoms of transverse myelitis. This form is usually rapid in onset and has a tendency to affect the lower cervical and thoracic regions. However, in type II decompression sickness, neurologic deficits do not necessarily cause distinct spinal cord syndromes (i.e., an anterior or posterior spinal artery syndrome), nor will a definitive level necessarily be found, as lesions may be scattered throughout the spinal cord.[10] Autonomic involvement, with resulting incontinence and sexual dysfunction, is not uncommon. The pathophysiology of spinal cord decompression sickness seems to be initial bubbling in the low-pressure venous plexus system that first impedes and then obstructs venous outflow from the cord. Decreasing venous blood flow prevents dissolved nitrogen in spinal cord tissues from egressing, and in situ bubbles within the spinal cord develop (called *autochthonous bubbles*).

Vestibular Symptoms Vestibular decompression sickness usually occurs after deep, long dives, although it has been reported in sport divers. Signs are vertigo, hearing loss, tinnitus, and disequilibrium. The vestibular syndrome can be differentiated from inner ear barotrauma mainly by the history, because patients with inner ear barotrauma develop symptoms in the water and, generally, immediately after a forced Valsalva maneuver to equalize the middle ear pressure.[11]

Other, nonspecific symptoms such as headache, nausea, dizziness, or unusual fatigue are also reported. It may be difficult to differentiate fatigue from decompression sickness from the expected fatigue from the exertion of diving.

Patent Foramen Ovale The association between decompression sickness and patent foramen ovale is unclear. There appears to be an increased prevalence in patients with inner ear and cutaneous decompression sickness. It is reasonable to screen divers with recurrent, unexplained decompression sickness for a patent foramen ovale. Closure of a large defect will reduce arterialization of venous gas emboli, although it has yet to be shown if such closure will reduce the incidence of subsequent decompression sickness.[12]

ARTERIAL GAS EMBOLISM

Arterial gas embolism occurs when air enters the left side of the vascular system. In the setting of diving, this most often results from pulmonary barotrauma. Arterial gas embolism can also occur as a complication of certain medical procedures, such as central vascular catheterization and cardiac bypass. Air inadvertently introduced into the venous circulation can cross from the right side of the circulation from intracardiac or pulmonary arteriovenous shunts. Air bubbles may also arterialize through these same shunts, sometimes making the source of arterial bubbles difficult to determine.[13] Whatever the source, when air embolizes systemically, distribution depends mainly on blood flow and not gravity.

Clinical Features The most dramatic effect of arterial gas embolism is on the brain, resulting in a variety of stroke syndromes, symptoms, and signs, depending on the part of the brain affected. Rarely, diving-related arterial gas embolism from pulmonary barotrauma causes immediate apnea and cardiac arrest. The mechanism of cardiovascular collapse appears to be air in the entirety of the large arteries and veins of the central vascular bed.[14] The effects of arterial gas embolism secondary to pulmonary barotrauma usually occur on ascent or immediately upon surfacing. If the victim does not die immediately, the symptoms of cerebral arterial gas embolism often include loss of consciousness, seizure, blindness, disorientation, or hemiplegia. Symptoms may spontaneously improve as the gas enters the venous cerebral circulation after a spike in blood pressure. Sometimes, by the time the patient reaches the clinician, the only signs that remain are subtle defects. In particular, parietal lobe signs and symptoms are easily overlooked. A cascade of inflammatory processes also occurs in air embolism, just as in decompression sickness.[4]

Laboratory Testing The hematocrit may elevate from hemoconcentration and third spacing of fluids. The creatine phosphokinase (and other enzymes such as lactate dehydrogenase, alanine aminotransferase, and aspartate aminotransferase) will become elevated secondary to the systemic distribution of bubbles. The degree of elevation of creatine phosphokinase corresponds to the embolism severity. Cardiac troponins may also be elevated and most likely do not represent occlusive coronary artery disease.[4]

Treatment of Decompression Sickness and Arterial Gas Embolism **The treatment includes administering 100% oxygen, increasing tissue perfusion with IV fluids, and rapid recompression.** Some advocate placing patients with air embolism in the Trendelenburg position or in the left lateral decubitus position to "trap" air in the left ventricle. By the time the victim is brought onto the dive boat or the ambulance arrives, the air has usually been distributed, and the Trendelenburg position merely increases intracranial pressure, decreases cerebral perfusion, and interferes with other first aid measures. Nonetheless, some divers with arterial gas embolism have collapsed when placed in a sitting or standing position. **As a result, a supine position—not Trendelenburg position—is recommended for patients with arterial gas embolism.** Vomiting patients should be placed in the lateral decubitus position to prevent aspiration.

Recompression therapy with hyperbaric oxygen treats by several mechanisms. See the chapter 21, titled "Hyperbaric Oxygen Therapy" for detailed discussion. The administered pressure decreases the size of bubbles, and the high partial pressure of oxygen in solution increases inert gas washout from bubbles and tissue. Mass action dictates a gas will travel down pressure gradients; therefore, nitrogen will move from bubbles with a high partial pressure of nitrogen into plasma, where it will travel to the lungs and be exhaled. Conversely, oxygen from plasma with a high partial pressure of oxygen will enter bubbles, but ultimately will diffuse into cells and be metabolized, further reducing bubble size. Hyperbaric oxygen also decreases tissue edema, increases oxygen delivery to ischemic tissues, and reduces neutrophil adhesion to the endothelium and neutrophil activation.[15]

Recompression using the U.S. Navy Treatment Table 6 is a commonly used method of management for decompression sickness, employing a maximal treatment pressure of 2.8 ATA (60 fsw). Table 6 is also used for air embolism, although some advocate an initial pressurization to 6 ATA (165 fsw) to maximize bubble compression, then continuation at 2.8 ATA (U.S. Navy Table 6A). Different treatment tables are used in other parts of the world, and there is some experience using lower treatment pressures for decompression sickness in monoplace chambers with reportedly comparable results.[16] Some patients may benefit from repeated treatments if symptoms do not fully resolve. Recompression should occur as soon as possible, and it should not be withheld in cases with delayed presentation.[4] Additionally, for divers who have missed needed decompression stops because of an emergency ascent or nonadherence to appropriate diving tables, it may be appropriate for them to undergo recompression therapy *even if asymptomatic*. U.S. Navy Table 5 recompression would usually be adequate in such a circumstance.

The administration of IV lidocaine as a therapeutic adjunct for cerebral arterial gas embolism has been advocated, because it appears to decrease neuropsychiatric deficits when given during anesthesia for cardiac procedures requiring bypass,[17-19] since bypass operations commonly cause the entry of air into the arterial system. Dosing of lidocaine in this setting is not standardized, although typical cardiac dosing is commonly used.[20]

The **Divers Alert Network** (telephone: 1-919-684-9111; Web site: http://www.diversalertnetwork.org) has staff available 24 hours a day to provide assistance to divers and to help clinicians treat patients with decompression sickness or arterial gas embolism. The Divers Alert Network can provide information and the location of the nearest recompression facility around the world.

SPECIAL CONSIDERATIONS

ASTHMA

There is some debate over the safety of diving for individuals with asthma. Although the relative risk of pulmonary barotrauma may be higher in asthmatics (possibly as much as twice that of the general diving population), the absolute risk is still low because of the rarity of pulmonary barotrauma in diving (approximately 1 in 125,000 dives).[21] A physician who specializes in diving medicine should examine divers or potential divers with asthma, and an exercise pulmonary function test should be performed. Asthmatics can be cleared for diving if, using their usual medications, they have a normal exercise pulmonary function test and if they understand the potential increased risk of pulmonary barotrauma.[22] A diver who develops a lung injury that cannot be explained by the circumstances of the dive (i.e., the diver did not have a rapid, breath-holding ascent) should be evaluated for congenital or acquired structural lung disease and should probably no longer dive.

IMMERSION PULMONARY EDEMA

Pulmonary edema can occur while diving. Because the first reported cases occurred in cold water, this condition was first described as "cold water" or "cold-induced" pulmonary edema. However, many cases have subsequently been reported in warm water, up to 27°C (80.6°F).[23] Typical symptoms of pulmonary edema (dyspnea, chest discomfort, coughing up pink frothy secretions) occur at depth and usually improve over time or with standard treatments for pulmonary edema. The cause is unknown despite human studies.[24] This syndrome generally occurs in divers with no structural or ischemic heart disease, but diagnostic evaluation for heart conditions is indicated for those with risk factors for underlying heart disease. Immersion pulmonary edema is not caused by decompression and is not treated with recompression therapy. Interestingly, some divers will experience repeated episodes, whereas others may never experience another episode.

NITROGEN NARCOSIS

Inert gas narcosis occurs when air is breathed at a depth of 100 fsw or greater. Symptoms include loss of fine motor skills and high-order mental processes as well as behavior similar to that seen in alcohol intoxication. Symptoms increase as depth is increased beyond 100 fsw. Divers have codified this increase in symptoms as the "martini rule" (with many variations). A common description is that each 33 ft of depth (1 ATA) in excess of 100 fsw is the equivalent to drinking one martini. Nitrogen narcosis can cause divers to engage in dangerous or foolish activities during deep dives. At depths greater than 300 fsw, unconsciousness may occur from the anesthetic effect of nitrogen. At depths greater than 200 fsw, helium is often used in place of nitrogen in gas mixtures to prevent nitrogen narcosis.

OXYGEN TOXICITY

Oxygen toxicity usually affects the lungs or brain, depending on the partial pressure of oxygen delivered and duration of exposure. Pulmonary oxygen toxicity generally occurs at lower partial pressures of oxygen but with longer exposures, whereas cerebral oxygen toxicity occurs at high partial pressures with generally short exposures. Pulmonary oxygen toxicity can occur at partial pressures of oxygen at or below 1 ATA, for example, in patients requiring prolonged mechanical ventilation with high fractions of inspired oxygen. Pulmonary oxygen toxicity is unusual in diving.

Cerebral oxygen toxicity most often occurs with partial pressures of oxygen >1.4 ATA in the water. Some divers may breathe "nitrox" or *oxygen-enriched air* with fractions of oxygen of 32% to 36%. Therefore, cerebral oxygen toxicity can occur at lesser depths and actually is the factor that limits diving depth with nitrox. Additionally, there are rebreather systems (*closed-circuit systems*), with the diver breathing within a continuous circuit of gas that has a very high fraction of oxygen (>95%), with carbon dioxide being scrubbed out. With these systems, cerebral oxygen toxicity can occur at depths as little as 25 ft.

Signs and symptoms of cerebral oxygen toxicity include twitching, nausea, paresthesias, dizziness, and seizures. If a seizure develops in the water as the initial manifestation of cerebral oxygen toxicity, drowning may result. High partial pressures of oxygen are used clinically in hyperbaric chambers (2.4 ATA, 2.8 ATA, and sometimes 3.0 ATA), but cerebral

oxygen toxicity in this setting is rare, reported in <1 per 1000 patients. This is because patients in hyperbaric chambers are dry, warm, and at rest, while divers are wet, often cold, and exerting themselves—and all of these latter factors exacerbate cerebral oxygen toxicity. Cerebral oxygen toxicity is affected by partial pressure of arterial carbon dioxide and cerebral blood flow and may be caused by an increase in nitric oxide production, although this is still an area of active investigation.[25]

Besides nitrogen narcosis and oxygen toxicity, other gas-related conditions important in diving medicine are toxicity from carbon monoxide and the adverse effects of elevated partial pressures of carbon dioxide. Additional issues, especially with very deep dives, include heat loss from breathing helium and the high-pressure nervous syndrome, characterized by tremor and loss of fine motor function caused by the direct effects of pressure.

OTHER CONDITIONS

Injuries and medical conditions occurring during and immediately after compressed air diving are often misattributed as decompression sickness or cerebral arterial gas embolism. Be aware that any medical condition can occur under the water. Acute myocardial infarction, pulmonary embolism, stroke, seizure, encephalitis, and even appendicitis have been erroneously attributed to diving. True diving accidents or cardiac sudden death can be misattributed to drowning—a common final pathway of submersion.[26]

CHAPTER 215

Drowning

Stephen John Cico
Linda Quan

INTRODUCTION AND EPIDEMIOLOGY

Drowning is submersion in a liquid medium resulting in respiratory difficulty or arrest.[1] As with other causes of accidental death, drowning injury typically involves otherwise healthy, young individuals, but can involve individuals of any age or background.

Worldwide, drowning accounts for >500,000 deaths annually and is the leading cause of injury death among children <15 years of age. In the United States, there are >500,000 drowning events each year and 1100 deaths, which makes drowning the second leading cause of unintentional death of individuals from birth to age 19 years old.[2,3] However, the rate of drowning deaths has decreased over the past 40 years. In 1970, there were nearly 8000 deaths due to drowning in the United States,[4] and education with public awareness has been the major contributor to the decreased incidence. The vast majority of victims survive submersion events, with effects ranging from minimal or transient injury to profound neurologic insult.

Drowning incidence peaks in three age groups: The highest is in children <5 years old, the second peak is in those aged 15 to 24 years, and the third peak is in the elderly. Toddlers drown primarily after falling into swimming pools or open water, but they also drown in bathtubs and buckets in the home. Physicians also need to evaluate for intentional drowning (child abuse) or factitious disorder by proxy (formerly Munchausen's by proxy). In teenagers and adults, suicide, homicide, and domestic violence can be causes of drowning. The elderly also have an increased risk of bathtub drowning, often related to comorbid medical conditions or medications. Even in coastal areas, most drownings take place in warm, freshwater bodies of water (especially swimming pools).

TABLE 215-1 Disorders and Injuries Associated with Drowning

Disorders Associated with Drowning
Alcohol or other intoxicants
Syncope (e.g., due to hyperventilation prior to underwater diving)
Seizures
Cardiac conditions (e.g., dysrhythmias including prolonged QT syndromes, Brugada's syndrome, ischemic heart disease)
Dementia
Intentional (suicide, homicide, child abuse or neglect in young children)
Injuries Associated with Drowning
Spinal cord injuries due to diving into shallow water, significant falls from heights, or boating/personal watercraft mishaps
Hypothermia
Aspiration
Respiratory failure, insufficiency, or distress

Additional injuries or disorders that either precipitate or are associated with drowning events are shown in **Table 215-1**.

PATHOPHYSIOLOGY

After submersion, the degree of hypoxic insult to the central nervous system determines the ultimate outcome. It was previously thought that parasympathetic activation of the **diving reflex** (i.e., bradycardia, apnea, peripheral vasoconstriction, and central shunting of blood flow) provided transient protection during submersion. The diving reflex is strongest in infants <6 months of age, but the effects decrease with age.[5] In adults, vertical immersion (head out) and vertical submersion (head under) activate both the sympathetic and parasympathetic systems, which blunts any effect of the diving reflex.[6] Furthermore, physiologic stress associated with submersion also activates the sympathetic nervous system. Thus, the diving reflex is not protective. Cerebral protection in cold water submersions most likely results from rapid central nervous system cooling before significant hypoxic damage occurs.

Physiologic scoring systems[7,8] to predict drowning outcome have been devised but are not clinically helpful. The vast majority of patients who arrive at the hospital with stable cardiovascular signs and awake, alert neurologic function survive with minimal disability, whereas those who arrive with unstable cardiovascular function and coma do poorly because of the hypoxic-ischemic insult. Predictors are not accurate for the 15% to 20% of drowning victims whose condition on arrival is between these two extremes.[9]

End organs can also be affected by hypoxemia and metabolic acidosis. Aspiration of substances such as contaminated foreign material, particulate matter, bacteria, vomitus, or chemical irritants can affect eventual pulmonary recovery. **Electrolyte abnormalities are seldom significant and are usually transient unless there is significant hypoxia, central nervous system depression, renal injury from hemoglobinuria, or myoglobinuria.**[8,9] Hematologic values are usually normal unless there has been massive hemolysis. Disseminated intravascular coagulation can be a complicating factor in drowning outcome but usually occurs following severe hypoxic insult.

TREATMENT

PREHOSPITAL CARE

Rapid resuscitation of a drowning victim (quickly restoring ventilation and oxygenation) optimizes outcome. After safe removal of the victim from the water, CPR should be initiated as quickly as possible. Trauma as a cause of drowning is uncommon, and most injured drowning patients have a history of trauma or signs of injury on examination.[10] Cervical spine injury is rare (0.5%) in drowning unless there is a history of diving, falling from a significant height, or motorized vehicle crash.[11] Use cervical spine precautions if the history warrants it.

Administer high-flow oxygen by facemask if the patient is breathing or by positive-pressure bag-valve mask ventilation if the patient is not breathing. For patients who do not recover spontaneous respiratory effort, endotracheal intubation and positive-pressure ventilation are necessary.

All patients with drowning amnesia for the event, loss of or depressed consciousness, or an observed period of apnea, as well as those who require a period of artificial ventilation, should be transported to an ED for evaluation, even if they are asymptomatic at the scene. The patient should be warmed and monitored, and IV access should be established (**Figure 215-1**).

ED MANAGEMENT

Upon the patient's arrival at the ED, **assess and secure the airway, provide oxygen, determine core temperature, and assist ventilation as necessary**. If the patient is hypothermic, administer warmed isotonic IV fluids and apply warming adjuncts (e.g., blankets, overhead warmers, warming devices). Address any associated injuries. **Because cervical injury is rare without a history of diving or associated trauma, routine cervical immobilization and CT of the brain are not necessary.**[11]

Patients who present to the ED with a Glasgow Coma Scale score of >13 and an oxygen saturation of ≥95% are at low risk for complications (Figure 215-1) and should be observed for 4 to 6 hours. If the pulmonary examination does not reveal rales, rhonchi, wheezing, or retractions and arterial oxygen saturation on room air remains ≥95%, the patient can be safely discharged home. Laboratory studies and radiographs are unnecessary and are not predictive of discharge.[12] The patient should be told to return if fever, mental status changes, or pulmonary symptoms occur. If, after 4 to 6 hours, the patient develops an oxygen requirement, the findings on pulmonary examination are abnormal (rales, rhonchi, wheeze, retractions, etc.), or the patient's condition deteriorates, reassessment and admission or transfer to a monitored bed are needed.

Patients who present to the ED with a Glasgow Coma Scale score of <13 should be maintained on supplemental oxygen and ventilatory support as needed. If high-flow oxygen (fraction of inspired oxygen of 40% to 60%) cannot maintain an adequate partial pressure of arterial oxygen (>60 mm Hg in adults, >80 mm Hg in children), then intubate the patient and provide positive-pressure ventilation. Chest radiography and laboratory studies should be done to evaluate for pulmonary aspiration and other complications (Figure 215-1). Although aspiration is common, prophylactic antibiotics have not been shown to improve outcome and may be associated with resistant infections.[13] Continuous cardiac monitoring, pulse oximetry, temperature monitoring, and frequent reassessments should be performed for all patients. Hypothermia is a concern in patients who have been submerged in cold water (see chapter 209, Hypothermia).

If the patient is normothermic upon arrival in the ED and in cardiopulmonary arrest or asystole, serious thought should be given to discontinuing resuscitation efforts because recovery without profound neurologic complications is rare.[14,15]

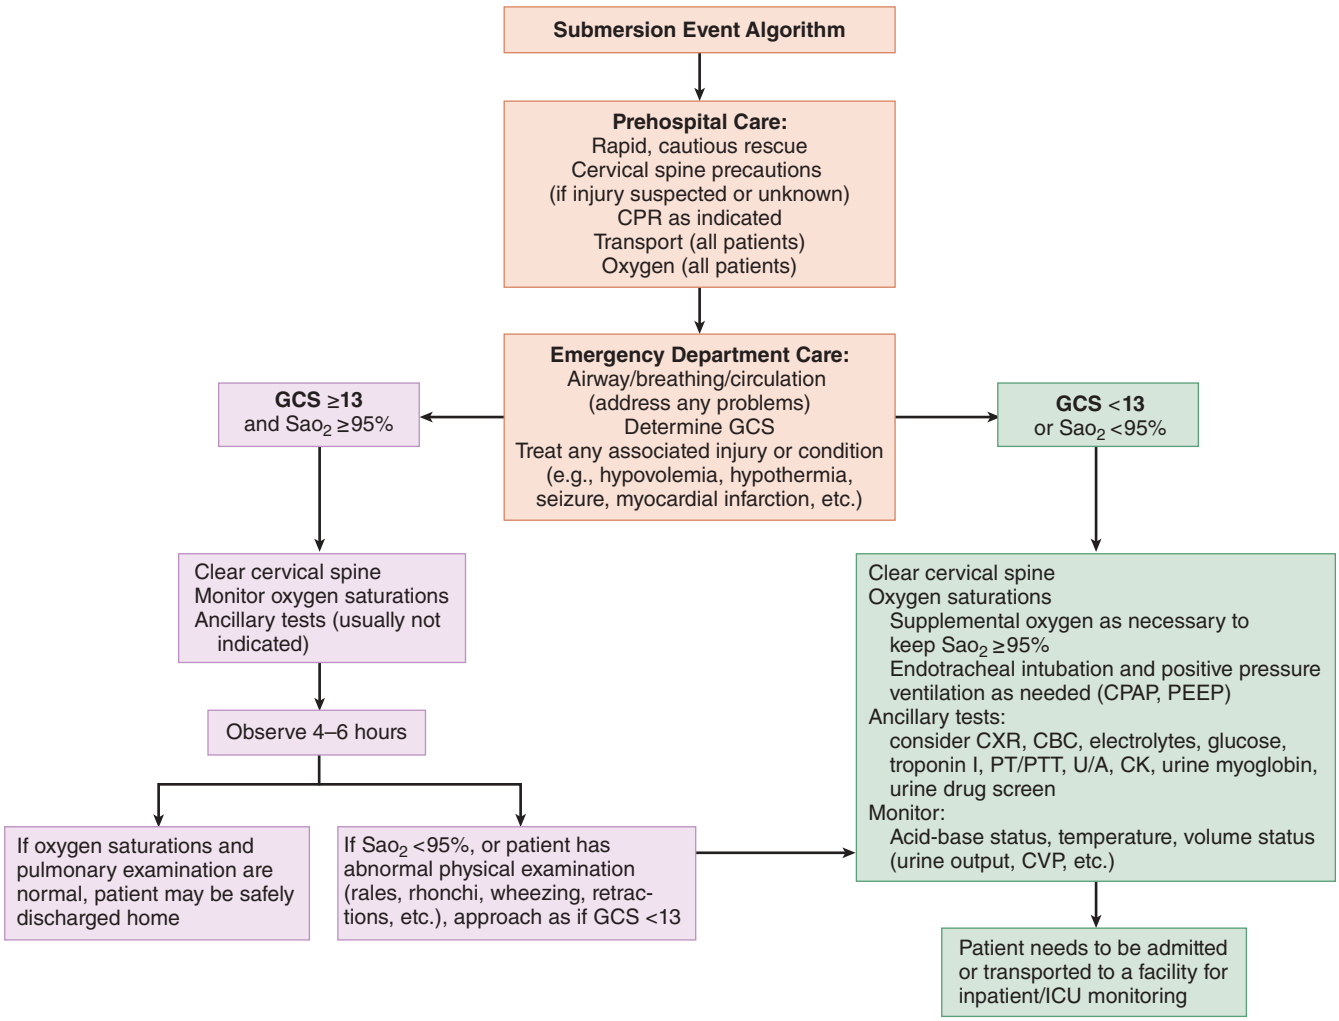

FIGURE 215-1. Drowning event algorithm. CBC = complete blood count; CK = creatine kinase; CPAP = continuous positive airway pressure; CVP = central venous pressure; CXR = chest radiograph; GCS = Glasgow Coma Scale score; ICU = intensive care unit; PEEP = positive end-expiratory pressure; PT = prothrombin time; PTT = partial thromboplastin time; Sao_2 = oxygen saturation (via pulse oximetry); U/A = urinalysis.

CONTINUED MANAGEMENT

Hospital management of drowning victims is largely supportive.[16] All drowning victims who require ED resuscitation should be admitted to an intensive care unit for continuous cardiopulmonary and frequent neurologic monitoring. Most victims of significant submersion injury benefit from mechanical ventilation. Supernormal levels of positive end-expiratory pressure may be used to recruit fluid-filled lung units and aid oxygenation. Most patients demonstrate rapid improvement in oxygenation in the first 24 hours. Patients presenting with a significant aspiration pattern or cardiovascular collapse are predisposed to develop acute respiratory distress syndrome. Although prophylactic antibiotics lack supporting evidence, delayed pulmonary infection, particularly among patients requiring mechanical ventilation, is a risk, and unusual organisms, including *Aeromonas* species, should be considered if treatment is initiated. Care should be taken to avoid lung overdistention and ventilator-associated barotrauma.

For patients who have been resuscitated from cardiac arrest, the hemodynamic response to exogenously administered epinephrine is frequently short-lived, and most require a continuous infusion of dopamine or epinephrine in the ED or intensive care unit. Invasive (pulmonary artery catheter) or noninvasive (echocardiogram) measurement of ventricular function is often instructive. Hemodynamic recovery, when it occurs, can be expected within 48 hours. Patients demonstrating no hemodynamic recovery after 48 hours may slowly improve over the first week but are more likely to have long-term neurologic damage.[17]

Results of "brain resuscitation" after significant warm water drowning have been disappointing.[9,16] The degree of cerebral edema is largely determined by the duration of the anoxic or ischemic insult at the time of submersion. Efforts to control cerebral edema, including the use of mannitol, loop diuretics, hypertonic saline, fluid restriction, and mechanical hyperventilation, have not shown benefit.[16] Controlled hypothermia, barbiturate "coma," and intracranial pressure monitoring do not improve outcome in pediatric drowning victims.[9] Although rare, complete or near-complete neurologic recovery after asystole has been reported in both children and adults after icy water submersion episodes.

PROGNOSIS, DISPOSITION, AND FOLLOW-UP

Family members should be counseled about likely outcome. Based on initial presentation, resuscitation, laboratory data, and serial examinations, experienced practitioners should be able to provide accurate predictions of outcomes in most cases.[17] There are no standardized terms for describing drowning incidents.[1] This chapter uses the terms *asymptomatic* and *symptomatic drowning*.

ASYMPTOMATIC DROWNING

Drowning victims who are asymptomatic or mildly symptomatic can be observed for 4 to 6 hours. If the findings of pulmonary examination and oxygen saturation on room air remain normal, patients can be discharged home. If deterioration is going to occur, it will do so within the 4- to 6-hour observation period.[12,18,19] No data are available regarding long-term outcomes, but it is unlikely that there are any measurable adverse effects. Patients and/or parents should be advised to seek medical care for any respiratory complaints or fever.

SYMPTOMATIC DROWNING

Because submersion duration is frequently unknown or only estimated, the extent of required resuscitation is often the most objective measure of the degree of anoxic or ischemic insult (Table 215-2). Details of initial presentation and resuscitation are frequently strong prognostic indicators.

For patients who require hospital admission, if the submersion victim does not require cardiopulmonary resuscitation at the scene or in the ED, complete recovery within 48 hours is expected. A small fraction of patients with significant aspiration may develop severe, even life-threatening acute respiratory distress syndrome.

Victims requiring bystander CPR at the scene have a guarded prognosis. Of scene-resuscitated pediatric victims, about 20% later die in the hospital, and about 5% are left with severe hypoxic-ischemic encephalopathy.[15,20] Those victims who demonstrate continuous neurologic and cardiovascular improvement after hospital admission generally make a good recovery. Frequently, neurologic and cardiovascular examinations are normal within 24 hours of the drowning event. Victims who later die in the hospital usually demonstrate deteriorating cardiovascular and neurologic status.

TABLE 215-2 Factors Associated with Poor Resuscitation Prognosis in Near-Drowning

Need for bystander CPR at scene
CPR in the ED
Asystole at scene or in ED after warming

Victims undergoing CPR in the ED have a poor prognosis. Prolonged (>30 minutes) CPR in drowning victims indicates significant anoxic or ischemic insult to the heart, brain, and other vital organs. Complete neurologic recovery is rare, with only anecdotal reports of neurologic recovery after ED CPR of pediatric drowning victims. Asystole, whether noted at the scene or in the ED, is a near-universal sign of poor prognosis in both adult and pediatric drowning injury.[16,21]

For the emergency physician, the answers to the questions of whom and how vigorously to resuscitate remain challenging.[16,20] **Complete or near-complete neurologic recovery after asystole has been reported in both children and adults after drowning in icy water, although such occurrences are rare** and documented mostly in case reports or small series. A large series of 1377 open-water drowning victims found *no* intact survivors among the group submerged for more than 15 minutes, whether in warm or cold water, and there were no survivors of submersion greater than 60 minutes.[22] There was also no difference in survival for children compared with adults in several studies, which contradicts the common belief that pediatric patients do better than adults.[7,21] For asystolic victims of drowning with short submersion durations (i.e., a few minutes) and short transport times who receive CPR en route, a vigorous resuscitation attempt is reasonable.[23] CPR should be abandoned if no response is noted. Conversely, because of the poor prognosis for intact neurologic survival, ED resuscitation attempts can reasonably be withheld from asystolic victims of drowning with longer submersion and transport times.[15,20]

PREVENTION

Submersion episodes in children <1 year of age are best prevented by parental vigilance during bathing. Child abuse or neglect, particularly bathtub drownings in young children, and those with atypical presentations, should be considered.[24] Bath seats may give parents a false sense of reassurance. Parents should never leave infants in bath seats unattended.[25] Bathtub drownings are rare outside of the toddler age range, so abuse or seizures should be suspected.[26] Among preschool children, adult supervision in conjunction with properly installed and maintained four-sided pool fences that completely isolate the pool could prevent 50% to 90% of drownings.[27,28]

Teen and young adult drownings may be reduced by avoiding alcohol and illicit drug use, which has been implicated in 40% of all adult drownings and 75% of boating-related adult drownings.[29] The use of personal flotation devices decreases boating-related drowning deaths.[30] Practical experience suggests that the ability to swim protects against teen and adult drowning, but evidence only supports the efficacy of swimming lessons for decreasing drowning death in young children.[31] Efforts to decrease risk-taking behavior in the high-risk adolescent and young adult age groups need to be developed.

Swimmers with seizure disorders must be constantly monitored by an experienced professional or competent bystander while they are in the water.

In the elderly, drowning locations closely parallel those of infant and toddler drowning. Adequate pool fencing and bathtub handrails are important preventive measures for the elderly population and patients with premorbid conditions.

CHAPTER 216

Thermal Burns

E. Paul DeKoning

EPIDEMIOLOGY

An estimated 450,000 individuals in the United States receive medical treatment each year for burn injuries. Although 40,000 patients require hospitalization and more than 60% of those are treated at one of 127 specialized burn centers,[1] the vast majority of burn patients are treated in the acute setting by emergency physicians and discharged with outpatient follow-up.[2,3]

Nearly 70% of burn victims are male,[1] and risk is highest between the ages of 18 and 35. Seventy-seven percent of all injuries are accounted for by fire or scalding; 43% of scald injuries occur in children less than 5 years of age.[4] Although overall survival exceeds 96%, fire, burn, and smoke inhalation still account for approximately 3400 deaths each year in the United States.[1] Elderly patients understandably have a disproportionately higher death rate.[4-6] The risk of death from a major burn increases with larger burn size, older age, the presence of inhalation injury, and female sex.[6]

The Centers for Disease Control and Prevention lists the following groups as being at increased risk of fire-related injuries and death: children ≤4 years of age, adults ≥65 years of age, African Americans and Native Americans, persons living in rural areas, persons living in manufactured homes or substandard housing, and persons living in poverty.[7]

Care of the acute burn–injured patient has improved significantly over the last several decades.[8,9] The rate of hospital admissions has decreased owing to improvements in both the acute care provided in the ED and outpatient care at specialized burn centers. Only approximately 4% of those treated in specialized burn treatment centers die from their injuries or associated complications.[4,10]

PATHOPHYSIOLOGY

Skin consists of two layers: the epidermis and the dermis (**Figure 216-1**). Skin thickness varies both by age and anatomic location: it is relatively thinner at extremes of age, whereas it is thicker on the palms, soles, and upper back. Thus, the depth and severity of thermal injury varies by both the age of the victim and the anatomic location exposed.

Skin functions as a semipermeable barrier to evaporative water loss, protects against environmental assault, and aids in the control of body temperature, sensation, and excretion. Partial-thickness thermal injury disrupts these barrier functions and contributes to free water deficits. This effect may be significant with moderate to large burns.

Thermal injury results in a spectrum of local and systemic homeostatic disorders that contribute to burn shock (**Table 216-1**). These include disruption of normal cell membrane function, hormonal alterations, acid-base disturbance, hemodynamic changes, and hematologic derangement.

The fluid and electrolyte abnormalities seen in burn shock are largely the result of alterations of cell membrane potential causing intracellular influx of water and sodium, and extracellular migration of potassium, secondary to dysfunction of the sodium pump. In patients with burns greater than 60% of total body surface area, depression of cardiac output results in a lack of response to aggressive volume resuscitation. Although

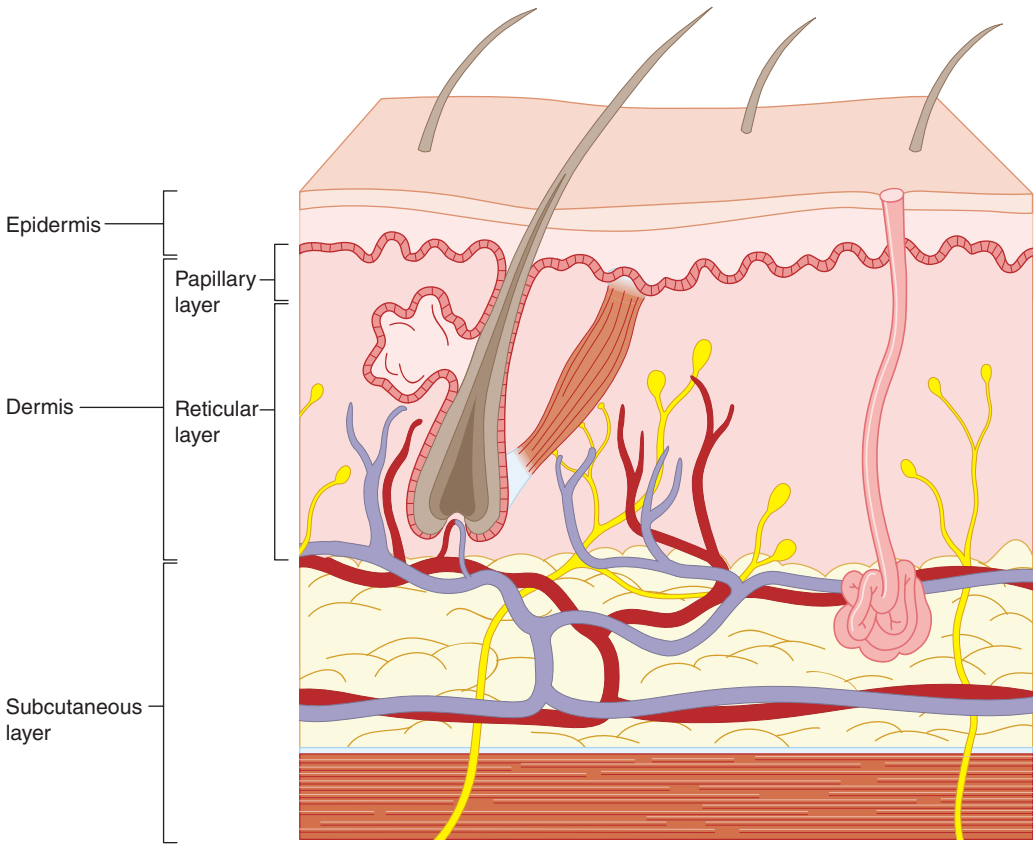

FIGURE 216-1. Layers of the skin.

TABLE 216-1 Physiologic Effects of Thermal Injury

Disruption of sodium pump
Intracellular influx of sodium and water
Extracellular efflux of potassium
Depression of myocardial contractility (>60% of body surface area burned)
Increased systemic vascular resistance
Metabolic acidosis
Increase in hematocrit and increased blood viscosity
Secondary anemia from erythrocyte extravasation and destruction
Local tissue injury
Release of histamines, kinins, serotonins, arachidonic acids, and free oxygen radicals

disputed by others, Baxter and Shires[11] have explained this phenomenon on the basis of circulating myocardial depressants. Systemic vascular resistance is increased. A significant metabolic acidosis may be present even in the early stages of a large burn injury. Massive thermal injury results in an increase in hematocrit with increased blood viscosity during the early phase, followed by anemia from erythrocyte extravasation and destruction. Surprisingly, however, transfusion is seldom required for patients with isolated burn injury, and aggressive transfusion has been associated with increased morbidity and mortality.[12-14]

Thermal injury is progressive. Local effects of thermal injury include the liberation of vasoactive substances, disruption of cellular function, and formation of edema. The subsequent systemic response alters the neurohormonal axis and further extends the injury. Implicated in these events are histamine, kinin, serotonin, arachidonic acid metabolites, and free oxygen radicals. These substances exert their primary effects at the local level and cause progression of the burn wound. **Although many factors may influence prognosis, the severity of the burn, the presence of inhalation injury, associated injuries, the patient's age, comorbid conditions, and acute organ system failure are most important.**[5,6] Cell damage occurs at temperatures of >45°C (113°F) owing to denaturation of cellular protein. The size and depth of the resulting burn are functions of the burning agent, its temperature, and the duration of exposure. Burn wounds are described as having three zones: the zone of coagulation, in which tissue is irreversibly destroyed with thrombosis of blood vessels; the zone of stasis, in which there is *stagnation* of the microcirculation; and the zone of hyperemia, in which there is *increased* blood flow. The zone of stasis can become progressively more hypoxemic and ischemic if resuscitation is not adequate. In the zone of hyperemia, there is minimal damage to the cells and spontaneous recovery is likely.

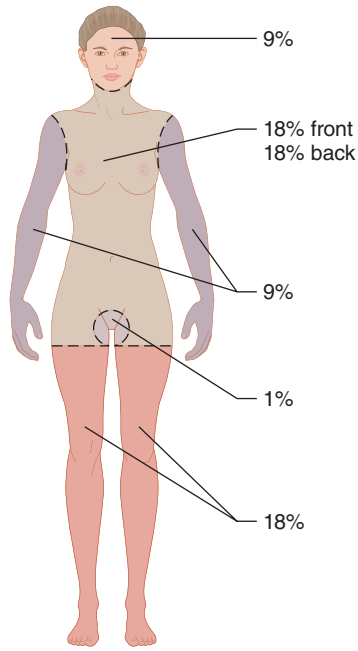
CLINICAL FEATURES

BURN SIZE

The size of a burn injury is quantified as the percentage of body surface area involved.[9] The **Rule of Nines** is a simple and commonly used method to calculate burn size (**Figure 216-2**), It divides the body into segments that are approximately 9% or multiples of 9%, with the perineum forming the remaining 1%. Because of the proportionately larger heads and smaller legs of infants and children, this method must be modified in pediatric burn injury.

A second method assumes that **the area of the back of the *patient's* hand is approximately 1% of their total body surface area. The number of "hands" that equal the area of the burn can approximate the percentage of body surface area burned.** A third and more precise method uses the **Lund-Browder burn diagram** (**Figure 216-3**). This allows an accurate age-adjusted determination of burn size for a given depth, allowing for the anatomical differences of children.[15]

Experienced burn care nurses and physicians can reliably estimate burn size regardless of the method used. Although it is common for inexperienced individuals to estimate burn size incorrectly when patients are first assessed in the ED, it remains a vital determinant of both fluid resuscitation and the need for ultimate transfer.



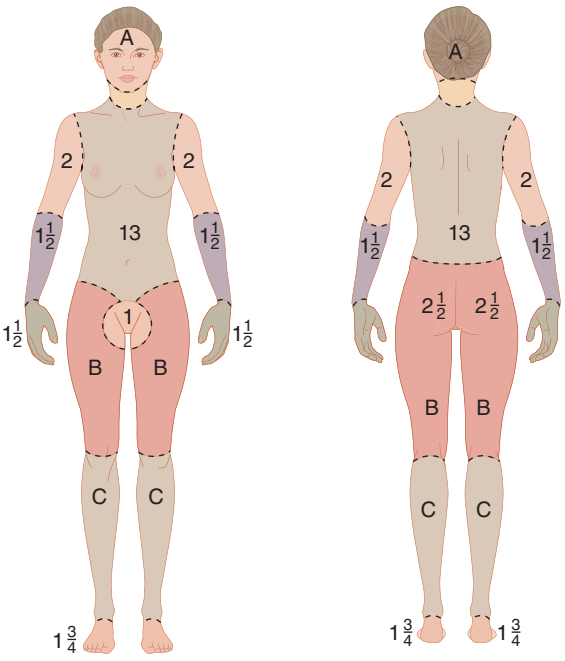


FIGURE 216-2. Rule of Nines diagram for estimation of adult burn size.

Relative percentages of areas affected by growth (age in years)

	0	1	5	10	15	Adult
A: half of head	9½	8½	6½	5½	4½	3½

TABLE 216-2 Burn Depth Features Classified by Degree of Burn

Burn Depth	Histology/Anatomy	Example	Healing
Superficial (first degree)	Epidermis	Sunburn	7 d
	No blisters, painful		
Superficial partial-thickness (superficial second degree)	Epidermis and superficial dermis	Hot water scald	14–21 d, no scar
	Blisters, very painful		
Deep partial-thickness (deep second degree)	Epidermis and deep dermis, sweat glands, and hair follicles	Hot liquid, steam, grease, flame	3–8 wk, permanent scar
	Blisters, very painful		
Full-thickness (third degree)	Entire epidermis and dermis charred, pale, leathery; no pain	Flame	Months, severe scarring, skin grafts necessary
Fourth degree	Entire epidermis and dermis, as well as bone, fat, and/or muscle	Flame	Months, multiple surgeries usually required

BURN DEPTH

The depth of a burn has historically been described in degrees: first, second, third, and fourth (**Table 216-2**). However, a classification of burn depth according to the need for surgical intervention has become the accepted approach in burn treatment centers: superficial partial-thickness, deep partial-thickness, and full-thickness burns[8] (**Table 216-3**). Determination of burn depth requires clinician judgment using commonly observed wound features. There is no objective method of measuring burn depth, and burn wound biopsy is not routine practice.

A superficial burn involves only the epidermal layer of skin. Sunburn is frequently given as an example, even though it is caused by ultraviolet light instead of thermal injury.[16] **The burned skin is red, painful, and tender without blister formation.** Superficial burns usually heal in about 7 days without scarring and require only symptomatic treatment (**Figure 216-4**).

Partial-thickness burns extend into the dermis and are subdivided into superficial partial-thickness (**Figure 216-5**) and deep partial-thickness burns (**Figure 216-6**).

In superficial partial-thickness burns, the epidermis and the superficial dermis (papillary layer) are injured while the deeper layers of the dermis, hair follicles, and sweat and sebaceous glands are spared. Superficial partial-thickness burns are often caused by hot water scalding. **The skin is blistered, and the exposed dermis is red and moist.** These wounds are exceedingly painful to touch. The dermis is well-perfused with intact capillary refill. Healing typically occurs in 14 to 21 days, scarring is usually minimal, and there is full return of function.

Deep partial-thickness burns extend into the deep dermis (reticular layer) (Figure 216-6). Hair follicles and sweat and sebaceous glands are damaged, but their deeper portions usually survive. Hot liquids (e.g., oil or grease), steam, or flame usually cause this type of injury. **The skin may be blistered, and the exposed dermis is pale white to yellow in color. The burned area does not blanch; it has absent capillary refill and absent pain sensation.** Deep partial-thickness burns may be difficult to distinguish from full-thickness burns. Healing takes 3 weeks to 2 months; scarring is common and related to the depth of the dermal injury. Surgical debridement and skin grafting may be necessary to obtain maximum function.

Full-thickness burns involve the entire thickness of the skin (**Figure 216-7**). All epidermal and dermal structures are destroyed. These injuries are typically caused by flame, hot oil, steam, or contact with hot objects. **The skin is charred, pale, painless, and leathery.**

TABLE 216-3 Burn Depth Features: American Burn Association Burn Classification

Burn Classification	Burn Characteristics	Disposition
Major burn	Partial-thickness >25% BSA, age 10–50 y	Burn center treatment
	Partial-thickness >20% BSA, age <10 y or >50 y	
	Full-thickness >10% BSA in anyone	
	Burns involving hands, face, feet, or perineum	
	Burns crossing major joints	
	Circumferential burns of an extremity	
	Burns complicated by inhalation injury	
	Electrical burns	
	Burns complicated by fracture or other trauma	
	Burns in high-risk patients	
Moderate burn	Partial-thickness 15%–25% BSA, age 10–50 y	Hospitalization
	Partial-thickness 10%–20% BSA, age <10 y or >50 y	
	Full-thickness burns ≤10% BSA in anyone	
	No major burn characteristics present	
Minor burn	Partial-thickness <15% BSA, age 10–50 y	Outpatient treatment
	Partial-thickness <10% BSA, age <10 y or >50 y	
	Full-thickness <2% in anyone	
	No major burn characteristics present	

Abbreviation: BSA = body surface area.

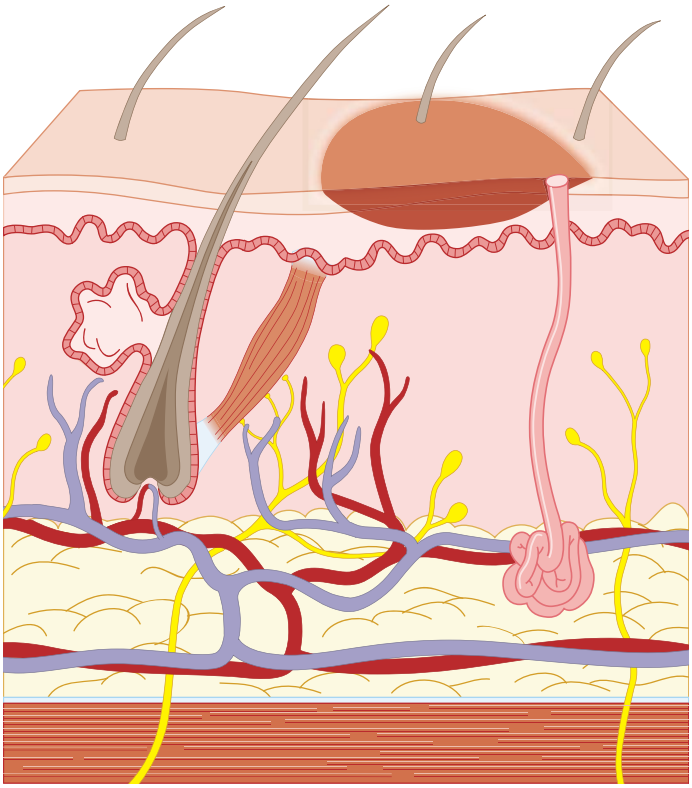

FIGURE 216-4. Superficial burn.

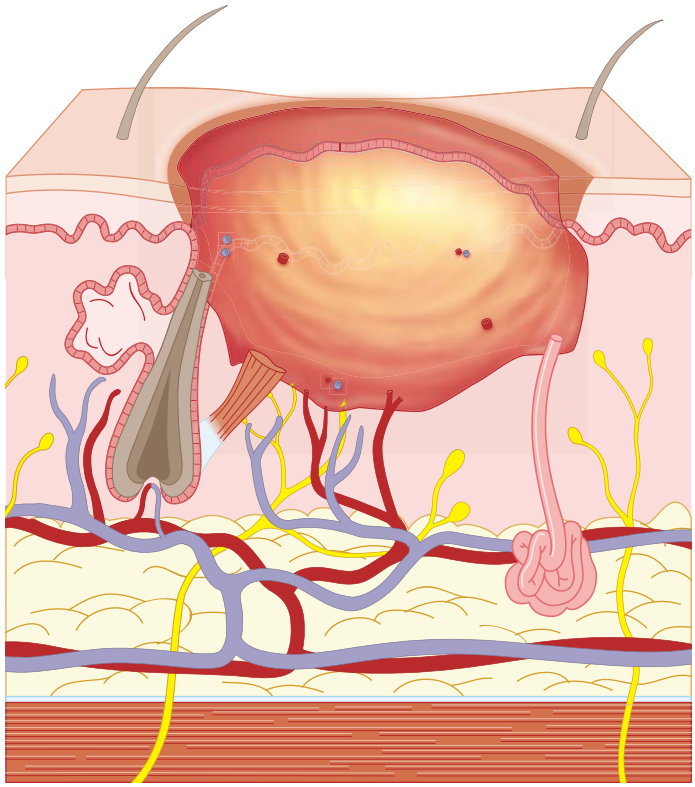

FIGURE 216-6. Deep partial-thickness burn.

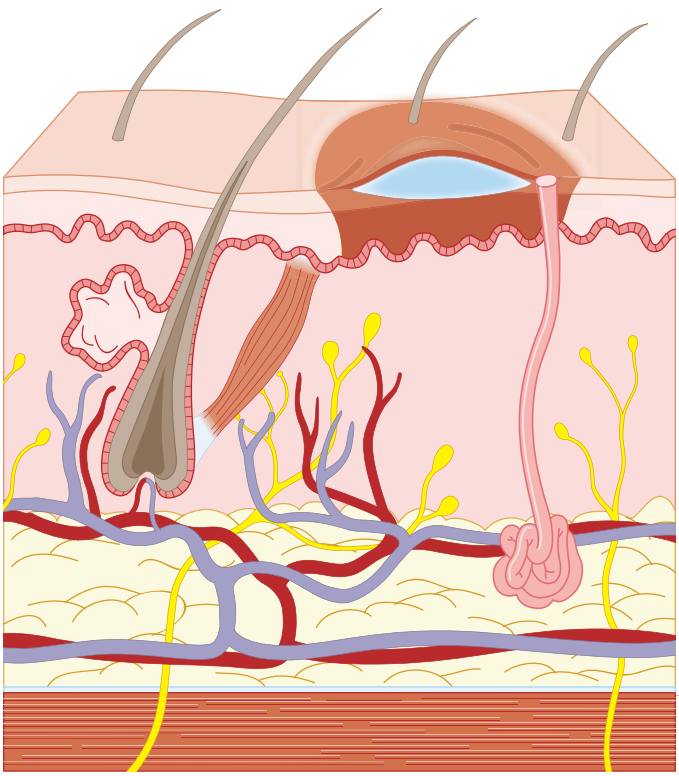

FIGURE 216-5. Superficial partial-thickness burn.

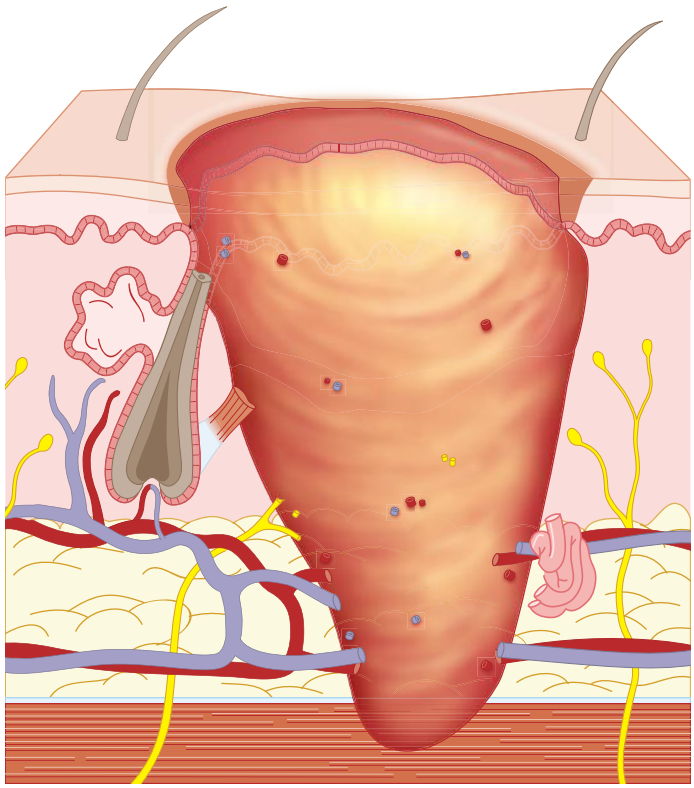

FIGURE 216-7. Full-thickness burn.

TABLE 216-4 American Burn Association Burn Unit Referral Criteria

Full-thickness/third-degree burns in any age group
Electrical burns, including lightning injury
Chemical burns
Inhalation injury
Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
Burn injury in any patients with concomitant trauma (such as fractures) in whom the burn injury poses the greatest risk of morbidity or mortality
Burn injury in children in hospitals without qualified personnel or equipment to care for children
Burn injury in patients who will require special social, emotional, or long-term rehabilitative intervention
Burn injury in children <10 y and adults >50 y of age

Because all dermal elements are destroyed, these injuries do not heal spontaneously. Surgical repair and skin grafting are necessary; significant scarring is the norm.

Fourth-degree burns are those that extend through the skin to the subcutaneous fat, muscle, and even bone. These are devastating, life-threatening injuries. Amputation or extensive reconstruction is sometimes required.

BURN CENTER TRANSFER

The American Burn Association provides guidelines for referral to a burn center, in addition to indications based on burn depth (**Table 216-4**).[9,17] Children <10 years of age and adults >50 years are considered high-risk patients. Patients with significant comorbidities, such as heart disease, diabetes, or chronic pulmonary disease, are also likely to require prolonged care and should be considered for transfer to a burn unit. Burn severity, underlying medical and social conditions, and the capabilities of the institution initially receiving the patient must all be considered in the decision to transfer the patient to a burn unit. As always, use clinical judgment. While some institutions may transfer all burn patients to a burn center, others may choose to care for patients with minor and some moderate burns locally.

INHALATION INJURY

As treatment of burn shock and sepsis has improved, inhalation injury has become the main cause of mortality in burn patients. Most fire-related deaths are due to smoke inhalation.[5,6,10] Inhalation injury is associated with closed-space fires and conditions that decrease mentation, such as overdose, alcohol intoxication, drug abuse, and head injury. Exposure to smoke includes exposure to heat, particulate matter, and toxic gases.[18] Direct thermal injury is usually limited to the upper airway; thermal injuries below the level of the vocal cords can occur in cases of steam inhalation.

Smoke contains particulate matter, usually <0.5 μm in size, which is formed from incomplete combustion of organic material. Small particles may reach the terminal bronchioles, where they can initiate an inflammatory reaction that leads to bronchospasm and edema. Toxic inhalants are divided into three large groups: tissue asphyxiants, pulmonary irritants, and systemic toxins.[18] The two major tissue asphyxiants are carbon monoxide and hydrogen cyanide.

Carbon monoxide poisoning is a well-known consequence of smoke inhalation injury. Severe carbon monoxide poisoning produces brain hypoxia and coma. Comatose patients lose airway protective mechanisms, which may result in aspiration and further pulmonary injury. All patients with suspected carbon monoxide exposure should receive 100% oxygen by nonrebreather mask and should be evaluated for hyperbaric oxygen therapy (see chapter 222, "Carbon Monoxide"). Hydrogen **cyanide** is formed by the combustion of nitrogen-containing polymers such as wool, silk, polyurethane, and vinyl. Cyanide binds to and uncouples mitochondrial oxidative phosphorylation, which leads to profound tissue hypoxia. Specific treatment for cyanide toxicity may be required (see chapter 204, "Industrial Toxins").

Inhalation injury damages endothelial cells, produces mucosal edema of the small airways, and decreases alveolar surfactant activity, resulting in bronchospasm, airflow obstruction, and atelectasis. Bronchospasm may occur early. Although lower airway edema may not be clinically evident for up to 24 hours, upper airway edema can occur rapidly. Over time, tracheal and bronchial epithelial sloughing occurs. Approximately half of intubated burn patients admitted to burn centers develop acute respiratory distress syndrome.[19] **Therefore, when inhalation injury is present, careful fluid resuscitation guided by hemodynamic monitoring can help avoid pulmonary edema and acute respiratory distress syndrome.**

The initial diagnosis of smoke inhalation is made from a history of exposure to fire in an enclosed space and physical signs that include facial burns, singed nasal hair, soot in the mouth or nose, hoarseness, carbonaceous sputum, and expiratory wheezing. No single method for diagnosing the extent of inhalation injury exists. Measurement of arterial carboxyhemoglobin is used to document prolonged exposure to products of incomplete combustion. The chest radiograph may be normal initially. Bronchoscopy and radionuclide scanning may also be helpful in evaluating the full extent of injury.

Treat suspected inhalation injury *prior to* definitive diagnosis. Provide humidified oxygen (100%) by facemask. Obtain arterial blood gas concentrations, ***including carboxyhemoglobin levels***. Control of the upper airway is achieved by prompt endotracheal intubation. Indications for intubation include (1) full-thickness burns of the face or perioral region, (2) circumferential neck burns, (3) acute respiratory distress, (4) progressive hoarseness or air hunger, (5) respiratory depression or altered mental status, and (6) supraglottic edema and inflammation on bronchoscopy. Additionally, consider the patient's anticipated clinical course.

BURN TREATMENT

The management of patients with *moderate to major* burns can be divided into three phases: (1) prehospital care, (2) ED resuscitation and stabilization, and (3) admission or transfer to a specialized burn center.

PREHOSPITAL CARE

The basis of prehospital care of the burn-injured patient consists of the following: (1) stop the burning process; (2) assess and, if necessary, secure the airway; (3) initiate fluid resuscitation; (4) relieve pain; (5) protect the burn wound; and (6) transport the patient to an appropriate facility.

On-site assessment of a burned patient is divided into primary and secondary surveys. In the primary survey, identify and treat immediately life-threatening conditions. Initial management of the burn-injured patient is similar to that of any other trauma patient: airway, breathing, circulation, and cervical spine immobilization where appropriate. During the secondary survey, perform a thorough head-to-toe evaluation.

The patient must be extricated from the burning environment, and burning clothing must be immediately removed. The remainder of the clothing should be removed after the airway, breathing, and circulation are secured. Remove rings, watches, jewelry, and belts because they retain heat and produce a tourniquet-like effect on the extremity, causing ischemia. Give oxygen by facemask. **Pay close attention to the airway: rapid deterioration may occur even when the initial assessment judges the airway to be acceptable.** Consider prophylactic intubation in patients with perioral burns sustained in a closed-space fire. Give IV isotonic crystalloid. Cover the patient with clean sheets to protect the wound. While early cooling can reduce the depth of burn and reduce pain, uncontrolled cooling may result in hypothermia. Provide analgesia according to protocol or with direction of the online medical control physician. Transport the patient to the nearest ED capable of caring for a burn-injured patient or, if none is available, to the nearest ED for stabilization and subsequent transfer.

ED MANAGEMENT

INITIAL ASSESSMENT

Obtain a directed history from the patient and EMS personnel to determine the burning agent(s), involvement of chemicals, the duration of exposure, and if the injury was sustained in an open or enclosed space. Assess for loss of consciousness, risk of blast injury from explosion, contact with electricity, or other trauma. Assess the adequacy of, or need for, cervical immobilization. Obtain the general history, including past medical and surgical illnesses, chronic disease, allergies, medications, and tetanus immunization status.

Quickly assess the patient's respiration and circulation and initiate stabilization (**Table 216-5**). Examine the patient for signs of inhalation injury, as evidenced by respiratory distress, facial burns, carbonaceous sputum, singed nasal hair, and soot in the mouth. **If there is any evidence of airway compromise with swelling of the neck, burns inside the mouth, or wheezing, perform early endotracheal intubation.**

Assess the adequacy of circulation by noting the blood pressure, pulse rate, capillary refill time, mental status, and urinary output. Insert IV lines in unburned areas, but when this is not possible, a burned area can be used and resuscitation started according to a burn fluid resuscitation formula.

During the secondary examination, perform a head-to-toe assessment, including examination of the eye for corneal burns. Estimate and record the size and depth of the burn injury. In patients with partial-thickness burns of >20% of body surface area, nasogastric tube insertion is routinely required due to frequent development of ileus. Insert a urinary catheter to measure urinary output and to prevent urinary retention in patients with perineal burns.

Routine laboratory tests, including a CBC and measurement of electrolyte, BUN, creatinine, and glucose levels, should be performed. In patients with moderate/severe burns or suspected inhalation injury, obtain an arterial blood gas analysis, carboxyhemoglobin level, serum creatine kinase, urinalysis for myoglobin, chest radiograph, and ECG. Fiberoptic bronchoscopy is indicated in suspected inhalation injury and in intubated patients for both diagnostic and therapeutic purposes. Additional radiographs should be taken as indicated for other suspected trauma.

Treat suspected inhalation injury with humidified 100% oxygen, intubation and ventilation, bronchodilators, and aggressive pulmonary toilet; hyperbaric oxygen may be necessary for severe carbon monoxide poisoning.

Burn injury in the pregnant woman is associated with significant morbidity to mother and child. The outcome of the pregnancy is determined by the extent of injury to the mother. Spontaneous termination of pregnancy is common in large–body surface area burns. Resuscitation requirements may exceed those estimated using common guidelines. Fetal monitoring and early consultation with the obstetrician and burn specialist are recommended.

FLUID RESUSCITATION

The burn shock resuscitation formulas in use today are derived from laboratory studies of burn shock and resuscitation, and the utility of such formulas has been called into question.[20] Although the importance of early fluid resuscitation is supported by clinical experience,[20,21] no consensus exists on the appropriate assessment of resuscitation and its effect on outcome.[20] Additionally, over-resuscitation is not without consequence. In general, resuscitation should be guided by monitoring cardiorespiratory status and urine output rather than strict adherence to a formula. **The following formulas are a guide for fluid resuscitation of the burn-injured patient. Monitor and adjust according to individual patient response.**

TABLE 216-6 Parkland Formula for Fluid Resuscitation

Adults
LR 4 mL × weight (kg) × % BSA burned* over initial 24 h
Half over the first 8 h from the time of burn
Other half over the subsequent 16 h
Example: 70-kg adult with 40% second- and third-degree burns:
4 mL × 70 kg × 40 = 11,200 mL over 24 h
Children
LR 3 mL × weight (kg) × % BSA burned* over initial 24 h plus maintenance
Half over the first 8 h from the time of burn
Other half over the subsequent 16 h

Abbreviations: BSA = body surface area; LR = lactated Ringer's solution.

*Partial- and full-thickness burns only.

The Baxter or Parkland formula is likely the most widely used thermal injury resuscitation regimen in North America.[8,9] This formula calls for 4 mL of lactated Ringer's solution multiplied by the percentage of body surface area burned (partial- and full-thickness burns only) multiplied by patient body weight in kilograms. Half of the total is administered in the first 8 hours after injury and the remainder during the following 16 hours (**Table 216-6**). Volumes may be large, and hemodynamic monitoring techniques should be used to protect against inadvertent volume overload.

Patients with thermal injury and concomitant multisystem trauma and those with inhalation injuries generally require fluid resuscitation in excess of calculated needs. Burn patients with preexisting cardiac or pulmonary disease require much greater attention to fluid management. Monitor fluid resuscitation closely by frequent assessment of vital signs, cerebral and skin perfusion, pulmonary status, and urinary output, as well as hemodynamic monitoring. Urine output should be 0.5 to 1.0 mL/kg/h.

Because the ED is primarily responsible for initial fluid resuscitation, discussion with burn specialists may be helpful in avoiding early under- or over-resuscitation. Patients with major burns can quickly receive excessive IV fluid during the prehospital and ED phases, particularly if two large-bore peripheral catheters are in place with fluid infusing at a wide-open rate. Document total fluid infused and titrate infusion to the patient's response. Clear documentation of fluid resuscitation should accompany all patients transferred to burn centers.

There are several methods of calculating fluid resuscitation for infants and children. The Parkland formula can be modified to maintain a urinary output of 1 mL/kg/h. Alternatively, a pediatric maintenance rate for 24 hours can be calculated, and an additional 2 to 4 mL/kg multiplied by

TABLE 216-5 ED Care of Patients with Major Burns

Airway	Breathing	Circulation	Adjuncts
Reevaluation of airway	Continuous pulse oximetry with supplemental O_2	Establishment of two large-bore peripheral IV lines in unburned skin	Placement of Foley catheter
Early intubation for any sign of breathing difficulty, airway burn, swelling, or suspected inhalation injury			Insertion of nasogastric tube
	Determination of carboxyhemoglobin level	IV administration of lactated Ringer's solution using Parkland or other burn resuscitation formula	Administration of tetanus booster
	Bronchoscopy if inhalation injury is a concern	Cardiac monitoring	Assessment for other trauma using Advanced Trauma Life Support guidelines
	Mechanical ventilation as needed		Pain control

percentage of body surface area burned is then added to the total. The entire amount is infused over the first 24 hours. In children weighing <25 kg, a goal urine output of 1.0 mL/kg/h is necessary. Add 5% dextrose to maintenance fluids for children weighing <20 kg due to smaller glycogen stores.[8]

Two additions or modifications to isotonic crystalloid resuscitation have been studied: adjuvant colloid and hypertonic saline. However, neither improves patient outcome. Adjuvant colloid given along with isotonic crystalloid resuscitation is not beneficial and is associated with decreased glomerular filtration rate.[22] Discussion of the use of adjuvant colloid continues, but it is used very little in North America and the United Kingdom,[23] although Israeli investigators have reported favorable results with the addition of colloid to their burn formulas.[24] Use of hypertonic saline has been associated with an increased rate of renal failure and death.[25] In an effort to decrease burn edema, protein loss, and abdominal compartment syndrome, investigators have also studied the efficacy of *permissive hypovolemia* in reducing burn edema and the multiple organ dysfunction that follows.[26] This practice necessitates invasive monitoring and is of interest, but it is not standard of care and should not be used in ED resuscitation at this time.

Electrical injuries, incineration burns, and associated crush injuries may produce rhabdomyolysis and myoglobinuria, leading to renal failure. Acute renal failure occurs in approximately 15% of patients admitted to burn centers and is associated with severe burns (mean body surface area involvement of 48%).[27] Therapy to limit renal damage from myoglobinuria should be initiated as outlined in chapter 89, "Rhabdomyolysis."

WOUND CARE

After evaluation and resuscitation of the patient, attend to burn wounds.[2] Initially, wounds are best covered with a clean, dry sheet. Later, small burns can be covered with a moist saline-soaked dressing while the patient is awaiting admission or transfer. The soothing effect of cooling on burns is most likely due to local vasoconstriction. Cooling stabilizes mast cells and reduces histamine release, kinin formation, and thromboxane B_2 production. For large burns, sterile drapes are preferred, because application of saline-soaked dressings to a large area can cause hypothermia.

Consult the admitting service or burn center early. Avoid the use of antiseptic dressings in the ED, because the admitting service will need to assess the wound. Wound care for transferred patients should be discussed with the accepting burn center. Do not delay transfer for wound debridement. For transferred patients, the referring facility should follow the accepting regional burn center's treatment protocol if available.

Escharotomy Patients with circumferential deep burns of the limbs may develop compromise of the distal circulation, particularly after initiation of resuscitation. The distal vascular status of such patients must be monitored closely, including pulses, capillary refill, pulse oximetry, and skin temperature. Doppler flow testing may likewise be useful. If vascular compromise is evident, escharotomy is indicated. The eschar is incised with a scalpel to the level of the fat on the mid-lateral portion of the limb, using care to avoid incising the fascia (i.e., fasciotomy). Elevated compartment pressures can be clinically evident. The incision may be extended to the hand and fingers (**Figure 216-8**). Escharotomy may provoke substantial soft tissue bleeding. Consider consultation by phone with a burn surgeon.

If there are circumferential burns of the chest and neck, eschar may restrict ventilation. An escharotomy of the chest wall should be performed to allow adequate ventilation. Incisions are made at the anterior axillary line from the level of the second rib to the level of the twelfth rib. These two incisions should be joined transversely so the chest wall can expand (**Figure 216-9**).

PAIN CONTROL

Burn injuries are exceedingly painful, and superficial partial-thickness burns are the most painful. Burn injury not only makes an otherwise already injured area and surrounding tissue more painful, but also causes hyperalgesia, chiefly mediated by A fibers. Local cooling may be soothing but does not provide pain control and can cause hypothermia;[28] additional pain management should be provided.

FIGURE 216-8. Escharotomy of the hand.

During the acute phase, the preferred route for most medication is IV. Opioids (e.g., morphine, fentanyl, hydromorphone) are the mainstay of treatment, and relatively large dosages may be required. Anxiolytic agents may also be given. Ensure adequate analgesia for patients being discharged, including a regimen for both background and breakthrough pain associated with dressing changes. Achieving adequate pain control is required for patients being considered for discharge.

CARE OF MINOR BURNS

Minor burns typically qualify for ambulatory care. Minor burns should be isolated, should not cross joints or be circumferential, and should not meet criteria for burn center care. Consider the patient's social situation and medical comorbidities when electing ambulatory care. Treatment of minor burns is listed in **Table 216-7**. Even in patients with burn injury <10% body surface area, patients at the extremes of age and/or patients with significant comorbidities, challenging social situations, or inadequate pain control should be treated as inpatients and possibly transferred to a burn center. Additionally, the patient's reliability should be considered as an important factor in deciding whether outpatient treatment is appropriate. Care of minor burns in discharged patients requires appropriate wound care instructions, adequate pain control, and coordination between the ED and the physician who will see the patient in follow-up.[2]

Because burns are painful, appropriate analgesia is required. After appropriate analgesia, clean the burn wound with mild soap and water or dilute antiseptic solution. Debride ruptured blisters. Also debride

FIGURE 216-9. Escharotomy of the chest wall.

TABLE 216-7 ED Care of Minor Burns

Provide appropriate analgesics before burn care and for outpatient use
Cleanse burn with mild soap and water or dilute antiseptic solution
Debride wound as needed
Apply topical antimicrobial:
1% silver sulfadiazine cream (not on the face or in patients with a sulfa allergy)
Bacitracin ointment
Triple-antibiotic ointment (neomycin, polymyxin B, bacitracin zinc)
Consider use of synthetic occlusive dressings
Provide detailed burn care instructions with follow-up in 24–48 h

large intact blisters or those over very mobile joints. Small blisters on nonmobile areas should be left intact. Tetanus immunization status should be assessed, and tetanus toxoid and/or immunoglobulin should be administered as needed.

Topical antimicrobials play an important role in reducing bacterial colonization and enhancing the rate of healing in burns.[8,9] A wide variety of topical agents are commonly used for minor burns. The most common is 1% silver sulfadiazine due to its easy application and minimal toxicity. It should not be used in patients with sulfa allergy or glucose-6-phosphate dehydrogenase deficiency, in pregnant patients near term, or in premature or young infants less than 2 months of age. Excretion into breast milk is not known; thus, silver sulfadiazine should be used with caution in nursing mothers. Do not use it on the face because it can stain the skin gray. When dressings are changed, remove silvadene to avoid gray discoloration, cleanse the skin, and apply new silvadene.

There are less costly and equally effective alternatives to silver sulfadiazine.[29,30] Alternative topical agents include bacitracin and triple-antibiotic (neomycin, polymyxin B, and bacitracin zinc) ointments. Although 8.5% mafenide acetate cream and 0.2% nitrofurazone ointment are available for topical application, these are not good choices for treatment of large burns in an outpatient setting. Mafenide penetrates the eschar well and is useful in treating patients with invasive infections, but it is a carbonic anhydrase inhibitor and can cause metabolic acidosis. Nitrofurazone is supplied in a polyethylene glycol vehicle that can be toxic if absorbed in patients with compromised renal function. Mafenide and nitrofurazone have little utility in the ED management of the acutely burn-injured patient. **Dressings should ideally be changed twice daily, gently removing residual ointment, for as long as the wounds continue to weep, then daily until healing is complete.**

Synthetic occlusive dressing is an alternative method of managing partial-thickness burns in outpatients. Wounds are cleansed and debrided prior to application of these dressings (e.g., Biobrane, Dow Hickam Pharmaceuticals, Sugar Land, TX; Tegaderm, 3M Health Care, St. Paul, MN; DuoDERM, Bristol-Myers Squibb, New York, NY). This strategy is most appropriate for clean burns on flat surfaces. The goal is for the dressing to adhere to the wound and act as artificial skin. Adherence is important because most bacteria causing infection wound infections produce fibrinolytic agents. Wounds should be reevaluated at 24 to 48 hours for adherence. The dressing is left in place until spontaneous separation of the dressing occurs. Wounds treated with synthetic occlusive dressings are well tolerated by patients, require few dressing changes, and heal with good appearance.[31]

Reassess burn wounds at 24 hours for depth and extent of burn. Explain the follow-up visit schedule and prescribe analgesics. Discharge instructions should include home burn care, pain control, and the symptoms and signs of infection. Burned extremities should be elevated for 24 to 48 hours to prevent edema. Advise patients to return to the ED with signs or symptoms of infection or if pain is inadequately controlled. Patients with deep partial-thickness, full-thickness, and mixed-thickness burns not requiring admission should be referred to a plastic surgeon or burn care specialist in 2 to 4 days for reevaluation and consideration for skin grafting.

CHAPTER 217

Chemical Burns

Anthony F. Pizon
Michael J. Lynch

INTRODUCTION AND EPIDEMIOLOGY

More than 25,000 products are capable of producing chemical burns. Exposures occur both occupationally and in homes. As many as 10% of all burn center admissions are the result of chemical burns. Although a smaller percentage of total burns, the mortality is high and may account for as many as 30% of all burn deaths.[1] Careful individual attention is required for chemical burn treatment due to the nature of concomitant tissue injury and chemical exposure.

PATHOPHYSIOLOGY

The skin is a barrier and transition zone between the internal and external environments. Although the outer stratum corneum layer of the skin functions as an excellent barrier against many chemicals, some penetrate it readily. Chemicals can produce burns, dermatitis, allergic reaction, thermal injury, and/or systemic toxicity.

Most chemicals produce tissue damage by their chemical reaction rather than by thermal injury. Certainly, some chemicals produce significant heat by means of an exothermic reaction. However, most skin damage is the result of the chemical's unique characteristics. Unlike thermal burns, chemical burn injuries require tailored evaluations and treatments based on the specific agent involved. Multiple factors influence tissue damage and percutaneous absorption of chemicals (**Tables 217-1 and 217-2**).

Most chemical burns are caused by acids or alkalis. At similar volumes and manner of contact, alkalis usually produce far more tissue damage than acids. **Acids tend to cause coagulation necrosis with protein precipitation and form a tough leathery eschar.** The eschar typically limits deeper penetration of the agent. **Alkalis produce liquefaction necrosis and saponification of lipids.** The result is a poor barrier to chemical penetration and deeper, ongoing burns. Other chemical injuries occur by various pathophysiologic mechanisms. Some chemical agents cause injury by more than one mechanism (**Table 217-3**).

Death early after severe chemical burns is usually related to hypotension, acute renal failure, and shock as a result of fluid loss. However, systemic toxicity and subsequent morbidity and mortality may also occur if chemicals are absorbed. Acidosis, hypotension, hyperkalemia, dysrhythmia, and shock can occur with systemic absorption of acids (**Table 217-4**).

GENERAL APPROACH TO CHEMICAL BURNS

The initial goal of treatment is to remove the patient from the exposure and prevent any further chemical exposure. If not performed prior to arrival, remove all exposed clothing immediately. With few exceptions, aggressive irrigation with water is the cornerstone of initial treatment for chemical burns. Chemical agents will continue to damage tissue until they are removed or inactivated. Dry chemical particles such as lime should be brushed away before irrigation. Sodium metal and related compounds should be initially covered with mineral oil or excised, because water can cause a severe exothermic reaction. Dilution of phenol (carbolic acid) with water may enhance penetration. **For the most**

Nature of the chemical
Lipid solubility, pH, concentration
Duration of contact
Poor irrigation, chemical-soaked garments, occlusive dressings

part, however, use of water or saline to irrigate a chemical burn should not be delayed while searching for other treatment agents and should ideally begin immediately at the scene of the accident. Almost universally, earlier irrigation means a better prognosis.

Hospital personnel should maintain universal precautions while decontamination is ongoing. At the very minimum, mask, face shield, chemical-resistant gown, gloves, and water-impervious boots should be worn at all times. The exact personal protective equipment worn will ultimately depend on the specific agent involved.

The amount of elapsed time to initiate dilution or removal of chemical agents is directly related to the eventual depth and degree of injury. Wounds irrigated 3 minutes after contact with some chemicals have a twofold greater chance of becoming full-thickness burns than wounds irrigated within 1 minute of chemical contact. The time required for irrigation varies. Severe alkali burns may require several hours of irrigation. Use pH indicator paper to determine continued presence of alkali or acid in burn wounds and possible need for further irrigation. Irrigation should continue until pH is neutral or near neutral.

Although thermal energy is produced in an exothermic reaction when using water irrigation, copious amounts of water will decrease the rate and intensity of the chemical reaction and dissipate the heat.[2] Continue irrigation at a gentle flow to avoid continued skin contact with chemicals.

After irrigation and debridement of remaining particles and devitalized tissue, apply topical antimicrobial agents to affected areas, and provide tetanus immunization as needed. Other than measures specific for a particular chemical burn, treatment following initial therapy is similar to that of thermal burns (**Table 217-5**). Aggressive fluid replacement is needed if extensive chemical burns are sustained. Analgesics may be needed, and in the case of allergic responses to chemicals, epinephrine, antihistamines, and steroids may be required.

ACID BURNS

Do not limit the examination of a patient with a significant chemical acid burn to the skin because acids may cause respiratory and mucous membrane irritation as well. Furthermore, skin absorption of some compounds may occur and result in systemic signs and symptoms.

With the exception of hydrofluoric acid, strong acids produce coagulation necrosis from the denaturation of proteins in the superficial tissue. Injury severity is related to the physical characteristics of the acid. Most substances with a pH <2 are strong corrosives. Other important tissue-damaging properties of acids include concentration, molarity, and complexing affinity for hydroxyl ions. The higher each of these factors is, the greater is the tissue damage. **Contact time with the skin is the most important chemical burn feature that healthcare professionals may alter.** For example, instantaneous skin decontamination of 18M sulfuric acid will cause no burn, but a 1-minute exposure can cause full-thickness skin damage.

TABLE 217-3 Classification of Chemicals

Classification of Chemical Damage	Mechanism of Injury
Acids	Protein denaturation as proton donors
Alkalis	Protein denaturation as proton acceptors
Organic solvents	Disruption of cellular membranes
Inorganic solvents	Scavenge ions and salt production within tissues

TABLE 217-4 Systemic Effects Associated with Chemical Burns

Chemical	Systemic Toxicity
Hydrofluoric acid	Hypocalcemia, hypomagnesemia, hyperkalemia, cardiac arrhythmias, sudden death
Tannic acid, chromic acid, formic acid, picric acid, phosphorus	Hepatic necrosis, nephrotoxicity
Cresol	Methemoglobinemia, massive hemolysis, multiple organ failure
Gasoline	Severe pulmonary, cardiovascular, neurologic, renal, and hepatic complications
Phenol (carbolic acid)	Cardiovascular and central nervous system toxicity
Sodium nitrate, potassium nitrate	Severe methemoglobinemia with refractory cyanosis
Dichromate solution	Liver failure, acute renal failure, death despite hemodialysis

ACETIC ACID

The dilute (<40%) acetic acid solution found in hair-wave neutralizer solutions is perhaps the most common cause of chemical burns to the scalp in women. Prolonged contact, especially with an already damaged scalp, can cause a partial-thickness burn that heals slowly and is prone to infection. Initial treatment is copious water irrigation. Oral antibiotics should be prescribed if the scalp burn has created open skin lesions.

CARBOLIC ACID (PHENOL)

Phenol (carbolic acid), a corrosive organic acid used widely in industry and medicine, denatures proteins and causes chemical burns characterized by a relatively painless white or brown coagulum. Paradoxically, dilute phenol penetrates tissue more readily than the concentrated form. Systemic absorption may result in life-threatening cardiac dysrhythmias or seizures. The unpleasant, acrid odor of phenol, detectable in air at 0.047 parts per million, and its low volatility help prevent airborne exposure. Although commercially available in concentrations up to 90%, even dilute solutions of 1% to 2% phenol may cause a burn if contact is prolonged or extensive. Chemically related phenolic compounds that induce skin damage include cresol, creosote, and cresylic acid.

Coagulation necrosis of the involved area is common. Necrotic tissue may delay absorption temporarily, but phenol may become entrapped under the eschar. Remove contaminated clothing and begin water irrigation immediately. Water lavage alone may not be totally effective, because the necrotic coagulum inhibits water penetration to the deeper layers.

Decontamination is more effective by the use of an undiluted polyethylene glycol solution of molecular weight 200 to 400 or by a gentle wash with isopropyl alcohol. Adequate supplies of either irrigation solution should remain stored for such use. Either irrigation solution reduces the extent of cutaneous corrosion and also decreases systemic toxicity. **An isopropyl alcohol rinse is equivalent to polyethylene glycol in removing phenol.**[3] The advantage of isopropyl alcohol is its ready availability. If neither polyethylene glycol nor isopropyl alcohol is available in adequate supplies, large volumes of water should be used.

CHROMIC ACID

Chromium hexavalent compounds (Cr^{6+}) are powerful oxidizers. The chromate ion in chromic acid produces a chronic penetrating ulcerating lesion of the skin. Associated signs and symptoms of chromic acid

TABLE 217-5 Treatment of Select Chemical Burns

Chemical	Treatment	Comments
Acids		
All acid burns require prompt decontamination and copious irrigation with water		
Acetic acid	Copious irrigation	Consider systemic antibiotics for extensive scalp burns
Phenol (carbolic acid)	Copious irrigation	Isopropyl alcohol may also be used
	Sponge with undiluted polyethylene glycol 200–400	
Chromic acid	Copious irrigation	Observe for systemic toxicity
Formic acid	Copious irrigation	Dialysis may be needed for severe toxicity
Hydrofluoric acid	Copious irrigation	Consider intradermal injection of 10% calcium gluconate or intra-arterial calcium gluconate for severe cases Monitor serum calcium and magnesium in severe exposure
	10% calcium gluconate intradermal	
	Topical calcium gluconate gel	25 mL of 10% calcium gluconate in 75 mL of sterile water-soluble lubricant (K-Y jelly or US jelly)
Nitric acid	Copious irrigation	Consult with burn specialist
Oxalic acid	Copious irrigation	Evaluate serum electrolytes and renal function
	IV calcium may be required	Cardiac monitoring for serious dermal exposure
Alkalis		
All alkali burns require prompt decontamination and copious, prolonged irrigation with water		
Portland cement	Prolonged copious irrigation	May need to remove cement particles with a brush, such as a preoperative scrubbing brush
Elemental Metals		
Water is generally contraindicated in extinguishing burning metal fragments embedded in the skin		
Elemental metals (sodium, lithium, potassium, magnesium, aluminum, and calcium)	Cover metal fragments with sand, foam from a class D fire extinguisher, or mineral oil	
	Excise metal fragments that cannot be wiped away	
Hydrocarbons		
Gasoline	Decontamination	
Tar	Cool before removal	Baby oil can be used
	Remove using antibiotic ointment containing polyoxylene sorbitan (polysorbate)	
Vesicants		
Mustards	Decontaminate	If limited water supply, adsorbent powders (flour, talcum powder, fuller's earth) can be applied to the mustard and then wiped away with a moist towel
	Copious irrigation	
Reducing Agents		
Alkyl mercury compounds	Copious irrigation	Blister fluid is high in metallic mercury content
	Debride, drain, and copiously irrigate blisters	
Lacrimators		
Tear gas	Copious irrigation	May cause respiratory symptoms if inhaled
Pepper spray	Copious irrigation	May cause respiratory symptoms if inhaled
Miscellaneous		
White phosphorus	Remove clothing	Systemic toxicity is a significant concern
	Copious irrigation, keep exposed skin areas wet or submerged until all particles have been removed due to risk of ignition when exposed to air	
	Debride visible particles	
Airbag	Prolonged copious irrigation	

exposure are conjunctivitis, lacrimation, and ulceration of the nasal septum. Systemic chromium toxicity can cause liver or renal failure, GI bleeding, coagulopathy, and CNS disturbances. Significant symptoms may occur after only 1% to 2% body surface area burns. **A 10% body surface area cutaneous burn caused by chromic acid can be fatal due to systemic toxicity.** Any acute skin exposure to chromic acid should be treated with copious water irrigation and observation for systemic effects. Aggressive excision is the best method for prevention of systemic effects because depth of the burn is difficult to determine and absorption of chromium may continue after irrigation.[4]

FORMIC ACID

Formic acid in 60% solution is used by acrylate glue makers, cellulose formate workers, and tanning workers. Formic acid produces coagulation necrosis of the skin. Systemic effects, including decreased respiration,

anion gap metabolic acidosis, and hemolysis have been reported.[5] Treatment includes immediate decontamination and irrigation with water. Systemic toxicity may require intravenous sodium bicarbonate for the metabolic acidosis or exchange transfusions for severe hemolysis.

HYDROCHLORIC AND SULFURIC ACIDS

The dermal toxicity of hydrochloric acid and sulfuric acid is so well recognized that early decontamination and water irrigation usually prevent severe burns to the skin. These acids can burn the skin dark brown or black. Toilet bowl cleaners may contain 80% solutions of sulfuric acid, and some drain cleaners may be 95% to 99% sulfuric acid solutions. Munitions, chemical, and fertilizer manufacturers commonly use 95% to 98% sulfuric acid solutions in their industrial processes. Automobile battery fluid is 25% sulfuric acid. Most household bleaches are only 3% to 6% hypochlorite solutions, which, although acidic, cause little damage unless they are in contact with skin for a prolonged time. Treatment is the same as for formic acid burns.

HYDROFLUORIC ACID

Hydrofluoric acid is used in the production of high-octane fuel, etching and frosting glass, semiconductors, microelectronics/microinstruments, germicides, dyes, plastics, tanning, and fireproofing material and is used in cleaning stone and brick buildings. It is also a very effective rust remover.

Unlike other acids, hydrofluoric acid penetrates deeply and will cause progressive tissue loss. It produces burns in two ways. First, hydrogen ions cause direct cellular damage as other acids do through protein denaturation. Second, free fluoride ions scavenge intracellular cations, such as calcium and magnesium, disrupt cellular membranes, and inhibit the sodium/potassium/ATPase. This leads to systemic hypocalcemia, hypomagnesemia, and hyperkalemia. Locally, free fluoride ions cause spontaneous depolarization of nerve tissue and severe pain. Pain will persist until all free fluoride ions have been neutralized.

The dermal effects may not be immediately noted and appear to be more related to the concentration of hydrofluoric acid than to the duration of exposure. Solutions >50% produce immediate pain and tissue destruction. Solutions <20% may not produce signs and symptoms until 12 to 24 hours after exposure. The skin often develops a blue-gray appearance with surrounding erythema.

The treatment of hydrofluoric acid burns consists of two phases. The first, immediate phase is copious water irrigation of the affected skin for 15 to 30 minutes. This may be the only treatment that is needed if the hydrofluoric acid solution is <20% concentration, the duration of exposure was very brief, and decontamination is begun immediately. Severe, persistent pain denotes a more serious injury requiring the second phase of treatment.

The second phase of treatment is aimed at replacing calcium and magnesium and detoxifying the enzyme-poisoning fluoride ion. Two ions—calcium (Ca^{2+}) and magnesium (Mg^{2+})[6]—bind the fluoride ion and curtail its toxic effects. However, the overwhelming clinical experience to date has been with calcium gluconate, so it is the agent of choice. Calcium gluconate can be administered as a topical preparation, subcutaneous/intradermal injection, or intra-arterial infusion. A calcium gluconate gel made with a water-soluble lubricant is generously applied to the affected skin. **The topical preparation is made by mixing 3.5 grams of calcium gluconate powder in 5 oz of water-soluble lubricant, or 25 mL of 10% calcium gluconate in 75 mL of water-soluble lubricant.** Calcium chloride or calcium carbonate can be substituted if no calcium gluconate is available. The main limitation of topical therapy is the impermeability of the skin to calcium, and therefore, topical therapy is limited to use in mild, superficial burns. Most importantly, topical therapy should not delay intradermal or intra-arterial injections for severe burns.

Treatment with intradermal injection of a 10% calcium gluconate solution through a 27-gauge needle into the hydrofluoric acid–burned skin is a very effective treatment. **A typical dose of 0.5 mL of 10% calcium gluconate per square centimeter of burned skin is recommended.** Pain relief is nearly immediate, and, indeed, the elimination of pain may be used as a guide for further therapy. Recurrence of pain indicates the need for further therapy. Unfortunately, injection therapy has several disadvantages: (1) only limited amounts of calcium are delivered to the tissue; (2) hyperosmolarity and inherent toxicity of free calcium ions cause more pain initially, and more tissue damage is possible if calcium is not bound to fluoride; (3) vascular compromise can result if too much fluid is injected, especially into digits; and (4) rapid penetration of hydrofluoric acid beneath the nail requires nail removal to administer the calcium gluconate into the nail bed adequately. **Acute hydrofluoric acid contamination of the hands, feet, digits, or nails requires consultation with a medical toxicologist and plastic surgeon.**

Intra-arterial infusion of calcium gluconate may be used to prevent tissue necrosis and stop the pain associated with hydrofluoric acid burns.[7] This should be performed as soon as possible after the initial burn, preferably within 6 hours of insult. Place an intra-arterial catheter in the appropriate vascular supply (the brachial artery if the entire hand is affected) and connect to a three-way stopcock to which is attached an arterial pressure-monitoring device and the infusion syringe of calcium gluconate. A 50-mL syringe may be filled with 10 mL of a 10% calcium gluconate solution and 40 mL of 5% dextrose in water and infused over 4 hours. The arterial pressure-monitoring device ensures that the catheter has not dislodged from the lumen of the cannulated artery. Repeat infusion may be needed if pain recurs within 4 hours. Intra-arterial infusion avoids the disadvantages of local infiltration therapy, but it has its own disadvantages: it is an invasive vascular procedure that (1) may result in arterial spasm or thrombosis, (2) requires more time and hospital resources, and (3) requires experience in the technique.

Inhalation of hydrofluoric acid can cause immediate or delayed pulmonary injury. All cases of suspected inhalation injury should be admitted for observation even if asymptomatic. Nebulized calcium gluconate may be attempted in these cases, but no controlled studies exist for its use. **The solution is made by adding 1.5 mL of 10% calcium gluconate solution into 4.5 mL of sterile water or saline and is administered by nebulizer.**

Ocular exposure to hydrofluoric acid requires water irrigation for at least 30 minutes and requires emergent ophthalmologic consultation. An animal study suggests that calcium-containing irrigation fluids for eye exposures may be harmful.[8] Therefore, standard eye irrigation practices should be used. The possibility of severe injury and eye necrosis should not be taken lightly. In severe ocular exposures, systemic absorption is possible as well.

Systemic toxicity from dermal hydrofluoric acid exposure can result in ventricular fibrillation as a result of systemic acidosis, hyperkalemia, hypomagnesemia, and hypocalcemia. **In major hydrofluoric acid burns, immediately administer IV calcium and magnesium, using standard slow IV rates, before laboratory results are available.** Once patients develop hypocalcemia or hypomagnesemia, it is very difficult to restore these electrolyte deficiencies. Cardiac monitoring, IV access, and electrolyte monitoring should be performed in all cases of significant hydrofluoric acid dermal burns (**Table 217-6**).

METHACRYLIC ACID

Methacrylic acid, found in many artificial nail cosmetic products, can produce severe dermal burns, usually in preschoolers. Emergency treatment is copious water irrigation.

TABLE 217-6 Options for Treatment of Hydrofluoric Acid Skin Burns

1. Copious irrigation for 15–30 min immediately.
2. Application of calcium gluconate gel, 25 mL of 10% calcium gluconate in 75 mL of water-soluble lubricant.
3. Further treatment options as dictated by patient response:
   a. Dermal injection of 10% calcium gluconate at the rate of 0.5 mL/cm^2 of skin surface using a small-gauge needle.
   b. Arterial infusion over 4 h (40 mL of 5% dextrose in water with 10 mL of 10% calcium gluconate).
   c. Consider supplemental magnesium and calcium IV.

NITRIC ACID

Nitric acid is used in industry for casting iron and steel, electroplating, engraving, and fertilizer manufacturing. Upon contact with skin, nitric acid can produce tissue damage by oxidation and may turn the skin yellowish as it is burned. Emergency treatment consists of copious water irrigation and standard burn care (see chapter 216, "Thermal Burns").

OXALIC ACID

Oxalic acid is used for leather tanning and blueprint paper. Oxalic acid binds calcium and prevents muscle contraction. The wounds should be irrigated with water, and IV calcium may be required. Serum electrolytes and renal function should be evaluated, and cardiac monitoring should be instituted after serious dermal exposure.

ALKALI BURNS

Alkalis penetrate skin deeper and longer than acids and present a greater danger of toxicity from systemic absorption. Wounds may initially look superficial only to become full-thickness burns in 2 to 3 days. Alkalis combine with protein and lipids in tissue to form soluble protein complexes and soaps that permit passage of hydroxyl ions deep into tissue. Soft, gelatinous, friable, brownish eschars are often produced (**Figure 217-1**). Strong alkalis have a pH >12.

LYES

Strong, corrosive alkalis ("lyes") include ammonium, barium, calcium, lithium, potassium (caustic potash), and sodium (caustic soda) hydroxides. Lyes are widely used in industry and are found in home products such as drain and toilet cleaners, detergents, and paint removers. The urine sugar reagent tablet Clinitest® (Bayer) contains anhydrous sodium hydroxide.[9] Ammonium hydroxide is used in the production of synthetic fibers and extensively in agriculture. Exposure to these chemicals can result in severe toxicity including mucous membrane, ocular, dermal, GI, and inhalational/pulmonary injury. As a mode of assault, lyes have a lower mortality rate than gunshot wounds or stabbings, but victims often suffer long-term pain, scarring, and blindness. Suicidal ingestion of lye may result in rapid death from upper airway occlusion. Late morbidity related to esophageal and gastric necrosis may be minimized by early surgical intervention with esophagogastrectomy. The mainstay of treatment is immediate, voluminous, and persistent irrigation.[10] **Lyes are extremely corrosive and penetrating. Burns require copious irrigation for long periods of time.**

LIME

Lime (calcium oxide) is found in agricultural products and cements. There is considerable variability of lime content in different grades of cement, with fine to textured masonry cement having more lime than concrete. Lime is converted by water to the alkali calcium hydroxide. Upon skin contact, lime draws water out of the skin. **All dry lime particles should be brushed away before irrigation. Even a small amount of water may generate an exothermic reaction resulting in calcium hydroxide formation and tissue injury.** Brisk irrigation with a large volume of water (taking care to avoid splashing in eyes) should be used and will permit dissipation of heat.

FIGURE 217-1. Deep alkali burn. [Reproduced with permission from http://www.burnsurgery.org/Modules/initial_mgmt/sec_6.htm.]

PORTLAND CEMENT

Portland cement, which accounts for a major proportion of the cement used in the United States, is a mixture of sand, lime, and other metal oxides. In the presence of water, calcium hydroxide, sodium hydroxide, and potassium hydroxide may all be formed. Workers who kneel in wet cement or get cement in their boots may discover burns hours after initial contact. In addition, skin may become irritated from gritty material, and a contact dermatitis may develop in individuals sensitive to the chromate contained in the material. Treatment of cement burns may require cleaning the wound with a brush, such as a preoperative scrubbing brush, to remove cement particles imbedded in the dermis. Careful attention to appropriate donning of personal protective equipment should be emphasized to patients suffering dermatitis or burns from contact with cement.

METALS

Foundry workers are sometimes burned by molten metal, which may spill or splash on body parts and run down into the boots. Elemental metals, sodium, lithium, potassium, magnesium, aluminum, phosphorus, and calcium may all cause burns. When exposed to air, some elemental metals spontaneously ignite. **Water is generally contraindicated in extinguishing burning metal fragments embedded in the skin because the resultant explosive exothermic reaction can lead to significant tissue injury. Burning metal may be extinguished with a class D fire extinguisher, smothered with sand, or covered with mineral oil.** Wound debridement should include excision of metal fragments that cannot be wiped away. Metal fragments should be placed in mineral oil to prevent further ignition.

HYDROCARBONS

GASOLINE

Hydrocarbons cause a fat-dissolving corrosive injury to the skin referred to as defatting dermatitis. Gasoline, a complex mixture of alkanes, cycloalkanes, and aromatic hydrocarbons, is the most common hydrocarbon burn treated in the ED.

A hydrocarbon chemical burn typically resembles a thermal scald or a partial-thickness burn, although full-thickness burns can result from prolonged contact with gasoline.[11] During extremely cold weather, topical gasoline exposure may lead to frostbite when rapid gasoline evaporation causes heat loss from the skin. Systemic effects of hydrocarbon absorption include neurologic, pulmonary, cardiovascular, GI, and hepatic injuries. For further discussion, see chapter 199, "Hydrocarbons and Volatile Substances."

The primary treatment is decontamination by removing saturated clothing and irrigating exposed skin with soap and water. Otherwise, management is as for a thermal burn.

HOT TAR

Hot tar is derived from long-chain petroleum and coal hydrocarbons. Roofing tars and asphalt are heated to temperatures up to 500°F (260°C), and the burns sustained are usually more thermal than chemical. Although the surface area size of the burn is usually small, solidified material stuck to skin and hair is difficult to remove. **If hot, the tar should be cooled to prevent continued thermal injury.** Manual mechanical debridement can be painful and destructive to skin structures. Polyoxylene sorbitan (polysorbate), contained in many antibiotic

ointments, is an emulsifying agent that can be used to remove tar. Industrial removal agents such as De-Solv-It®, a citrus and petroleum distillate, are also effective in tar removal. Baby oil is also effective for tar removal.

VESICANTS (DIMETHYL SULFOXIDE, CANTHARIDES, AND SULFUR MUSTARD)

Dimethyl sulfoxide, cantharides, and mustard gas are vesicant or drying agents. Skin burns with edema and blister formation occur due to production of ischemia and anoxic necrosis at the site of contact. Dimethyl sulfoxide is a water-soluble organic solvent used in industry. It is available without prescription and is used topically for sprains, bruises, minor burns, and joint pain. Due to its chemical composition and solubility, dimethyl sulfoxide can penetrate barrier surfaces such as nitrile gloves. Cantharides ("Spanish Fly") is occasionally used for its supposed aphrodisiac effects. Sulfur mustard is a vesicant historically used in chemical warfare. An alkylating agent, exposure results in inhibition of cellular enzymatic activity, leading to necrosis. For further discussion, see chapter 8, "Chemical Disasters."

Skin damage following vesicant exposure can be severe and result in deep skin penetration, edema, blisters, ulcers, and serious morbidity. Immediate, copious irrigation with water or saline may mitigate the extent of tissue injury. Skin can also be decontaminated by using adsorbent powders such as flour, talcum powder, and fuller's earth if the supply of water is limited. These powders adsorb the mustard from the skin and should be wiped away with a moist towel. Almost any material can be used to brush the vesicant away from skin. The military uses M258A1 kits for skin decontamination. These kits contain three sets of towelettes, one of each containing phenol, sodium hydroxide, and sodium benzene sulphonochloramine (chloramine). Chloramine produces "free" chlorine, which inactivates sulfur mustard. Povidone iodine shows great promise in the prevention and early treatment of skin damage caused by sulfur mustard. Human data are currently lacking, but in animal models, both prevention of burns and immediate (<10 minutes) treatment of exposure yielded impressive skin protection.[12]

POTASSIUM PERMANGANATE

Potassium permanganate is an oxidizing agent that is mildly irritating in dilute solution, but in concentrated solution, it can produce dermal burns with a thick, brownish purple eschar of coagulated protein. Burns should be copiously irrigated with water.

ALKYL MERCURY COMPOUNDS

Alkyl mercury compounds, which are reducing agents used in disinfectants, fungicides, and wood preservatives, can produce dermatitis or burn lesions. Lesions typically are erythematous with blister formation. The blister fluid is high in metallic mercury content. The burning process continues as long as the agent remains in contact with skin. Partial-thickness burns deepen if the blister fluid is allowed to remain, so the blisters should be debrided, drained, and copiously irrigated. Repeated or prolonged exposure to topical mercury compounds may lead to systemic mercury toxicity.

LACRIMATORS OR TEAR GAS

Lacrimators, or tear gas, such as 2-chloroacetophenone, o-chlorobenzylidene malonitrile, and oleoresin capsicum (pepper spray), cause skin and mucosal irritation within 20 to 60 seconds of exposure and can lead to development of contact dermatitis. Although the skin injury is usually limited, inhalation and eye injuries may be severe. Treatment of skin exposure is rapid removal from the offending agent followed by saline irrigation. Ocular irritation is treated with copious water irrigation, followed by slit-lamp examination for corneal damage. Arrange ophthalmology follow-up in 24 hours. High concentrations of lacrimators cause structural damage of the cornea. Inhalation injuries are treated with respiratory support including oxygen and bronchodilators. There is no role for steroid therapy.[13]

WHITE PHOSPHORUS

White phosphorus is used as an incendiary in munitions and fireworks and as a component of insecticides, rodenticides, and fertilizers. It ignites spontaneously when exposed to air and is rapidly oxidized to phosphorus pentoxide. Burns caused by both its solid and liquid forms are seen in both the military and civilian populations. In munitions, white phosphorus is solid, but some of it may liquefy with detonation. Death has been reported in burns covering <10% body surface area.

Flaming droplets of inorganic phosphorus may embed beneath the skin. The heat of the reaction causes tissue destruction. Particles continue to oxidize slowly until debrided, neutralized, or completely oxidized. As long as phosphorous is exposed to air, it will continue to burn. Remove contaminated clothing and visible particles, and copiously irrigate burns with normal saline or water. Skin exposed to white phosphorus must remain wet or immersed in water until completely debrided to prevent further injury. **Wood's lamp** examination aids identification of remaining phosphorus as it fluoresces. **Copper sulfate solution should not be used despite its ability to detoxify phosphorous because it causes hemolysis and increases mortality.**

White phosphorus burns are characterized by slow healing and ongoing burning, necessitating early and aggressive treatment. Systemically absorbed phosphorous is a serious concern. Hypocalcemia, hyperkalemia, and hepatic and renal injury all have been reported. Even patients with small burns should be considered for admission or transfer to a burn center for aggressive hydration, monitoring, and further treatment.[14] Treatment providers should take care to wear protective equipment and avoid direct contact with the patient's clothing, feces, and emesis.

AIRBAG BURNS

Approximately 8% of individuals suffering injuries related to airbag deployment are burned. Airbags deploy by ignition of solid propellant—sodium azide and cupric oxide—that creates an exothermic reaction leading to rapid inflation of the airbag. Many other gases are created during activation, including corrosives such as sodium hydroxide, nitric oxide, ammonia, and multiple hydrocarbons. An airbag is deflated within 2 seconds of inflation through exhaust side ports on the bag. Burns associated with airbags include friction, thermal, and chemical burns.[15] Sodium hydroxide produced during airbag activation can cause chemical keratitis. Full-thickness skin burns have been reported. Perform slit-lamp examination for eye irritation to detect keratitis. Treatment of airbag chemical burns is similar to any alkali burn: immediate and copious water irrigation.

OCULAR BURNS

Chemical burns to the eyes are ocular emergencies requiring immediate treatment.[16]

If the nature of the chemical is not known, use pH paper to determine the presence of acid or alkali. Acid quickly precipitates the superficial tissue proteins of the eye, producing the typical "ground glass" appearance of the cornea. **Damage sustained secondary to acid burns is, in most cases, immediate and limited to the area of contact.** The posterior segment of the eye rarely suffers injury, but prolonged exposure, highly concentrated solution, or exposure to hydrofluoric acid may lead to deeper penetration and permanent injury.

Alkali burns are generally more severe, frequently with unsightly and disastrous results. Higher pH, more concentrated solution, and longer duration of exposure are associated with greater injury. **In a short period of time, strong alkalis can penetrate the cornea, anterior chamber, and retina, with destruction of all sensory elements, thus causing complete blindness** (see Figure 241-50 in chapter titled "Eye Emergencies").

The penetration of alkali can continue for hours to days, resulting in globe perforation. The vessels of the conjunctiva and sclera as well as collecting veins of the anterior chamber may be destroyed, leading to secondary glaucoma. Second- and third-degree burns of surrounding tissue can complicate the burn.

Treatment of eye burns should not be delayed. Immediate treatment is copious and continuous water irrigation at the scene, in transport, and at the hospital. Eye-irrigation kits may be used. Although specific solutions may be beneficial in irrigation of the injury, delay in irrigation cannot be justified. Sterile water or saline is recommended. **In general, 1 to 2 L of normal saline for each eye for 30-minute continuous irrigation is the minimum treatment. Neutralizing substances should not be used.**

Acid burns may not require as much volume or treatment time as alkali burns. For treatment of severe alkali burns, 24 hours or more of continuous irrigation may be necessary. Checking the pH in the conjunctival sac to see whether it has returned to 7.4 is helpful in determining need for further irrigation. However, extended 2- to 3-hour irrigation, despite apparent conjunctival pH correction, is recommended in the setting of strong alkaline or hydrofluoric acid burns with obvious examination abnormality to correct anterior chamber pH as well as conjunctival pH. **During irrigation, the eyelid may have to be held open manually or with retractors due to severe orbicularis spasm (see chapter 241).** The eyelids should be everted. **Sweep the fornices with a wet cotton applicator to remove any particulate matter, especially if the pH is not responding well to irrigation.**

Pain control with topical anesthetics during evaluation and treatment is necessary. Systemic opioids may be necessary for severe pain or associated injuries. **Emergency ophthalmology consultation is needed for corneal burns.** For additional discussion, see chapter 241.

IATROGENIC CHEMICAL BURNS

Iatrogenic chemical burns have been caused by the use of potassium permanganate at an inappropriately high concentration to treat dermatologic problems. Dimethyl sulfoxide used as a transcutaneous vehicle for minor sprains has caused burns. Patients in the operating room may develop burns from skin preparation solutions. Thimerosal, which has a high mercury content, is the most common agent implicated. Mechanical abrasion of the skin from scrubbing and from pooling of the skin preparation agent under the torso or tourniquet predisposes patients to burns. Blister formation, skin sloughing, and eschar development have been reported in neonates when isopropyl alcohol pledgets were substituted for conducting paste beneath limb electrocardiograph electrodes. Silver nitrate used to cauterize umbilical granulomas in infants reportedly has caused periumbilical burns.

CHAPTER 218

Electrical and Lightning Injuries

Caitlin Bailey

INTRODUCTION

Electrical injuries are divided into high-voltage injuries (≥1000 V), low-voltage injuries (<1000 V), and electric arc flash burns, which by definition do not result in passage of current through the tissues. Lightning injury is an extreme and unique form of electrical injury. This chapter also discusses injuries caused by electronic control devices, such as the **Taser®**. Burns from electrical accidents can result from heating due to electric current flow through tissues, explosions, and burning of flammable liquids, clothes, and other objects. Burns are discussed in the chapter 216, "Thermal Burns."

EPIDEMIOLOGY

Approximately 6500 electrical injuries occur per year in the United States, accounting for 4% of total burns. Of these, the majority are work related (61%), mostly industrial injuries. The overall complication rate is 10.6%, with the fewest complications among children age 1 to 5 years (2%).[1] The most common high-voltage injuries in the United States are also work related and include arc burns in electricians and high-voltage injuries in power line workers.[2] The Electrical Safety Foundation International estimates that contact with electric current caused nearly 1800 workplace fatalities between 2003 and 2010.[3] High-voltage power line injuries are particularly disabling because they often lead to deep-muscle necrosis and the need for fasciotomy and amputation.[2]

BASICS OF CURRENT FLOW

Electric current is the movement of electrical charges. **Table 218-1** lists a few key terms related to electricity.

Current flow is measured in amperes. Current flow is driven by an electrical potential difference, which is measured in volts. Intervening material between two or more contact points resists electric current flow; this resistance is measured in ohms. Ohm's law describes the relationship between current (I), voltage (V), and resistance (R) and states that the *current* through a conductor between two points is directly proportional to the potential difference or voltage drop across the two points and inversely proportional to the resistance between them. For example, a person who grasps a grounded pipe in one hand and a metal cable connected to a 120-V source in the other hand will experience a current flow through the body, the magnitude of which varies inversely with the resistance of the circuit. If the total resistance from the power source, through the person, and to ground is estimated to be 1000 Ω, the current would be I = (120 V)/(1000 Ω) = 0.120 A = 120 mA.

Conductors are materials that allow electric current to flow easily. Insulators are materials that do not allow electric current flow. Most biologic materials conduct electricity to some extent. Tissues with high fluid and electrolyte content conduct electricity better than tissues with less fluid and electrolyte content. Bone is the biologic tissue with the greatest resistance to electric current, whereas nerves and vascular structures have low resistance. Dry skin has high resistance, but sweaty or wet skin has much less resistance.

Many of the physiologic effects of electric shock are related to the amount, duration, and type of current (alternating current [AC] or direct current [DC]) and the path of current flow (**Table 218-2**). DC current flows in a constant direction, whereas AC current alternates direction in a cyclical fashion. **Standard household electricity is AC. Electricity in batteries and lightning is DC. Low-frequency (50- to 60-Hz) AC can be more dangerous than similar levels of DC because the alternating current fluctuations can result in ventricular fibrillation.** The identification of electric shock as due to AC or DC is also important

TABLE 218-1 Electrical Terms and Units of Measure

Term	Unit of Measure
Electric current Movement of electrical charges	Amperes
Current flow Driven by voltage or electrical potential difference	Volts
Resistance Hindrance to flow of current	Ohms
Ohm's law (current = voltage/resistance) The current is proportional to voltage. The current is inversely proportional to resistance.	—

TABLE 218-2 Effects of Current

Effect	Current Path	Minimum Current: 60 Hz AC (mA)*
Tingling sensation, minimal perception	Through intact skin	0.5–2.0
Pain threshold	Through intact skin	1–4
Inability to let go: tetanic contractions of hand and forearm tighten grasp, decreasing skin resistance	From hand through forearm muscles into trunk	6–22
Respiratory arrest: can be fatal if prolonged	Through chest	18–30
Ventricular fibrillation	Through chest	70–4000
Ventricular standstill (asystole): similar to defibrillation; if current stops, sinus rhythm may resume	Through chest	>2000

*Ranges are approximate and depend on various factors.

to reconstruct the mechanism of injury. AC current can produce muscular tetany, during which the victim cannot let go of the electrical source. Both AC and DC current can hurl the victim away from the current source, which results in severe blunt force injury.

For current to flow through an individual, a complete circuit must be created from one terminal of a voltage source to a contact area on the body, through the subject, and then from another contact on the person to the other terminal of the voltage source (or to a ground that is connected to the voltage source). Current flows through a person from one contact area to another along multiple, somewhat parallel paths. For example, electrical power source contacts just on the left hand and left leg would result in current flow through those limbs and the trunk, including the heart, muscles of respiration, and other tissues in the trunk. Current would not flow through the other limbs or head, because they are not in an electrically conductive path between the two power source contacts. The pattern of current flow through the body, if known, can be used to raise or lower suspicion of injury to certain body parts; for instance, hand-to-hand flow involves crossing the thorax and heart, raising the suspicion for cardiac involvement.

An exception to the requirement that a circuit be present occurs with electrostatic discharge. Electrostatic discharge is the transfer of excess charge to or from a person or object to another object and results when objects at different potentials come into direct contact with each other. An example is static electricity, which can cause pain and reflex movements.

MECHANISMS OF ELECTRICAL INJURY

HIGH- AND LOW-VOLTAGE INJURIES

The risk for serious and fatal electrical injury increases with voltage, especially >600 V (Table 218-2). High voltage is usually defined as >1000 V. Power lines in U.S. residential areas typically carry 7620 V AC. This is stepped down by transformers to 240 V AC before entering most residential and nonindustrial buildings. **In the United States, home outlets are 120 V, and in Europe and Australia, they are 240 V.** Urban subway electrical third rails may be 600 V or more AC or DC. High-voltage injuries are more often associated with severe musculoskeletal, visceral, and nervous system injury than are low-voltage injuries.

Electricity-induced injuries can occur via several mechanisms: (1) direct tissue damage from the electrical energy, (2) tissue damage from thermal energy, and (3) mechanical injury from trauma induced by a fall or muscle contraction.

ELECTRICAL BURNS

Electrical burns are severe when high voltages are involved, because only a fraction of a second of current flow is necessary for severe damage to occur.[4] Burns are less common with low-voltage injuries, because low-voltage contact produces little heat energy in the skin and other tissues.[5]

ELECTRIC ARC INJURIES

Electricity arcing from one conductor to another may radiate enough heat to burn and even kill persons 10 or more feet from the arc. There can also be a blast force that throws the person. Arcs that do contact a person directly will have heating due to current flow through the body, in addition to the flash burn and mechanical blast forces**.** Serious burns often result.[6] The voltages that create an electric arc are usually in the thousands of volts. Temperatures as high as 20,000°C (35,000°F) are created. Serious, and sometimes fatal, burns may result from heat radiated by the arc and clothing ignited by the arc.

TETANIC CONTRACTIONS

Electric current can induce sustained muscular contraction, or tetany. The overall effect varies according to type (AC or DC), frequency, voltage, and extent of contact.[4,7] For example, AC current flowing through the forearm can cause flexor tetany of the fingers and forearm that overpowers actions of the extensor muscles. Forceful muscle contractions can cause fractures and joint dislocations, especially around the shoulders.[8] If the hand and fingers are properly positioned, the hand will grasp the conductor tightly, leading to prolonged, low-resistance contact with the power source because the person cannot let go. This allows current to flow for many seconds or minutes.

The increased duration of contact and the decreased contact resistance caused by a tight sustained grasp greatly increase the heat-related damage to deep tissues. Heating due to electric current builds over time. Because heating is directly proportional to the duration of current flow and proportional to the square of the current amplitude (until burning and other tissue changes occur), a person who is unable to let go of a conductor for 30 seconds receives about 90 times as much tissue heating as a person who recoils from the voltage source in one third of a second. To make injury still more severe, a tight grasp on a conductor decreases contact resistance, which leads to an increase in current flow. Thus, heat-related injury to deep tissues is often more than a hundred times worse when there is a history of the patient's being unable to let go of the conductor.

Current flow through the trunk and legs may cause brief, but strong, opisthotonic (arching) posturing and leg movements. The person appears to be thrust from the voltage source due to these muscle contractions and may sustain mechanical trauma in addition to electrical injury. If a person does manage to hold on to a high-voltage source, severe tissue damage occurs.

CLINICAL FEATURES OF ELECTRICAL INJURY

Electric current can induce immediate cardiac dysrhythmias, respiratory arrest, and seizures. Current that traverses the chest vertically (hand to foot or head to toe) or horizontally (hand to hand) can produce arrhythmias and respiratory arrest.

CARDIAC DYSRHYTHMIAS

Fatalities due to asystole or ventricular fibrillation usually occur prior to arrival in the ED.[5] **Asymptomatic patients with normal ECGs on arrival to the hospital do not develop later dysrhythmias after low-voltage (<1000 V) injuries.**[9-13] However, nerve and deep-muscle injuries are relatively common following contact with voltages >400 V. Therefore, carefully examine for peripheral nervous system and CNS function and burns, and check for elevated serum creatine phosphokinase.

CNS, SPINAL CORD, AND PERIPHERAL NERVOUS SYSTEM INJURY

Neurologic impairment is common in electrical injuries, occurring in approximately 50% of patients with high-voltage injuries.[2] Nerve tissue

has the lowest resistance in the body, encouraging electrical passage through these tissues and causing associated damage. Given the multisystem dysfunction present in many electrical injury patients, document a neurologic exam, if possible, before intubation and sedation.

Brain Injury Electrocution can result in a broad range of CNS dysfunction. Transient loss of consciousness is common and may be followed by seizures. Victims may be confused and agitated or deeply comatose and require airway protection. Patients may also demonstrate focal neurologic deficits such as quadriplegia, hemiplegia, aphasia, or visual disturbances. Obtain head and cervical spine CT to rule out traumatic etiologies for these deficits; MRI may be necessary for purely electrical damage. Electrical injury can cause blindness[14] due to occipital lobe injury as well as direct injury to the optic nerve.[15,16] Neurologic deficits may be transient, but survivors may have persistent difficulties with attention, working memory, and learning.[17]

Spinal Cord Injury Spinal cord injury can occur in up to 8% of high-voltage electrical injuries.[18] Spinal cord injuries can be the result of compressive vertebral fractures, sometimes at multiple levels.[19] However, damage can also occur due to purely electrical damage without fractures, through direct cellular damage as well as vascular injury.[20] With electrical trauma, initial spinal cord MRI results do not necessarily correlate with prognosis. MRI findings may be normal in electrical trauma patients with permanent spinal cord injury,[21-23] although newer MRI imaging protocols may detect abnormalities silent on standard MRI.[24] With mechanical trauma, emergency MRI after spinal cord injury provides accurate prognostic information regarding neurologic function.

Neurologic deterioration can occur days to months after the initial injury[25-27] and generally has incomplete resolution. There is a motor predominance in deficit in most of these cases. Delayed onset of spinal cord dysfunction may be due to progressive vascular injury (especially to the spinal artery branch supplying the anterior horn cells) or delayed cell membrane damage via the cumulative effect of free radicals (electroporation), leading to progressive demyelination.[21,28] The clinical features may take the form of transverse myelitis, amyotrophic lateral sclerosis, or a Guillain-Barré–like illness.[29]

Peripheral Nerve Injury Peripheral nerve injuries often involve the hands after the individual touches a power source. Paresthesias may be immediate and transient or delayed in onset, appearing up to 2 years after injury.[2,30] Extensive peripheral nerve damage may occur with minimal thermal injury. Electrical contact with the palm produces median or ulnar neuropathy more often than radial nerve injury.[31] Brachial plexus lesions have also been reported. Persistent symptoms related to peripheral nerve damage can occur despite normal results on nerve conduction studies.[32]

CUTANEOUS BURNS

Cutaneous burns are often seen at the electrical contact areas (often referred to as *entry* and *exit wounds* in the case of DC current, or *contact wounds* in the case of AC current). Many seriously injured patients have burns on either the arm or skull, paired with burns on the feet. Burns are typically painless, gray to yellow, depressed areas. Most patients with burns from electrical injury need admission and care by a burn specialist. See chapter 216 for detailed discussion of management of cutaneous burns.

ORTHOPEDIC INJURY

Fractures may be caused by tetanic muscle contractions or associated falls. Fractures may be missed on initial assessment due to altered mental status and the overall severity of systemic illness. A comprehensive tertiary survey should be performed when clinically feasible to detect orthopedic injuries. Although fractures are more likely to result from high-voltage injury, fractures of the wrist, forearm, humerus, femoral necks, shoulders, and scapulae have been reported from exposure to household voltages (120 to 220 V AC) without associated trauma.[7,33,34] Posterior shoulder dislocations are commonly seen with electrical injury.

VASCULAR AND MUSCLE INJURY

Vascular and muscle injuries occur most commonly in the setting of high-voltage injury, such as power line contact. Electric current passing along peripheral arteries may cause early spasm and persistent deficits in endothelial and smooth muscle function,[35] as well as subsequent thrombosis, stenosis, or aneurysm formation. Because of concomitant vascular and muscular destruction, **patients with high-voltage shocks are at significant risk for development of compartment syndrome, even if the contact (or arcing) lasted <1 second.** Compartment syndrome has also been noted in patients with injuries from 120 V AC or higher who sustain contact for longer than a few seconds. Patients typically exhibit ongoing muscle pain with movement.[6]

Contact with >1000 V, prehospital cardiac arrest, crush injury, and full-thickness skin burns are associated with significant tissue damage requiring surgical intervention. Fasciotomy and amputation are frequent sequelae of high-voltage injuries, occurring in 29% and 41% of patients in one study.[36] High-voltage electrical injury is associated with rapid loss of body fluids into the areas of tissue damage, requiring aggressive resuscitation.

COAGULATION DISORDERS

Thermal injury or tissue necrosis from electric current can cause a variety of coagulation disorders. Low-grade disseminated intravascular coagulation may be a result of hypoxia, vascular stasis, rhabdomyolysis, and release of procoagulants from damaged tissue. Transient coagulopathies have also been reported with high-voltage injury, including acquired, transient factor X deficiency.[37] Electrical injury may unmask underlying vascular injury and has been reported in association with ischemic stroke at low voltage.[38]

BLAST INJURY

Electric arcs in the industrial environment or near a power line can produce a strong blast pressure, similar to those seen in other types of explosions.[39] Cognitive complaints following blast injury may resemble those that result from moderate mechanical head trauma. Mechanisms of brain injury include mechanical trauma related to the blast and arterial air emboli associated with blast-related alveolar disruption (see chapter 7, "Bomb, Blast, and Crush Injuries").

INHALATION INJURY

Chemical toxins such as ozone can be produced by coronas and arcs. Acute effects of ozone exposure include mucous membrane irritation, temporarily reduced pulmonary function, and pulmonary hemorrhage and edema. Fires and explosions associated with electric incidents may lead to inhalation of carbon monoxide and other toxic substances.

OCULAR INJURY

Electrical shock can cause a wide range of ocular trauma, most commonly to the cornea (epithelial erosion/defect, keratitis, scarring), as well as uveitis, retinal detachment, macular edema, optic nerve damage, and intraocular bleeding and thrombosis.[15,40,41] Obtain a full ophthalmologic evaluation for any electric shock patient with an ocular complaint to document related injury. Cataract formation has been described weeks to years after electrical injury to head, neck, or upper chest.[7] Cataracts have also occurred after electric arc or flash burns.

AUDITORY INJURY

The auditory system may be damaged by current or by hemorrhage in the tympanic membrane, middle ear, cochlea, cochlear duct, and vestibular apparatus. Delayed complications include mastoiditis, sinus thrombosis, meningitis, and brain abscess. Hearing loss may be immediate or develop later as a result of complications. Hearing should be briefly checked in the ED, with follow-up formal testing arranged for any patient who appears to have a deficit.

GI INJURY

Pain due to bowel perforation and intra-abdominal hemorrhage may be attributed to more obvious coexisting injuries.[42] There are reports in the literature of lethal intra-abdominal injuries from electric current that were found only at autopsy. Ileus may develop in association with spinal cord injury.

SCENE AND PREHOSPITAL CARE

Table 218-3 outlines prehospital care of the patient with electrical injury.

RESCUER SAFETY

Stay away from downed power lines. The scene of a high-voltage electric incident contains many hazards for rescue personnel. Power lines are almost never insulated, although a line may appear to be insulated because of atmospheric contaminants deposited on the line over time. Electrocution is possible when walking on ground near a downed power line because of voltage gradients in the ground. **Stay at least 10 m (32 ft) from downed power lines. Even this distance is not without risk.**

Reapplication of voltage to downed lines sometimes occurs as circuit breakers automatically reset, which makes the lines physically jump many feet with great force. This danger may be mitigated by placing a heavy object over the line, but this maneuver itself is fraught with risk.

Support structures may be electrically alive. Metal cables that support telephone and power poles are normally grounded, but may be energized if they are broken or disconnected from a ground attachment and contact is made with a nearby power line.

Victims still in contact with a source of voltage may transmit an electric current to would-be rescuers. It is best first to turn off the source of electricity if it can be done quickly. If this cannot be done quickly, precautions must be taken to prevent electrical injury to the rescuer. With voltages above about 600 V, dry wood and other materials may conduct significant amounts of electric current and therefore cannot be used to remove the person from a voltage source. A rescuer standing on the ground touching any part of a vehicle that is in contact with a power line is likely to be killed or seriously injured. Electric shock is not prevented in this situation by the rescuer's wearing rubber gloves and boots, unless these are designed for the voltage present and have been recently tested for insulation integrity. Persons inside a vehicle in contact with a power line are likely to be killed as they step out of the vehicle and may also receive a shock if they touch objects at different potentials inside the vehicle.

SCENE RESUSCITATION AND STABILIZATION

Rescue breathing for line workers in respiratory arrest on utility power poles should be initiated by rescuers while the injured individual is still on the pole as long as the injured worker and rescuers are no longer in contact with the energized line. As soon as the patient is lowered to the ground, chest compressions can be done if there is cardiac and respiratory arrest.

Low-voltage AC can produce ventricular fibrillation by direct stimulation of the heart, or it can occur after several minutes of respiratory arrest resulting from paralysis of respiratory muscles (Table 218-2). **High-voltage AC and DC are more likely to produce transient ventricular asystole.** Asystole sometimes reverts spontaneously to normal sinus rhythm with pulses, but prolonged apnea may continue. **Apnea with pulses** sometimes occurs in linemen working above the ground near high-voltage lines. Supporting respirations above ground may be all that is needed to stabilize the patient. Maintain vigorous resuscitation efforts for cardiac arrest from electric shock, because there may be insignificant tissue damage despite the potentially lethal dysrhythmia.[43]

Maintain spinal immobilization during resuscitation to the extent possible, because spinal fractures can be caused by tetanic muscle contractions, falls, and other secondary trauma.

TABLE 218-3 Scene and Prehospital Care

Stay at least 10 m (32 ft) from downed power lines, jumping power lines, and support structures.
Turn off the source of electricity prior to rescue, if possible.
If electrical source cannot be quickly turned off, take precautions to prevent electrical injury to the rescuer.
Wear gloves and shoes rated for the power line voltage.
Initiate rescue breathing and resuscitation efforts while injured person is still on pole, if no contact with source of electricity is assured.
Maintain spinal immobilization of injured person, if possible.

ED DIAGNOSIS AND TREATMENT

Provide the usual evaluation (airway, breathing, circulation) and resuscitation for major trauma victims. Maintain spinal immobilization during resuscitation until adequate imaging and examination can be done.

Treat cardiac arrhythmias according to accepted advanced life support guidelines. Institute ED cardiac monitoring for patients with high-voltage injuries as well as all symptomatic patients.[9,10] Cardiac complications are more common in patients with high-voltage injuries and in those with loss of consciousness and include ventricular and atrial dysrhythmias, bradydysrhythmias, and QT-interval prolongation.[44-46] **Admission for cardiac monitoring is not needed for asymptomatic patients with normal ECG on presentation after a low-voltage electrical injury.**

Assess for tissue damage and identify associated complications. A careful vascular and neurologic examination of involved extremities is important. Normal findings on initial assessment do not exclude serious injury or the possibility of delayed spinal cord injury following high-voltage contact.

Focus next on systematic assessment and treatment, especially for injuries specific to or common in electrical injury, as outlined in **Table 218-4**. Laboratory and radiographic evaluation of high-voltage injuries should follow standard trauma guidelines (see chapters in Section 21, "Trauma," and Section 22, "Injuries to Bones and Joints").

TABLE 218-4 Assessment and Treatment of Complications Associated with Electrical Injuries

Organ or System	Assessment/Treatment/Comments
Circulatory	Start with Parkland fluid resuscitation formula.*
Renal	Initiate fluid resuscitation.
Myoglobinuria	Initiate fluid resuscitation†
Central and peripheral nervous	Order head CT if mental status is abnormal; assess for spinal cord and peripheral nerve injury.
Skin	Assess and treat cutaneous burns.*
Musculoskeletal	Perform careful assessment of spine, pelvis, long bones, and joints. Assess for compartment syndrome and need for fasciotomy.
Vascular	Spasm may occur leading to delayed thrombosis, aneurysm formation, or muscle damage.
Coagulation	Treat coagulation disorders by eliminating the precipitating factor through early surgical debridement. If bleeding is present, replace coagulation factors.‡
Lungs	Assess for inhalation injury, carbon monoxide, or alveolar injury from blast.
Eyes	Document complete eye examination. Delayed cataracts may develop.
Ears	Assess for blast injury. Document hearing. Middle and inner ear disorders and hearing loss may occur.
GI	Intra-abdominal injury may occur from current or blast.
Lips and oral cavity	Watch for delayed bleeding.

*Refer to chapter 216, "Thermal Burns."
†Refer to chapter 89, "Rhabdomyolysis."
‡Refer to chapter 254, "Trauma in Adults."

TABLE 218-5 GI Injury in Electrocution

When to Suspect GI Injury
Electrical burns of the abdominal wall
History of a fall, nearby explosion, or other mechanical trauma
Evaluation
US and CT
Surgical consult as indicated
Treatment
Ileus: nasogastric tube insertion
Stress (Curling) ulcer prophylaxis: histamine-2 blockers, antacids, proton pump inhibitors
Monitoring for development of ileus, bowel perforation, hemorrhage, and other delayed complications
Surgical management as appropriate

In the case of **low-voltage injuries**, laboratory testing and imaging are usually not required unless the patient is symptomatic or has abnormal physical examination findings. Symptoms such as chest pain, palpations, loss of consciousness, altered mental status, confusion, weakness, dyspnea, abdominal pain, burn with subcutaneous damage, vascular compromise, or abnormal results on ECG require further testing.

FLUID RESUSCITATION

Fluid resuscitation guided by the Parkland formula (4 mL/kg multiplied by the percentage of body surface area burned, administered over 24 hours) is a reasonable starting point in fluid management. Extensive deep tissue damage resulting from high-voltage injury may be present even when the cutaneous burn seems limited. Therefore, fluid requirements are often greater than predicted by the Parkland formula and physical examination.

MYOGLOBINURIA

Patients with suggestive symptoms or high-voltage injury should be monitored for the onset of compartment syndrome, rhabdomyolysis, and renal failure. If myoglobinuria is suspected, institute aggressive IV fluid resuscitation to maintain a urinary output of between 1 and 2 mL/kg/h, with attention to correction and prevention of electrolyte abnormalities. Evidence of effectiveness of sodium bicarbonate is not well documented. Initial IV rate in the adult is up to 1.5 L/h (more if there is hypotension or obvious blood loss). Maintain a high urine output until serum creatine kinase level is less than five times normal or urine myoglobin measurements return to normal. **Monitor serum, not urine, pH.** Urine pH measurements are influenced by hemochromogens in the urine and, therefore, may not be useful.

Prognostic factors associated with the need for a fasciotomy within 24 hours of injury are (1) myoglobinuria, (2) burns over 20% of total body surface area, or (3) a full-thickness burn over 12% body surface area.[36] Presence of any one of these three factors is predictive of development of the need for fasciotomy.

GI INJURY

GI injuries should be suspected in all patients with a history of electrical burns to the abdominal wall or mechanical trauma associated with the electrical injury. **Table 218-5** summarizes an approach to GI injury.

DISPOSITION AND FOLLOW-UP

LOW-VOLTAGE INJURIES <600 V

Although there is no universally accepted protocol for management and disposition of patients with low-voltage injuries, **in general, asymptomatic patients who sustain an electric shock of ≤240 V AC can be discharged home if they have a normal ECG on presentation and normal examination findings.**[9,10] Patients who feel unwell or have any new ECG abnormality should be monitored for 6 hours and reassessed.[9,10]

HIGH-VOLTAGE INJURIES

All patients having contact with ≥600 V AC should be admitted for observation, even if there is no apparent injury. Routine cardiac monitoring is not required unless the patient is symptomatic or the initial ECG findings are abnormal. Low-voltage injury patients with symptoms beyond superficial skin injury or abnormal lab/ECG results may have systemic injury and require admission as well. Patients with extensive cutaneous burns should be transferred to a specialized burn center after initial trauma stabilization. This is especially true in children.[47]

SPECIAL POPULATIONS

PREGNANT WOMEN

In addition to the measures recommended above, in pregnant women beyond 20 to 24 weeks of gestation, monitor fetal heart rate and uterine activity for at least 4 hours because of the possibility of mechanical trauma related to the electric shock and electrical discharge to the fetus.[48-50]

CHILDREN

Children are more likely to sustain household current electrical injury than high-voltage injury. Overall outcome appears to be better, including a lower incidence of amputation and fasciotomy than in adults, although skin grafts may be required (25% in one 10-year study of pediatric burn center referrals).[47]

Oral and Lip Burns Serious oral injury can occur in a child who places the end of a power cord in the mouth. The electric field and current flow created between the two wires near the end of the cord can produce high temperatures and significant tissue damage. Most injuries are unilateral, involving the lateral commissure, tongue, and/or alveolar ridge[4,51,52] (**Figure 218-1**). Systemic complications of oral burns are uncommon. **Vascular injury to the labial artery is not immediately apparent** because of vascular spasm, thrombosis, and overlying eschar. Severe bleeding from the labial artery occurs in up to 10% of cases when the eschar separates, usually after 5 days. For this reason, children with this injury are sometimes

FIGURE 218-1. Oral burn in a child from power cord. A 2-year-old boy sustained a third-degree burn to the commissure of the mouth after biting down on an electrical cord. This photograph was taken 3 days after initial treatment. [Reproduced with permission from Shah BR, Lucchesi M: *Atlas of Pediatric Emergency Medicine*. © 2006 by McGraw-Hill, Inc., New York.]

admitted to the hospital. However, some authors believe that outpatient management is adequate in the right circumstances.[53] If the parents are reliable, can monitor the child, and can be shown how to control bleeding, outpatient management may be considered. Parents should be educated that bleeding may occur up to 2 weeks after injury. Prior to discharge, however, specialty consultation should be obtained and follow up secured, because of the risk of deforming scar formation during the healing process, in which new cells tend to migrate medially, reducing the span of mouth opening. Splinting and other measures are often needed to prevent the development of this deformity and dysfunction. Home care includes saline or hydrogen peroxide rinses and gentle swabbing to debride necrotic tissue and promote formation of healthy granulation tissue. Topical application of petrolatum-based antibiotics may have a soothing effect.

Hand Wounds Children who sustain hand wounds from electrical outlet injuries with no other injury and no evidence of cardiac or neurologic involvement can be discharged after local wound care is provided and careful follow up ensured. A child with a home situation of equivocal safety or reliability should be admitted.

LIGHTNING INJURIES

Lightning causes approximately 500 injuries each year in the United States, with an average of 51 deaths per year over the last 20 years (1984 to 2013).[54] Lightning fatalities constitute fewer than 3% of weather-related deaths, which are more commonly due to extreme heat or cold.[55] Lightning fatalities are most common in fishermen, but also occur in other outdoor recreational activities such as golf and camping.[54] Lightning injury reporting is inexact and biased toward the more severe and fatal events. Approximately 70% to 90% of persons struck by lightning survive, but as many as three quarters of these survivors have permanent sequelae.[56,57]

Lightning most often occurs during thunderstorms in association with large cumulonimbus clouds. However, approximately 10% of lightning occurs without rain and when the sky is blue.[58] In addition, lightning can occur during dust storms, sandstorms, tornados, hurricanes, snowstorms, and nuclear explosions, and in the clouds over volcanic eruptions. Lightning injuries can also occur while riding in airplanes. Lightning injury associated with indoor telephone use during lightning storms has been reported. A study in Australia identified up to 80 such injuries yearly without any reported fatalities.[59]

Even though lightning is electrical energy, lightning injuries differ substantially from high-voltage electrical injuries seen in association with human-generated sources. There are differences in injury patterns, injury severity, and emergency treatment[48,60,61] (**Table 218-6**).

PATHOPHYSIOLOGY

Lightning often travels over the surface of the body in a phenomenon called *flashover* and is therefore less likely to cause internal cardiac injury or muscle necrosis than is human-generated electrical energy. Wet skin may actually decrease the risk of internal injury, helping the current travel along the outside of the body. Flashover explains how victims may survive a lightning strike with little or no injury. Lightning causes internal injury through blunt mechanical force, current flow through the body, and other mechanisms. The large current flow in lightning creates a pulsed magnetic field that can induce current flow in a nearby person[62] and can produce destructive effects.

Lightning emits brief but intense thermal radiation that produces rapid heating and expansion of the surrounding air. Tympanic membrane perforation and internal organ contusion may occur. Vaporization of sweat from the skin can occur with tearing of clothing, giving the appearance of an assault.[63] Lightning may inflict thermal injury as moisture on the victim's skin is transformed into steam, as electric current flows through deeper tissues, and through resistance heating of metal objects on the body or in clothing pockets. Lightning may melt metallic objects on the victim. Lightning can be conducted along metal fences, bleachers, plumbing pipes, and other structures. Intense photic stimulation may damage the retina or produce cataracts.

STUNNING (KERAUNOPARALYSIS)

Neurologic and muscular "stunning," referred to as *keraunoparalysis*, can follow lightning strike and may initially produce a variety of neurologic signs and symptoms.[64] Keraunoparalysis is associated with successful resuscitation after cardiorespiratory arrest. In cases of keraunoparalysis that resolve within an hour, there can be lower limb weakness that is greater than upper limb weakness. Other extremity-related signs and symptoms include sensory abnormalities, pallor, coolness, and diminished and absent pulses. Excessive autonomic nervous system stimulation may be responsible for these transient symptoms.[65] In some cases, keraunoparalysis persists for a longer time. In such cases, there is typically amnesia and "neurotic" behavior that slowly clears over a week. More persistent and sometimes permanent sequelae can include muscular weakness and pain, photophobia, and disturbances of neurologic control.[62]

TYPES OF LIGHTNING STRIKES

Lightning strikes in a number of different ways, some of which injure multiple victims. A *direct strike* occurs when the victim is struck directly by the lightning discharge. A *side flash* occurs when a nearby object is

TABLE 218-6 Comparison of Lightning and Electrical Injuries

Factor	Lightning	High-Voltage AC	Low-Voltage AC
Current duration	10 μs to 3 ms	Generally brief (1–2 s), but may be prolonged	0.3 s or many minutes
Typical voltage and current range	10 million to 2 billion V, 10 to 200,000 A	600–200,000 V, <1000 A	<600 V, usually <20–30 A
Current characteristics	Unidirectional (DC)	Alternating (AC)	Alternating (AC)
Current pathway	Skin flashover; deeper pathways can result in burns	Horizontal (hand to hand), vertical (hand to foot)	Horizontal (hand to hand), vertical (hand to foot)
Tissue damage	Superficial and minor if no deep-tissue pathway	Deep-tissue destruction	Sometimes deep-tissue destruction
Initial rhythm in cardiac arrest	Asystole	Asystole more than ventricular fibrillation	Ventricular fibrillation
Renal involvement	Myoglobinuria is uncommon, and renal failure is rare	Myoglobinuria and renal failure are relatively common	Myoglobinuria and renal failure occur occasionally
Fasciotomy and amputation	Rarely necessary	Relatively common	Sometimes necessary
Blunt injury	Caused by explosive shock wave that can throw the person and cause eardrum rupture	Caused by falls, being thrown from current source, tetanic contractions	Caused by tetanic contraction, falls, being thrown from current source
Immediate cause of death	Prolonged apnea, blunt injury, deep-tissue burns	Prolonged apnea, ventricular fibrillation, blunt injury, deep-tissue burns	Ventricular fibrillation, prolonged apnea, blunt injury

Abbreviations: AC = alternating current; DC = direct current.

struck and current then traverses through the air to strike the victim. A side flash may injure multiple victims at once, as when a group huddles close to a structure that is struck. A *contact strike* occurs when lightning strikes an object the victim is holding and current is transferred from the object through the person to the ground. Lightning injury from indoor telephone use during a lightning storm is an example of contact strike. A *ground current* occurs when lightning hits the ground and current is transferred through the ground to nearby victims. The amount of electrical voltage and current decrease as the distance between the victim and strike point increases. This ground current can create a *stride potential* or step voltage between the victim's separated feet. The foot closer to the strike point will experience a higher electrical potential than the foot further away. Therefore, electric current can enter one foot, travel up that leg, through the torso, and down the other leg and exit the other foot. This can result in isolated neurovascular injury to the legs. Recently, a fifth mechanism, in which a weak *upward streamer* does not become connected to the completed lightning channel, was implicated in a fatal lightning injury.[66]

Immediate cardiac arrest from lightning strike results from depolarization of the myocardium and sustained asystole. Immediate respiratory arrest after lightning strike may be a result of depolarization and paralysis of the medullary respiratory center. **Both cardiac and respiratory arrest may be present without evidence of external injury.** Although cardiac automaticity may spontaneously return, concomitant respiratory arrest may persist and lead to a secondary hypoxic cardiac arrest. The duration of apnea, rather than the duration of cardiac arrest, appears to be the critical prognostic factor. Prolonged respiratory support with frequent monitoring of pulses can be effective in this situation.

CARE AT THE SCENE

Lightning can produce multiple victims because of multiple lightning strikes, stride potentials, and side flashes.[60] **In contrast to patients with cardiac arrest caused by mechanical trauma, persons with lightning injury who appear to be dead (in respiratory arrest, with or without cardiac arrest) should be treated first.** Such victims may have little physical damage, and they have a reasonable chance of successful resuscitation. Use of automated external defibrillators and other defibrillators along with CPR can be lifesaving. **Prolonged CPR is sometimes successful.**

During a storm, power lines may fall to the ground as a result of high winds, lightning-related damage to power lines and their support structures, and vehicular damage to power line support structures. Therefore, a person thought to have been hit by lightning may actually have been shocked by the stride potential related to a nearby power line lying on the ground. If a downed power line is found, safety precautions are important. Physical findings suggestive of lightning injury may be subtle or nonexistent. Therefore, information about the scene of the accident may be just as informative as examination of the patient.

ED DIAGNOSIS AND TREATMENT

The usual advanced cardiac and trauma treatment principles apply, including assessment and stabilization of the airway, breathing, and circulation. Lightning victims in cardiac arrest have a better prognosis than those in cardiac arrest from coronary artery disease, so aggressive resuscitative efforts are indicated.[43] Hypotension is not an expected finding following lightning injury and warrants an investigation for hemorrhagic blood loss. A careful secondary examination should be done to detect occult injuries.[67] Cutaneous burns may help identify the current path and suggest potential organ injury. Initial ancillary studies include CBC, serum electrolyte levels, creatinine level, BUN level, glucose level, creatine kinase level, urinalysis, and ECG. Imaging studies (plain radiography, US, or CT) should be performed as dictated by suspected injuries. Other ancillary studies may be indicated depending on clinical circumstances.

CARDIAC EFFECTS

In the victim with spontaneous circulation, hypertension and tachycardia are common findings, presumably because of sympathetic nervous system activation. Specific treatment is usually not necessary, because blood pressure and pulse rate will spontaneously decrease. Cardiac effects reported after lightning injury include global depression of myocardial contractility, coronary artery spasm, pericardial effusion, and atrial and ventricular arrhythmias. The ECG may show acute injury with ST-segment elevation and QT-interval prolongation. T-wave inversions may be seen, especially in the presence of neurologic injury. Myocardial infarction after lightning injury is unusual. CPR, automated external defibrillators, and other resuscitative measures should be used promptly.[43] Prolonged resuscitative efforts are sometimes successful.

NEUROLOGIC INJURY

Many lightning-strike victims are rendered unconscious or have temporary lower extremity paralysis. Seizures may result from the passage of electric current through the brain or may be the result of mechanical brain injury or hypoxia. The most lethal neurologic injuries involve heat-induced coagulation of the cerebral cortex, development of epidural or subdural hematoma, and intracerebral hemorrhage.

Autonomic dysfunction caused by lightning may produce pupillary dilation or anisocoria not related to brain injury, and these signs have no prognostic significance in comatose lightning-strike victims. Most neurologic injury related to lightning strike can be classified as immediate and transient or delayed and permanent, although some effects may be immediate and permanent. Transient effects that typically resolve in 24 hours include loss of consciousness, confusion, amnesia, and extremity paralysis. Delayed and often progressive disorders include seizures, muscular atrophy and amyotrophic lateral sclerosis, parkinsonian syndromes, progressive cerebellar ataxia, myelopathy with paraplegia or quadriplegia, and chronic pain syndromes.[28] Lightning can cause intracranial injury directly when passing through the head, as well as by secondary trauma. Therefore, CT scan is indicated in cases of coma, altered mental status, or persistent headache or confusion.

VASCULAR EFFECTS

Vasomotor spasm in an extremity is sometimes seen as a local response to lightning exposure. Possible mechanisms include sympathetic nervous stimulation, local arterial spasm, and ischemia of peripheral nerves. Skin color changes, from white to blue to red, may occur in extremities after lightning strike. Such changes are presumably from cycles of vasoconstriction and vasodilatation, with pallor and cyanosis followed by hyperemia. Severe vasoconstriction is thought to be responsible for loss of pulses, mottling of skin, coolness of extremities, loss of sensation, and paralysis due to ischemia of peripheral nerves. As vasoconstriction resolves spontaneously, these signs and symptoms often resolve. Because skeletal muscle injury is rare in lightning strike, compartment syndromes are less likely. If doubt exists, the presence of compartment syndrome and the need for fasciotomy may be confirmed by measurement of intracompartmental pressures and close clinical monitoring.

OCULAR INJURY

Ophthalmic injuries are common in lightning-strike victims, and lightning-induced cataracts are the most frequently observed ocular sequelae.[68] Cataracts caused by lightning are usually bilateral. Cataract formation without evidence of current flow through the head or eyes, such as after brief exposure to an electric arc, has been described. Perhaps this is a result of damage of the lens by radiant energy. Cataracts may form weeks to years after the lightning injury. Lightning can affect any part of the eye, producing hyphema, vitreous hemorrhage, corneal abrasion, uveitis, retinal detachment or hemorrhage, macular holes, and optic nerve damage. A patient with discomfort or visual changes deserves a careful examination with follow-up.

AUDITORY INJURY

Blast effect producing tympanic membrane rupture is relatively common. Victims sustaining lightning strike via a conventional corded telephone are at higher risk for otologic injury, including persistent tinnitus,

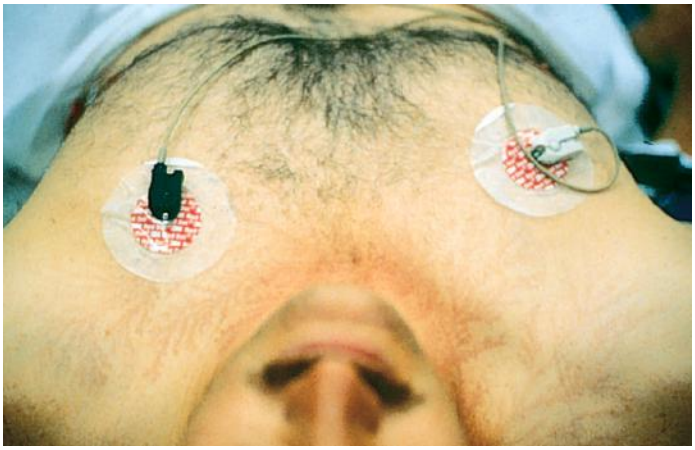

FIGURE 218-2. Lichtenberg figures with lacy fern pattern seen on the upper chest. [Reproduced with permission from Knoop KJ, Stack LB, Storrow AB: *The Atlas of Emergency Medicine, 2nd ed*. © 2002 by McGraw-Hill, Inc., New York.]

sensorineural deafness, ataxia, vertigo, and nystagmus.[59] In patients who are sleeping with an ear or eye on the ground near a lightning strike, temporary deafness or blindness can result.

MUSCULOSKELETAL INJURY

A variety of skeletal fractures can be seen from the blunt force injury associated with lightning strike. Intense myotonic contractions can produce shoulder dislocations. Rhabdomyolysis after lightning strike is unusual. Spinal fractures can be caused by tetanic muscle contractions, as well as by falls and other secondary trauma. Therefore, maintain spinal immobilization during retrieval and resuscitation, to the extent possible under the circumstances, until spinal stability can be assessed. Because spinal fractures often occur at multiple levels in the same patient, image the entire vertebral column when a fracture is found at one level.

CUTANEOUS INJURY

There are six main dermatologic manifestations of lightning injury. **Lichtenberg figures** are considered pathognomonic for lightning strike and consist of a superficial feathering or fern pattern (**Figure 218-2**). These figures are the result of electron showering over the skin and are not true thermal burns; they disappear within 24 hours. *Flash burns* are similar to those found in arc welders, appearing as mild erythema, and may involve the cornea. *Punctate burns* (**Figure 218-3**) look similar to cigarette burns in that they are usually <1 cm and are full-thickness burns. *Contact burns* occur when metal close to the skin is heated from the lightning current. *Superficial erythema* and *blistering burns* have been described. *Linear burns*, <5 cm wide, occur in areas of skin folds such as the axilla or groin. Contact wounds characteristic of electrical injury from human-produced sources are not commonly seen in lightning injuries. Cutaneous wounds are treated with customary wound or burn care, including tetanus prophylaxis, irrigation, debridement, and dressing.

PREVENTION

Safety recommendations include anticipating possible lightning storms (using resources such as the National Oceanic and Atmospheric Administration Weather Radio) and seeking safe shelter **indoors** when lightning is first seen or thunder is heard. Safer shelters include large structures with plumbing or electrical wiring, and fully enclosed metal vehicles. Dangerous locations to avoid include trees and other tall structures, open fields, open vehicles, and other open structures. During lightning storms, it is important to avoid being in or near water and to avoid contact with metal or wire fences and other conductive objects.[58]

DISPOSITION AND FOLLOW-UP

Patients should be carefully assessed for injuries. ECG and other monitoring is indicated as for any electric shock. Admission should be considered for most patients with persistent muscle pain, as well as those with persistent neurologic, cardiac rhythm, or vascular abnormalities. Follow-up is recommended to assess delayed effects of lightning, even for patients with no apparent injury.

SPECIAL POPULATIONS

In some cases, fetal injury and death have been noted to follow lightning strike with little or no maternal injury. One review reported that among 11 pregnant women who survived being struck by lightning, there were five cases of fetal death in utero, abortion, stillbirth, or neonatal death.[49] Abruptio placentae has also been reported. Monitoring of maternal uterine activity and fetal heart rate is recommended for at least 4 hours after a lightning strike to a pregnant woman. Such monitoring will alert the physician to the development of abruptio placentae, which can occur following any physical trauma.

INJURY DUE TO ELECTRONIC CONTROL DEVICES

Electronic control devices (also known as conductive energy devices), such as the cattle prod, stun gun, and the Taser®, can lead to injuries. Approximately 11% of "legal intervention injuries" (i.e., injuries sustained while being taking into custody) are related to electronic control devices, and the incidence is increasing. The vast majority of patients injured by electronic control devices are treated and released, but 6% are hospitalized.[69] TASER International, Inc. (Scottsdale, AZ), produces a series of devices that deliver high-voltage, low-amperage electrical pulses, typically at 10 to 20 cycles per second (subtetanic rate). The pulses are designed to induce involuntary muscle contraction, neuromuscular incapacitation, and/or pain. The likelihood of electrical injury is minimal;[70-73] however, reports have been published attributing cardiac arrest to these devices.[74,75] In addition, falls or other forceful movements resulting from electric current can lead to injury, as can use in flammable and other hazardous environments. Some devices shoot wires with fishhook-like barbs on the ends that penetrate and hook into the skin; penetrating injuries can result from this mechanism.

CLINICAL FEATURES

Most electronic control device injuries are limited to superficial punctures, minor lacerations, and cutaneous burns. Reported significant

injuries have included skull penetration,[76] eye perforation,[77,78] retinal detachment,[79] testicular torsion,[80] miscarriage,[81] and pneumothorax,[80] as well as blunt trauma from falls and burns. Burns may occur when electronic control devices are used in flammable environments or used to incapacitate someone on a hot surface.

Clinical evaluation should address the underlying agitation underlying the use of the electronic control device. Patients may be agitated due to stimulant intoxication or other causes of medical delirium (including alcohol withdrawal or thyroid storm) and should be fully evaluated for both the underlying cause and the metabolic consequences of delirium, including hyperthermia, electrolyte abnormalities, rhabdomyolysis, and acidosis.[82]

TREATMENT AND DISPOSITION

Cardiac monitoring and other testing is not needed just because an electronic control device has been used. An initial ECG should be obtained if the patient is symptomatic. A series of human studies have suggested that electronic control devices do not cause or worsen hyperthermia, hyperkalemia, hypoxia, acidosis, and a variety of other problems often seen with in-custody deathsm,[83-86] but many underlying medical conditions may be at play in the patient who has required electronic control device discharge for restraint. The physician should try to determine why the electronic control device was used and obtain a history of the patient's behavior. Careful evaluation and monitoring are needed in the ill-appearing patient with the differential considerations of agitated delirium.

Patients who have calmed down, have no history of loss of consciousness or significant cardiac disease, and appear well can usually be discharged with no ECG or other testing beyond vital signs and a physical examination.

Patients with a history of severe agitation may be discharged if they have calmed down, maintained stable vital signs for 2 hours, and have a normal 12-lead ECG, electrolytes, arterial blood gas, and creatine phosphokinase. Those with abnormal labs, a history of loss of consciousness or significant underlying cardiac disease, and abnormalities on ECG should be admitted for further observation.

CHAPTER 219

Mushroom Poisoning

Anne F. Brayer
Lynette Froula

INTRODUCTION AND EPIDEMIOLOGY

Mushrooms are a common toxic exposure, with >6600 poisonous mushroom exposures and six deaths reported to poison control centers in 2012 and more than half occurring in children <6 years of age.[1]

Fortunately, the majority of reported mushroom exposures have a benign outcome.[2,3] To prevent mushroom poisoning, avoid eating wild mushrooms. There are no easily recognizable differences between nonpoisonous and poisonous mushrooms. Mushroom toxins are not heat labile and so are not destroyed or deactivated by cooking, canning, freezing, drying, or other means of food preparation.

Depending on the type of mushroom, adverse effects from ingestion range from mild GI symptoms to major cytotoxic effects resulting in organ failure and death. Toxicity varies based on the amount ingested, the age of the mushroom, the season, the geographic location, and the way in which the mushroom was prepared prior to ingestion. One person may show significant effects, whereas others may be asymptomatic after ingesting the same mushroom (**Table 219-1**).

Mushroom toxicity is divided into early toxicity (within 2 hours after ingestion) and delayed toxicity (6 hours to 20 days later).

Mushroom poisoning occurs in four main groups of individuals: young children who ingest poisonous mushrooms inadvertently, wild mushroom foragers, individuals attempting suicide or homicide, and individuals looking for a hallucinatory "high." Identification of the mushroom ingested may be difficult and time consuming. Very often, foragers mix different species of mushrooms together, so it is not always clear that the species being identified is the same one that was ingested. Therefore, direct treatment by a patient's symptoms rather than by attempts at mushroom identification. Treatment for mushroom poisoning is based on case reports and small series.[3]

Nearly all fatalities in the United States and Europe occur from ingestion of mushrooms of the *Amanita* species (*Amanita phalloides*, *Amanita virosa*, and *Amanita bisporigera*).[4] If *Amanita* ingestion is suspected, identification of the species may be helpful but is difficult because there are many *Amanita* mushrooms that are nontoxic. *Amanita* species generally have warts on the cap (remnants of the membrane covering the emerging mushroom), which give it a spotted appearance. The gills are "free," ending before the stem begins. The stem characteristically has a membrane ring around it and widens as it enters the soil. In most cases, the stem of the mushroom is contained in a cup or volva, which may be underground (**Figures 219-1, 219-2, and 219-3**).

EARLY-ONSET GI SYMPTOMS

PATHOPHYSIOLOGY

Most wild mushroom ingestions cause mild GI irritation, and mushrooms that cause GI irritation can be of many types. In North America and in almost every country, *Chlorophyllum molybdites* is particularly common and is sometimes mistaken for an *Amanita*.[3] Many little brown mushrooms found commonly in lawns, and often accidentally ingested by children, are in this category. *Omphalotus*, *Boletus*, *Entoloma*, *Gomphus*, *Hebeloma*, *Lactarius*, and *Verpa* genera are other examples for this group (**Figure 219-4**). The actual toxin varies with the species of mushroom, but most toxins are poorly described.

CLINICAL FEATURES

The majority of mushroom-induced intoxications are mild and do not prompt a visit to the ED. *C. molybdites*, however, is an exception that may cause severe symptoms.[5] Typically, patients present with acute onset of vomiting and diarrhea <2 hours after ingesting the mushroom. There may be intestinal cramping, chills, headaches, and myalgias. Diarrhea is usually watery, but occasionally bloody with fecal leukocytes. Most commonly, symptoms are mild and self-limited. Symptoms usually resolve within 24 hours but may last up to several days. Vomiting and diarrhea can cause dehydration and electrolyte imbalance. The presentation may be confused with acute gastroenteritis or acute food poisoning if the patient does not offer the history of mushroom ingestion.

TREATMENT

Treat symptomatic toxic mushroom ingestion with activated charcoal 0.5 to 1.0 gram/kg, PO or by nasogastric tube. There is no role for prophylactic decontamination therapy of asymptomatic patients.[6] Other treatment is largely supportive and includes IV fluid and electrolyte replacement when necessary. Antiemetics can be given, but do not give antidiarrheal agents, because they may prolong exposure to the toxin.[2] In most cases, symptoms are self-limited, resolving within 12 to 24 hours. Some cases of *Amanita smithiana* ingestion present with early GI symptoms (between 30 minutes and 12 hours) and can progress to renal failure within 3 to 5 days.[7]

Once vomiting has subsided and the patient is tolerating oral fluids, discharge from the ED is safe. Rarely, symptoms may persist and hospitalization may be needed for fluid and electrolyte replacement. Recommend outpatient follow-up within 5 days, and provide return precautions (urinary changes, lumbar or flank pain).[7]

TABLE 219-1 Mushrooms: Symptoms, Toxicity, and Treatment

Symptoms	Mushrooms	Toxicity	Treatment
GI symptoms			
Onset <2 h	*Chlorophyllum molybdites* *Omphalotus illudens* *Cantharellus cibarius* *Amanita caesarea*	Nausea, vomiting, diarrhea (occasionally bloody)	IV hydration Antiemetics
Onset 6–24 h	*Gyromitra esculenta* *Amanita phalloides, Amanita bisporigera*	Initial: nausea, vomiting, diarrhea Day 2: rise in AST, ALT levels Day 3: hepatic failure	IV hydration, glucose; monitor AST, ALT, bilirubin, BUN, and creatinine levels, prothrombin time, partial thromboplastin time For *Amanita:* activated charcoal Consider penicillin G, 300,000–1,000,000 units/kg/d Silymarin, 20–40 milligrams/kg/d Consider cimetidine, 4–10 grams/d Consider hyperbaric oxygen therapy
Muscarinic syndrome Onset <30 min	*Inocybe* *Clitocybe*	SLUDGE syndrome (***s***alivation, ***l***acrimation, ***u***rination, ***d***efecation, ***G***I hypermotility, and ***e***mesis)	Supportive; atropine, 0.01 milligram/kg, repeated as needed for severe secretions
CNS excitement Onset <30 min	*Amanita muscaria* *Amanita pantherina*	Intoxication, dizziness, ataxia, visual disturbances, seizures, tachycardia, hypertension, warm dry skin, dry mouth, mydriasis (anticholinergic effects)	Supportive; sedation with diazepam, 0.1 milligram/kg IV for children; diazepam, 2–5 milligrams IV, or phenobarbital, 30 milligrams IV for adults
Hallucinations Onset <30 min	*Psilocybe* *Gymnopilus*	Visual hallucinations, ataxia	Supportive; sedation with diazepam, 0.1 milligram/kg or 5 milligrams IV for adults, or phenobarbital, 0.5 milligram/kg or 30–60 milligrams IV for adults
Disulfiram reaction 2–72 h after mushroom, and <30 min after alcohol	*Coprinus*	Headache, flushing, tachycardia, hyperventilation, shortness of breath, palpitations	Supportive; IV hydration β-Blockers for supraventricular tachycardia Norepinephrine for refractory hypotension
Dermatitis 1–2 d after ingestion	Shiitake	Whip-like, linear, erythematous wheals, blanching erythematous patches, scattered petechiae, pruritus	Oral antihistamines, 0.1% triamcinolone ointment twice daily; spontaneously resolves within 1–3 wk

Abbreviations: ALT = alanine aminotransferase; AST = aspartate aminotransferase.

EARLY-ONSET NEUROLOGIC SYMPTOMS

PATHOPHYSIOLOGY

Several classes of mushrooms can cause neurologic symptoms. These include the hallucinogenic mushrooms ("magic mushrooms") that contain the chemical psilocybin, which is rapidly dephosphorylated by alkaline phosphatase to the more psychoactive chemical psilocin.[8] Psilocin acts on serotonergic neurons in the CNS, causing effects similar to those of lysergic acid diethylamide. Mushrooms of the *Psilocybe* genus, which are the most commonly ingested in this class, are small brown or gold mushrooms that commonly grow on dung in warmer climates throughout the Pacific Northwest and southeastern United States as well as warm regions of Central America, South America, Asia, and Australia.[9] They characteristically turn a greenish blue when bruised or cut. They may also be cultivated at home from purchased spores. Nontoxic mushrooms may also be laced with phencyclidine or lysergic acid diethylamide and sold as hallucinogenic mushrooms.

Mushrooms containing the isoxazole derivatives ibotenic acid and muscimol also possess neurologic effects, which are thought to be mediated by

FIGURE 219-1. *Amanita muscaria.* [Photo used with permission of Jilber Barutciyan.]

FIGURE 219-2. *Amanita pantherina.* [Photo used with permission of Jilber Barutciyan.]

FIGURE 219-3. *Amanita phalloides.* [Photo used with permission of Jilber Barutciyan.]

γ-aminobutyric acid and anticholinergic activity. *Amanita muscaria* is the principle representative of this group of mushrooms and is easily identified (Figure 219-1). It has an orange or red cap with white warts (remnants of the universal veil present in young specimens), as well as a ring (annulus) and cup (volva) on the stem. *Amanita pantherina*, another member of the group, is 5 to 14 cm in length and diameter, with a white to brown cap, and has the ring and cup on the stem (Figure 219-2). Both specimens grow under trees in woodlands throughout North America.

CLINICAL FEATURES

Symptoms typically develop within 2 hours of ingestion of hallucinogenic mushrooms. Euphoria, a heightened imagination, a loss of the sense of time, and visual distortions or hallucinations are common. Tachycardia and hypertension may be noted because of the presence of phenylethylamine in psilocybin-containing mushrooms.[10] Fever and seizures have been reported in rare cases. Symptoms generally last 4 to 6 hours but can persist up to 12 hours.[11] There are infrequent reports of flashbacks for up to 4 months after ingestion, particularly in association with other substances that alter cognition such as alcohol or marijuana.[9]

Patients ingesting isoxazole-containing mushrooms usually present with symptoms within 30 minutes of ingestion. Signs of muscarinic poisoning are the first apparent (nausea, vomiting, diarrhea, vasodilation, diaphoresis, salivation). These are replaced by an atropine-like symptom complex about 30 minutes after ingestion (mydriasis, xerostomia, elevated temperature, increased blood pressure), along with drowsiness, amentia, dizziness, photosensitivity, euphoria, motor hyperactivity, ataxia, muscle jerking, hallucinations, and delirium with difficulty with perception of size, time, and place. Seizures have been reported in children. Symptoms are typically self-limited, resolving within 4 to 6 hours after ingestion. Headache and fatigue are reported to occur the day following ingestion, with headache lasting up to a few weeks.[9]

TREATMENT

Treatment for ingestion of hallucinogenic mushrooms is largely supportive. Place the patient in a darkened, quiet room, devoid of visual stimuli, and provide reassurance. If sedation is required, benzodiazepines such as diazepam or lorazepam are preferred. Do not give anticholinergic agents because they may aggravate delirium.

Treat symptomatic ingestion of isoxazole-containing mushrooms with activated charcoal. Do not give syrup of ipecac because of the potential for CNS depression and seizures, which place the patient at risk for aspiration. In patients with severe vomiting and diarrhea, replace fluids and electrolytes. Appropriately restrain patients who are agitated, and provide sedation as necessary with benzodiazepines (diazepam or lorazepam). Treat seizures with benzodiazepines.

Consider treatment with physostigmine only for patients with severe anticholinergic symptoms. Physostigmine can produce bradycardia, hypotension, and seizures, so administration should be reserved for severely symptomatic patients. The dose is 1 to 2 milligrams IV in adults and 0.5 milligram IV in children, administered slowly. Monitor continuous cardiorespiratory effects and blood pressure during administration. Base the decision to discharge from the ED on duration of symptoms and need for ongoing pharmacologic sedation or intubation.

EARLY-ONSET MUSCARINIC SYMPTOMS

Muscarine was the first mushroom toxin to be identified.[12] Mushrooms of the *Inocybe* and *Clitocybe* genera are common causes of muscarinic poisoning (**Figure 219-5**). The *Inocybe* mushrooms are small brown

FIGURE 219-4. *Omphalotus olearius.* [Photo used with permission of Jilber Barutciyan.]

FIGURE 219-5. *Clitocybe candicans.* [Photo used with permission of Jilber Barutciyan.]

mushrooms with conical caps, typically found under hardwoods and conifers. The *Clitocybe* mushrooms are usually found individually on lawns and in parks and are white to gray, with a cup-shaped cap. *A. muscaria*, despite its name, contains far less muscarine than these other groups and only rarely causes cholinergic poisoning symptoms. Isoxazole-containing mushrooms can cause transient muscarinic symptoms early after ingestion.

PATHOPHYSIOLOGY

Muscarine is a parasympathomimetic compound that is heat stable and acetylcholine like. It is not degraded by cholinesterase and, therefore, has a long duration of action.[13] Acetylcholine receptors on the heart, apocrine glands, and smooth muscle are activated by muscarine.[12] Mushrooms containing muscarine cause neurologic symptoms and muscarinic or cholinergic effects.

CLINICAL FEATURES

The symptoms of muscarinic intoxication are characterized by the **SLUDGE syndrome** (salivation, lacrimation, urination, defecation, GI hypermotility, and emesis). In addition to the SLUDGE syndrome, patients with muscarine ingestions can develop diaphoresis, muscle fasciculations, miosis, bradycardia, and bronchorrhea. Symptoms typically present within 30 minutes of ingestion and spontaneously resolve in 4 to 12 hours.

TREATMENT

In most cases, muscarinic symptoms are mild and self-limited. Supportive care is sufficient. Because emesis is a common presenting symptom, activated charcoal administration is often difficult. Patients with severe vomiting may require IV fluid and electrolyte replacement.

Atropine is an antidote for muscarinic symptoms and can be administered to patients with severe symptoms. It can be effective in treating bradycardia and hypotension unresponsive to IV fluid administration. Atropine is helpful in the treatment of diaphoresis, increased oral secretions, and bronchorrhea. It may also help reduce GI cramping, emesis, and diarrhea. The dose is 0.5 to 1.0 milligram IV for adults and 0.01 milligram/kg IV for children (minimum dose, 0.1 milligram; maximum does, 1 milligram). The dose can be repeated as necessary to control bronchorrhea, bradycardia, or hypotension. Large doses may be necessary to treat severe toxicity. Patients should be carefully monitored during administration. Oxygen and inhaled β agonists (albuterol) are recommended for the treatment of patients with increased pulmonary secretions and bronchospasm.

Because symptoms of muscarinic poisoning frequently resolve within 12 hours of ingestion, many patients can be safely discharged from the ED after observation when symptoms have subsided.

DELAYED-ONSET GI SYMPTOMS

Mushrooms of two different genera, *Gyromitra* and *Amanita*, cause significant toxicity, which characteristically presents several hours after ingestion. *Gyromitra esculenta* (the false morel) is an uncommon cause of poisoning in North America, but is more common in Scandinavia and Europe.[4] *G. esculenta* has a brown convoluted top resembling a brain and is often mistaken for the tasty morel mushroom. *A. phalloides* and *A. bisporigera* are common in the Northern Hemisphere and are particularly common from north central Europe through the Middle East. Mushrooms of these species are found throughout the West Coast, Midwest, and parts of the Northeast of the United States. Immigrants may mistake these mushrooms for edible varieties common in eastern Asia. Mushrooms of the *Amanita* genus are responsible for 95% of deaths associated with mushrooms. Toxic ingestions in North America occur most commonly in the autumn.

PATHOPHYSIOLOGY

Gyromitrin (*N*-methyl-*N*-formylhydrazone) is a volatile heat-labile toxin and primarily responsible for symptoms. Gyromitrin concentration decreases significantly after boiling and desiccation.[14] Gyromitrin is hydrolyzed in the stomach to form *N*-methyl-*N*-formylhydrazine and *N*-methylhydrazine. *N*-Methylhydrazine is chemically identical to rocket fuel, and workers exposed to this compound develop CNS toxicity. *N*-Methylhydrazine binds to pyridoxine and interferes with enzymes that require pyridoxine as a cofactor. γ-Aminobutyric acid is lowered in the CNS, which may be a cause of associated seizures. *N*-Methyl-*N*-formylhydrazine is converted into a free radical in the liver and causes local hepatic necrosis by blocking the activity of the cytochrome P-450 system, glutathione, and other hepatic enzyme systems.[14] These two chemicals explain the CNS and hepatic dysfunction characteristic of gyromitrin toxicity. The cause of the initial GI symptoms is not known.

A. phalloides contains several phallotoxins and amatoxins. Phallotoxin is a bi-cyclic peptide that alters the enterocyte cellular membrane, thereby causing early GI symptoms. Its effect is limited to the GI tract, because it is not absorbed by the intestine.[15] Amatoxins are bi-cyclic octapeptides that are rapidly absorbed through the intestinal mucosa. They are carried to the liver and undergo enterohepatic circulation, which results in prolonged toxin exposure after ingestion. Nine amatoxins have been identified, but α-amanitin (amanitin) appears the most physiologically active.[2] Kinetic studies in humans show that α-amanitin is cleared from the plasma within 48 hours.[16] Concentrations in the plasma are quite small. Amatoxins are not protein bound, but are actively transported into hepatocytes, where they bind to RNA polymerase II and inhibit the formation of messenger RNA. Free radical formation may also be involved in toxicity.[17] α-Amanitin has the greatest effect on cells that undergo rapid protein synthesis and turnover, including cells of the GI tract mucosa, hepatocytes, and renal tubular epithelium.[18] In adults, the dose that causes 50% mortality is 0.1 milligram/kg of body weight, which is commonly contained in a single mushroom.[15]

Pathologic changes are noted in both gyromitrin and amatoxin toxicity. Patients who ingest gyromitrin-containing mushrooms show diffuse hepatocellular damage and interstitial nephritis. Patients who ingest amatoxin-containing mushrooms show fatty degeneration of the liver, with intranuclear collection of lipids and extensive hepatic necrosis. Electron microscopy shows vacuolization of the mitochondria and clumping of the chromatin in the nucleoli. There are extensive lipid peroxidation changes in both the nucleus and the cytoplasm.

CLINICAL FEATURES

The distinctive characteristics of gyromitrin-containing mushroom toxicity are intense GI signs and symptoms (nausea, vomiting, and watery diarrhea) that develop 6 to 24 hours after ingestion, typically between 6 and 8 hours.

Hypovolemia is common during this phase of toxicity. In severe cases, hepatic failure is evident on day 3 and may result in death as early as day 7. Serum transaminase levels may be significantly elevated. **Hypoglycemia** occurs during the GI phase and again in the acute hepatic failure phase.

Initial GI symptoms can be accompanied by dizziness, headache, seizures, incoordination, and muscle cramps. The initial GI symptoms resolve within 2 to 5 days.[5] In a mild ingestion, the neurologic symptoms persist for several days and resolve without sequelae.

Patients who ingest amatoxin-containing mushrooms also have delayed onset of GI symptoms (6 to 24 hours). The gastroenteritis is intense, often requiring fluid and electrolyte replacement. There are four stages in amatoxin poisoning. The first (latent) stage is characterized by the absence of any signs or symptoms and lasts up to 24 hours after ingestion. During the 12 to 24 hours of the second stage, GI symptoms such as intense cramping abdominal pain, nausea, vomiting, and diarrhea dominate the clinical picture. Both stools and vomitus may become bloody. Although right upper quadrant tenderness and hepatomegaly may be noted, results of liver function tests are usually normal. Patients who present during this stage are frequently misdiagnosed with gastroenteritis. The third, or convalescent, phase lasts 12 to 24 hours. During this stage, the patient feels and looks better, but levels of liver enzymes, such as aspartate aminotransferase, alanine aminotransferase, and bilirubin, begin to rise, heralding the onset of liver damage. Renal function may also deteriorate. In the fourth and final stage, which begins 2 to 4 days

after ingestion, transaminase levels rise dramatically, and liver and renal function deteriorate. Hyperbilirubinemia, coagulopathy, hypoglycemia, acidosis, hepatic encephalopathy, and hepatorenal syndrome are noted.[2]

In both *Gyromitra* and *Amanita* toxicity, prothrombin time may be elevated and unresponsive to administration of vitamin K or fresh frozen plasma. Amylase and lipase elevation suggests pancreatic damage, although symptomatic pancreatitis is rare. Abnormal laboratory findings in amatoxin poisoning include a decrease in neutrophils, lymphocytes, and platelets, and abnormal thyroid function results. Hypophosphatemia (primarily noted in children), hypocalcemia, and elevated insulin levels occur. None of these laboratory abnormalities correlates with clinical disease, and their cause is unknown.

The mortality from *Gyromitra* ingestion is estimated at 15% to 35% and is generally attributed to hepatic failure, renal failure, or fluid and electrolyte disorders.[5] More recently, mortality has been reduced to 10% to 15%, because of improved care for hepatic failure and liver transplantation. Patients who survive severe hepatic failure from amatoxin may develop signs of chronic active hepatitis with persistent elevation in liver transaminase levels, development of anti–smooth muscle antibodies, and presence of cryoglobulins. No prolonged effects from gyromitrin toxicity have been reported.

DIAGNOSIS

The diagnosis of gyromitrin toxicity is generally assumed from the clinical features and the identification of the mushroom ingested, either by the patient or from samples. Identification of *Amanita* species generally requires a trained mycologist. The **Meixner colorimetric test** is used to look for the presence of amatoxin. A drop of fresh mushroom pulp, methanol extract from dried mushrooms, or gastric material is placed on a high-lignin paper (e.g., newspaper) and allowed to dry. A drop of 10-N or 12-N hydrochloric acid is then applied to catalyze the reaction of the amatoxin with the lignin in the paper. The area will turn blue within 1 to 2 minutes if amatoxins are present, but the appearance of color may be delayed up to 30 minutes if the amatoxin concentration is low.[2] Although the test is sensitive, it is not very specific, and other nontoxic mushrooms may give a positive test result. Tests using thin-layer chromatography, high-performance liquid chromatography, and radioimmunoassay have been developed to detect amatoxin. Unfortunately, these assays are not generally available to clinicians and are used most often in research settings.[2] Amatoxin can be detected in plasma, urine, GI tract contents, and feces. However, its presence merely confirms amatoxin poisoning. Levels do not appear to correlate with clinical severity, and amatoxin is not detected in many patients, presumably because of rapid clearance.

TREATMENT

Administer activated charcoal to patient presenting with severe vomiting and diarrhea within a few hours of mushroom ingestion. Repeated doses of charcoal for at least the first 24 hours may be effective, particularly in the presence of amatoxin (because it undergoes enterohepatic circulation).[15] Fluid and electrolyte replacement is mandatory. Glucose level should be monitored and glucose replaced as needed. **Hypoglycemia is one of the most common causes of death in early mushroom toxicity.**

All patients who have ingested amatoxin- or gyromitrin-containing mushrooms should be closely monitored for 48 hours for the development of hepatic and renal failure. Electrolyte levels, liver enzyme levels, and prothrombin time should be monitored several times a day. Patients should be treated with a low-protein diet and should receive standard supportive therapy for hepatic failure. Fresh frozen plasma and vitamin K can be used for the treatment of prolonged prothrombin time, but in many cases, coagulopathy does not respond to treatment.

Patients who develop hepatic failure should be monitored closely, and in severe cases, preparations should be made for liver transplantation. Although no firm criteria exist, progressive coagulopathy, encephalopathy, and renal failure despite maximal medical therapy are frequently listed indications for emergency liver transplantation.[19] Many patients have met these criteria and survived without transplantation, and many patients have died without meeting these criteria. Liver transplantation, however, does provide the only option for patients in fulminant hepatic failure and has been quite successful. Auxiliary liver transplantation has also been used. In this case, a portion of the damaged liver is removed and a temporary transplant provided, which allows time for the native liver to regenerate.[20]

Gyromitrin-Specific Treatment Treat the neurologic symptoms associated with gyromitrin with high-dose pyridoxine. **Pyridoxine** provides the cofactor required for the regeneration of γ-aminobutyric acid. High doses of pyridoxine, 25 milligrams/kg IV over 30 minutes up to a maximum of 25 grams/d, are recommended, but doses of pyridoxine in excess of 40 grams are associated with severe peripheral neuropathy.[21,22] Pyridoxine does not affect the development or course of hepatic failure, and there is no specific therapy for gyromitrin-induced hepatic failure.

Amatoxin-Specific Treatment Although multiple modalities have been tried in the past with mixed results, **activated charcoal**, *silybinum marianum,* and ***N*-acetylcysteine** are emerging as the best-supported treatment modalities.[15,23] Early in the clinical course, repeated dosing of activated charcoal is thought beneficial by reducing the absorption of amatoxin as it undergoes enterohepatic circulation. *Silybinum marianum,* a milk thistle isolate, is also thought to prevent toxicity by interfering with transmembrane transport during enterohepatic circulation and inhibiting the binding of α-amanitin to hepatocytes.[15,23] There is some evidence that *silybinum* has additional hepatoprotective effects that result from stimulating protein synthesis and inhibiting tumor necrosis factor-α release in damaged liver cells.[23] It is given as a loading dose of 5 milligrams/kg over 1 hour followed by 20 milligrams/kg/d for 6 days. This treatment is not currently approved by the U.S. Food and Drug Administration; it is available in Europe, and phase II/III clinical trials are in progress in the United States.[15] *N*-Acetylcysteine is also beneficial as a means of reducing reactive metabolites by providing sulfhydryl groups for this purpose. It is given intravenously in three sequential doses of 150 milligrams/kg over 1 hour, 50 milligrams/kg over 4 hours, and 100 milligrams/kg over 16 hours.

Despite these therapies, amatoxin toxicity may lead to fulminant liver failure. In cases of amatoxin-induced liver failure, the amatoxin itself is rapidly absorbed and excreted, which limits the utility of hemoperfusion and/or hemodialysis. The Molecular Adsorbent Recirculation System™ can support liver function while hepatocytes recover or until transplantation becomes feasible.[24] Although randomized controlled trials are not available, numerous case reports have shown improved liver functioning coinciding with this device.[24] Orthotopic liver transplantation (the entire organ is replaced with a graft) and auxiliary partial orthotopic liver transplantation (a portion of the native liver is removed and replaced with a graft until recovery occurs) are both surgical options.[15]

High-dose penicillin G and ceftazidime have both demonstrated a capacity for decreasing the uptake of amanitin by hepatocytes.[18,25] However, these therapies appear to be less effective than using *silybinum* alone.[23] Thioctic acid is a free radical scavenger and has been used for many years but has not yet gained support in the literature.

Patients suspected of ingesting amatoxin- or gyromitrin-containing mushrooms should be admitted and monitored for 48 hours, with monitoring of hepatic and renal function.

DELAYED-ONSET RENAL FAILURE

Delayed-onset renal failure is seen after ingestion of *Cortinarius* (*Cortinarius orellanus*, *Cortinarius speciosissimus*, and *Cortinarius gentilis*) and *A. smithiana* mushrooms.[26] *Cortinarius* species are found primarily in Europe. This mushroom is often mistaken for a pine mushroom and grows commonly in the Pacific Northwest. *A. smithiana* mushrooms are common in forest areas of western North America.[7]

PATHOPHYSIOLOGY

Orellanine and ortinarin A and B are the nephrotoxic compounds in species of *Cortinarius* (*C. orellanus*, *C. speciosissimus*, and *C. gentilis*). These toxins are heat stable, and their mechanisms of action are not well

known. Orellanine and its derivatives are believed to inhibit protein synthesis in the kidneys. Histopathologic examination indicates interstitial nephritis with edema and leukocyte infiltration, tubular necrosis, basal membrane rupture, and fibrosis without glomerular injury in patients poisoned with orellanine-containing mushooms.[18,22,27]

Allenic norleucine (aminohexadienoic acid) and chlorocrotylglycine are the nephrotoxins found in *A. smithiana*.[26] Allenic norleucine has been shown to induce renal tubular epithelial necrosis and tends to exert its effect earlier than orelline in cultured cell lines.[7]

CLINICAL FEATURES

Patients who ingest mushrooms containing nephrotoxins often present initially with GI symptoms, including nausea, vomiting, and nonbloody diarrhea. Symptoms begin several hours to days after ingestion and may persist for 3 days. Occasionally, paresthesias, abnormal taste, and cognitive dysfunction are reported. Symptoms of renal failure, including lumbar and flank pain, oliguria, or more rarely polyuria, begin between 3 and 20 days after ingestion. Patients who ingest *A. smithiana* tend to develop GI symptoms earlier, with a range of symptom onset between 30 minutes and 12 hours (median, 5 to 6 hours). Orellanine ingestion tends to present with GI symptoms later, with a range of 12 hours to 14 days after ingestion. Similarly, renal failure is noted to develop earlier in allenic norleucine cases (within 3 to 5 days) and occurs within 4 to 15 days of orellanine ingestion.[7] Orellanine poisoning can be confirmed by thin-layer chromatography of renal biopsy specimens or by plasma assays for orellanine or orelline, but these tests are not commonly available in clinical practice.[5] Many patients who ingest these mushrooms never develop renal dysfunction, which suggests variability in host sensitivity to their toxic effects. Consider allenic norleucine or orellanine toxicity from wild mushroom ingestion in a patient with unexplained acute renal failure.

TREATMENT

There is no specific treatment for patients who develop renal failure from ingestion of *Cortinarius* or *A. smithiana* mushrooms. Monitor urine output and electrolyte, calcium, magnesium, BUN, and creatinine levels. Hemodialysis is indicated for refractory hyperkalemia, refractory acidosis, uremic symptoms, or severe renal dysfunction. Supportive hemodialysis may be required, but many patients experience a spontaneous return of normal renal function. Because spontaneous improvement is reported, renal transplantation should be withheld for several months to monitor patient response. Renal transplantation has been used in several patients with good success.[28]

Monitor patients suspected of ingesting orellanine- or ortinarin-containing mushrooms for at least 72 hours for electrolyte abnormalities and renal failure.

DELAYED-ONSET DISULFIRAM REACTION

Perhaps most interesting, although clinically least important, is a mushroom toxin contained in the *Coprinus* genus. This mushroom, which is very common in North America, is known as "inky cap" or "shaggy mane." It is a tall, white, thin mushroom with a shaggy cap. As the mushroom ages, the cap liquefies and blackens, and black liquid drips from the necrosing cap. The mushroom contains coprine, which is chemically related to disulfiram.

PATHOPHYSIOLOGY

Coprine causes inhibition of alcohol dehydrogenase within 2 hours of ingestion, and activity may last up to 72 hours. If alcohol is consumed during this sensitive period, patients develop a typical disulfiram reaction. Mushrooms ingested at the same time as alcohol produce no toxicity.

CLINICAL FEATURES

Because of the delay between mushroom consumption and alcohol consumption, few patients link their symptoms to the ingestion of a mushroom. Symptoms include headache, paresthesias of distal extremities, metallic taste, flushing, palpitations, chest pain, nausea, vomiting, and diaphoresis and generally occur within minutes to several hours after alcohol consumption. Symptoms generally last for 2 to 4 hours but may last up to 2 days.[5] Most symptoms are mild. Diagnosis is made based on presence of the symptom complex and its association with alcohol consumption.

Because alcohol is readily absorbed from the GI tract, GI decontamination has no role and charcoal administration is not beneficial. Patients occasionally become hypotensive and respond to administration of IV fluids or, in refractory cases, norepinephrine. Excessive sympathetic activity can be inhibited by β-blockers.[5]

Most cases are self-limited, and patients can be discharged once they can tolerate oral fluids. Prior to discharge, educate patients about the link between alcohol consumption and mushroom ingestion.

SHIITAKE DERMATITIS

Shiitake dermatitis is a well-known entity in Japan, China, and Korea, and cases have been reported in Europe and the United States.[29,30] Shiitake dermatitis is a characteristic flagellate erythema appearing as whip-like, linear wheals that appear within 1 or 2 days of ingesting raw or cooked shiitake mushrooms. The rash tends to be pruritic and can also involve branching patches of erythema and scattered petechiae. The pathophysiology is not fully understood but is thought to be toxin-induced, involving the thermolabile polysaccharide lentinan that is found in the shiitake mushroom. Skin biopsy results are nonspecific.[29,30] Allergy testing in affected individuals is negative.[30]

Treat symptoms with 0.1% triamcinolone ointment twice daily and oral antihistamines. Regardless of treatment, the rash resolves spontaneously without hyperpigmentation in 1 to 4 weeks.[29,30]

The rash is self-limited, and no sequelae have been reported.

SPECIAL POPULATIONS

Toxic mushroom exposure during pregnancy has been reported.[28] In one series, a slightly lower birth weight was noted in infants born to mothers with toxic mushroom exposure than in infants of mothers with no such exposure. Most infants appeared to be healthy and developmentally normal, in keeping with the findings that amatoxins do not cross the placental barrier.[31,32]

CHAPTER 220

Poisonous Plants

Betty C. Chen
Lewis S. Nelson

INTRODUCTION

Common poisonous and injurious plants number in the hundreds and have a wide variety of toxicities. This chapter focuses on the most important plant-related exposures clinically relevant to emergency medicine (**Tables 220-1 and 220-2**).[1,2] Individual plants are discussed in terms of their pathophysiology, clinical features (toxidromes), and treatment.[3] Highly poisonous plants (Table 220-1) are highlighted in depth below, and brief reviews are provided for other common poisonous plants. Table 220-2 organizes common poisonous plants according to toxin structure.

TABLE 220-1 Some Highly Poisonous Plants

Poison hemlock (*Conium maculatum*)
Yew (*Taxus spp.*)
Foxglove (*Digitalis purpurea*)
Oleander (*Nerium oleander*)
Castor bean (*Ricinus communis*)
Rosary pea (*Abrus precatorius*)
Water hemlock (*Cicuta maculata*)
Buckthorn (*Karwinskia humboldtiana*)

EPIDEMIOLOGY

In 2012, the American Association of Poison Control Centers received 49,374 reports of plant exposures. Of these cases, 31,920 involved children less than 5 years of age. There were an additional 2918 nonexposure calls that provided information about plants to callers.[2] The vast majority of exposures (96%) are unintentional ingestions. Cutaneous and ophthalmic exposures are common but generally go unreported. Although inhalational exposures are possible, they are rarely reported.

Unfortunately, obtaining an accurate plant exposure history can be difficult. Most exposures occur in children and are usually unwitnessed. Uncertainty typically surrounds these cases, particularly whether ingestion truly occurred. The timing and amount of exposure is also difficult to quantify in many of these situations. Furthermore, even when a plant is available, identification errors are common and may require a botanist's expertise. In fact, data from the National Poison Data System demonstrate that medical providers and poison centers are unable to identify plants more than 22% of the time.[2]

CLINICAL FEATURES

Classification of plants and their toxicities is complex. The most straightforward approach for emergency physicians is to classify toxic plants by the mechanism of action of the toxin and then to further subclassify based on the specific toxin. This will help predict the toxicologic effects. The reverse process can be used if the patient presents with clinical findings (Table 220-2). Unfortunately, attributing one toxicologic syndrome

TABLE 220-2 Classification of Poisonous Plants

Classification	Mechanism of Toxicity	Example Plant Species
Alkaloids	Solanine and chaconine	Green potato leaves, American nightshade, black nightshade (Solanaceae)
	Anticholinergics	Deadly nightshade (*Atropa belladonna*) Angel's trumpet or jimsonweed (*Datura* spp.) Henbane (*Hycoscyamus niger*) Mandrake (*Mandragora officinarum*)
	Cholinergics	Calabar bean (*Physostigma venenosum*) Pilocarpus (*Pilocarpus* spp.)
	Nicotinic and nicotine-like	Tobacco (*Nicotiana* spp.) Poison hemlock (*Conium maculatum*) Golden chain (*Laburnum anagyroides*) Blue cohosh (*Caulophyllum thalictroides*) Lupin (*Lupinus* spp.)
	Psychotropics	Peyote (*Lophophora williamsii*) Nutmeg and mace (*Myristica fragrans*) Morning glory (*Agyreia* spp. and *Ipomoea* spp.) Hawaiian baby woodrose seeds (*Argyreia nervosa*)
	Hepatotoxic pyrrolizidines	Comfrey (*Symphytum officinale*) Sassafras (*Sassafras albidum*) Ragwort (*Heliotropium* spp.)
	Sodium channel modulators	Monkshood (*Aconitum* spp.) Larkspur (*Delphinium* spp.) False or green hellebore (*Veratrum* spp.) Yew (*Taxus* spp.)
	Antimitotic alkaloids and resins	Autumn crocus (*Colchicum autumnale*) Mayapple (*Podophyllum peltatum*) Wild mandrake (*Podophyllum emodi*) Glory lily (*Gloriosa superba*) Madagascar periwinkle (*Catharanthus roseus*)
Glycosides	Cardioactive steroids or cardiac glycosides	Foxglove (*Digitalis purpurea*) Lily of the valley (*Convallaria majalis*) Oleander (*Nerium oleander*) Christmas rose (*Helleborus niger*) Milkweed (*Asclepias* spp.) Squill (*Urginea maritime and Urginea indica*) Yellow oleander (*Thevetia peruviana*)
	Cyanogenic glycosides	Almond, apricot, and cherry pits (*Prunus* spp.) Tapioca plant, cassava (*Manihot esculenta*) Elderberry (*Sambucus canadensis*) Hydrangea (*Hydrangea macrophylla*)
	Saponins	Holly (*Ilex* spp.)
	Salicylates	Poplar species (*Populus* spp.) Willow species (*Salix* spp.)
Proteins, peptides, and lectins	Toxalbumins	Castor bean (*Ricinus communis*) Rosary pea (*Abrus precatorius*) Pokeweed (*Phytolacca americana*) Black locust (*Robinia pseudoacacia*) American mistletoe (*Phoradendron flavescens*) European mistletoe (*Viscum album*) Black vomit nut (*Jatropha curcas*)
	Hypoglycin	Ackee fruit (*Blighia sapida*)
Carboxylic acids	Calcium oxalate crystals	Dumbcane (*Dieffenbachia* spp.) Philodendron (*Philodendron* spp.) Caladium (*Caladium* spp.) Jack in the pulpit (*Arisaema triphyllum*) Elephant's ear (*Colocasia* spp.) Rhubarb (*Rheum raponticum*)
Alcohols	Convulsants	Water hemlock (*Cicuta maculate*)
Phenols and phenylpropanoids	Coumarins and derivatives	Sweet clover (*Melilotus* spp.) Tonka beans (*Dipteryx* spp.) Sweet-scented bedstraw (*Galium triflorum*) Red clover (*Trifolium pretense*)
	Capsaicin	Cayenne pepper (*Capsicum* spp.)
	Demyelination	Buckthorn or coyotillo (*Karwinskia humboldtiana*)
Terpenoids and resins	Grayanotoxin (sodium channel blockers)	Azalea and rhododendron (*Rhododoendron* spp.), mountain laurel (*Kalmia latifolia*)
	Kava lactones	Kava kava (*Piper methysticum*)
	Thujone	Wormwood (*Artemisia absinthium*)
	Anisatin	Star anise (*Illicum* spp.)
	Tetrahydrocannabinol	Marijuana (*Cannabis sativa*)

per plant oversimplifies the complexity of plant chemistry, because plants often contain multiple toxic compounds, each of which produces its own toxicologic effects.

Moderate systemic effects as a consequence of plant-related exposures occur in about 1% of patients. Severe life-threatening effects or disabling injuries are extremely uncommon and occur in only about 0.04% of patients. Death occurs in <0.001% of patients.

Dermatitis and GI irritation are the most commonly reported effects of plant toxicity. GI complaints occur commonly following ingestion, and additional toxic symptoms may accompany or follow. Although dermatitis is another commonly reported finding of plant toxicity, systemic toxicity rarely follows (see Table 220-3).

TREATMENT

Most plant-related exposures can be managed with supportive care. In patients able to tolerate oral administration and believed to have potentially concerning exposures, administer activated charcoal to prevent absorption of toxin from the GI tract. Because of the uncertainty surrounding plant exposures, observe asymptomatic or minimally symptomatic patients for 4 to 6 hours in the ED. Discharge asymptomatic patients and those with resolved minor toxicity after observation, with strict return precautions if symptoms develop. Admit those with more than minimal findings because toxicity may continue to evolve. This approach is generally applied to all patients with plant exposure because the scientific literature lacks adequate data to provide less conservative recommendations. There are few antidotes available to treat poisonings by plant toxins; none are unique to plant exposures but rather are generalized from use in other poisonings.

Report all exposures to the regional poison control center to obtain assistance with plant identification, to obtain assistance with patient management, and to enable collection of accurate data on toxic plant exposures. Unfortunately, data reported by the National Poison Data System does not require confirmation of exposure, and the incidence of adverse effects is diluted by inconsequential or unconfirmed ingestions.

NICOTINIC AND NICOTINE-LIKE TOXINS (POISON HEMLOCK)

In *Phaedo*, Plato details the death of Socrates: after drinking a potion consisting of the extracts of poison hemlock (*Conium maculatum*), he slowly develops paralysis and dies. All parts of poison hemlock contain coniine and similar alkaloids that are structurally and functionally analogous to nicotine. Overstimulation of nicotine receptors can rapidly progress from seemingly mild symptoms to death from respiratory failure. Symptoms may occur within hours. Mild effects include nervousness and tremor due to sympathomimetic stimulation. As toxicity progresses, patients exhibit more pronounced sympathomimetic features, parasympathetic findings, and paralysis from nicotinic receptor stimulation at the neuromuscular junction. Typically, ingestion of poison hemlock is due to misidentification because of its similarity in appearance to wild carrot or Queen Anne's lace (*Daucus carota*), parsley (*Petroselinum crispum*), parsnip (*Pastinaca sativa*) roots, or anise (*Pimpinella anisum*). Although most ingestions are unintentional, there are case reports of toxicity from intentional use by patients for a presumed opioid-like effect or for intentional self-harm.[4-6] Treatment consists of GI decontamination with activated charcoal and supportive care, which may include respiratory support and administration of IV fluids, antidysrhythmics, and anticonvulsants.

SODIUM CHANNEL TOXINS (YEW, RHODODENDRON, LAUREL, MONKSHOOD, LARKSPUR)

A number of plants across different classifications cause sodium channel effects that result in cardiac, respiratory, GI, and CNS effects. Yew (*Taxus* spp.) contains taxine alkaloids in all parts of the shrub except the aril, which is the berry's red fleshy portion. The hard seed inside of the berry contains taxine alkaloids that block sodium and calcium channels.[7,8] Few symptoms are to be expected if ingestions are small or if berries are consumed without crushing the central seed. However, large ingestions can lead to more serious effects.

Grayanotoxins are terpenoids, which inhibit the opening of sodium channels, and are found in the leaves, flowers, and nectar of several plants such as azaleas and rhododendron (*Rhododendron* spp.). They are also found in in the mountain laurel (*Kalmia latifolia*). Ingestion of the leaves, flower, or honey from the nectar of the flower can result in toxicity.[9]

Aconite, found in monkshood (*Aconitum* spp.) and larkspur (*Delphinium* spp.), is an alkaloid that activates cardiac, and less so neuronal, sodium channels. Monkshood is sometimes used in traditional Chinese medicine as an inotrope. False or green hellebore (*Veratrum* spp.) is often confused for leeks by foragers, and these plants contain veratridine and other assorted veratrum alkaloids, which function similarly to aconite.

Regardless of the particular alkaloid or terpenoid and its specific mechanism of cardiac toxicity, findings after ingestion include salivation, lacrimation, bradycardia or tachycardia, cardiac dysrhythmias, hypotension, hyperkalemia, paresthesias, muscle weakness, respiratory failure, seizures, and potentially death.[8-10]

Early after ingestion, activated charcoal may decrease absorption from the GI tract. No antidote is available, and symptomatic patients should receive supportive care such as IV fluids or vasopressors if hypotensive. Atropine is effective for bradycardia, but antiarrhythmics, such as amiodarone, carry variable efficacy, as reported in the literature. Cardioversion for wide complex dysrhythmias can be attempted in unstable patients with the understanding that instability may persist and dysrhythmias may recur given the underlying channelopathy. Case reports describe successful use of extracorporeal membrane oxygenation in treating critically ill patients with refractory cardiac toxicity from yew posioning.[8,11,12]

CARDIOACTIVE STEROIDS (FOXGLOVE, OLEANDER)

Cardioactive steroids are found in many plants, including foxglove (*Digitalis* spp.), oleander (*Nerium* spp.), dogbane (*Apocynum cannabinum*), lily of the valley (*Convallaria majalis*), and milkweed (*Asclepias* spp.). Cardioactive steroids, sometimes called cardiac glycosides, inhibit the sodium/potassium–adenosine triphosphatase pump. Acute toxicity closely resembles that from digoxin and includes early GI symptoms followed by cardiac dysrhythmias. Serum digoxin concentrations may be used to qualitatively confirm cardioactive steroid exposure due to cross-reaction with the laboratory assay, but the absolute value holds little clinical quantitative value. Early after ingestion, oral activated charcoal may decrease systemic exposure by preventing absorption.[13] Assess serum potassium concentration and obtain an ECG to aid in prognosis and therapy. Administer digoxin immune Fab fragments to patients with a serum potassium >5 mEq/L after an acute overdose or any cardiac dysrhythmia.[14] Antidote dosing should be empiric (unlike with digoxin), and the digoxin concentration should not be used to calculate dosing, because the assay is not an accurate reflection of toxin burden. Avoid transvenous pacing and calcium administration for the increased theoretical risks of inducing a dysrhythmia. Traditional treatments for hyperkalemia such as insulin, calcium, sodium bicarbonate, or hemodialysis are usually unnecessary if digoxin immune Fab is administered.

TOXALBUMINS (CASTOR BEAN, RICIN)

Ricin and abrin are examples of toxalbumins that can be extracted from the castor bean (*Ricinus communis*) and rosary pea (*Abrus precatorius*), respectively. Ricin, in particular, is a potential biologic weapon and has been implicated in a number of attempted assassinations.

These toxalbumins are proteins, peptides, or lectins, which exert their toxicity by entering cells and inhibiting protein synthesis. The clinical syndrome associated with the toxalbumins depends on quantity as well as route of exposure. Although one castor bean contains enough ricin to

kill, its toxicity is typically limited following ingestion. Even if the castor bean is chewed to break the protective hard shell that sequesters the toxin, the enteral absorption of ricin is poor and tends to limit toxicity to diarrhea and abdominal pain. Although delayed systemic toxicity is possible following large ingestions, these symptoms tend to occur more in parenteral exposures. Systemic organ dysfunction includes cardiac, neurologic, hepatic, and renal sequelae. Inhalational exposures are rapidly progressive and can result in life-threatening respiratory failure, circulatory collapse, and death within 36 hours.[15]

Treat toxalbumin ingestion by administration of activated charcoal followed by a lengthy observation period. All routes of exposure can be fatal, but hydration and aggressive supportive care significantly reduce mortality. More information about ricin can be found at the Centers for Disease Control and Prevention Web site (http://www.bt.cdc.gov/agent/ricin/).

Toxalbumins are found in a number of other plants such as American mistletoe (*Phoradendron flavescens*) and European mistletoe (*Viscum album*). The leaves and stems contain phoratoxin and viscumin, both of which are less potent than ricin. The berries also contain low levels of toxins that may result in gastroenteritis following large doses. These berries are abundant in homes during the holiday season and are attractive to children. Fortunately, significant morbidity after berry ingestion is rare, although single incidents of seizure, gait instability, hepatotoxicity, and death have been reported.[16] Provide GI decontamination with activated charcoal accompanied by fluid and electrolyte monitoring for minimally symptomatic patients.

CONVULSANTS (WATER HEMLOCK)

Cicutoxin is a diol found in the water hemlock (*Cicuta maculata*), western water hemlock (*Cicuta douglasii*), and hemlock water dropwort (*Oenanthe crocata*). These plants are often mistaken for wild parsnip, turnip, or parsley, causing toxicity through dermal or enteric absorption. All parts of the plant are poisonous, with the highest concentration of cicutoxin in the tuber. Cicutoxin's mechanism of action is not fully understood. However, it may impair γ-aminobutyric acid receptor or potassium channel function. Toxicity can manifest as early as 15 minutes following exposure. Mild symptoms include GI discomfort, followed by bradycardia, hypotension, respiratory distress, seizures, and death. Seizures may be severe and refractory to conventional anticonvulsant therapy. The mortality rate may be as high as 30%.[17] Treatment consists of GI decontamination with activated charcoal and supportive care. Treat seizures with γ-aminobutyric acid agonists such as benzodiazepines or barbiturates.

DEMYELINATING ANTHRACENONES (BUCKTHORN)

Buckthorn or coyotillo (*Karwinskia humboldtiana*), which is found in the southwestern United States, Mexico, Central America, and the Caribbean, contains demyelinating anthracenones that lead to progressive muscle weakness that resembles Guillain-Barré syndrome. Weakness occurs weeks after ingestion, rendering GI decontamination futile in symptomatic patients. In severe cases, respiratory paralysis can lead to death without respiratory support. There is no antidote, and treatment is largely supportive until recovery.[9]

BELLADONNA ALKALOIDS (NIGHTSHADE, JIMSONWEED, HENBANE)

Deadly nightshade (*Atropa belladonna*), jimsonweed (*Datura* spp.), and henbane (*Hyoscyamus niger*) all contain atropine-like alkaloids such as hyoscyamine and scopolamine. Ingestion or smoking results in antimuscarinic effects such as tachycardia, hyperthermia, mydriasis, decreased bowel sounds, urinary retention, altered mental status, and dry, flushed skin. Severe poisoning can include seizures, coma, and death. Onset of effects depends on route of exposure, but findings should be evident within 4 hours. Exposures most commonly are intentional, such as through experimentation with the plant's hallucinogenic properties.[18]

Treatment is largely supportive. Benzodiazepines are useful in calming patients, but avoid antipsychotics such as haloperidol to prevent further antimuscarinic activity. Physostigmine inhibits cholinesterase, resulting in increased synaptic concentrations of acetylcholine that can overcome the muscarinic antagonism from the atropine-like alkaloids. Physostigmine is generally indicated only for patients with moderate to severe symptoms. Improvement in symptoms may be transient, and patients can require repeat dosing if symptoms recrudesce. Patients who receive physostigmine improve faster and require shorter hospitalizations than patients receiving sedative-hypnotics.

ANTIMITOTIC ALKALOIDS (AUTUMN CROCUS, GLORY LILY, MAYAPPLE)

Colchicine is contained in all parts of the autumn crocus (*Colchicum autumnale*) and glory lily (*Gloriosa superba*). Colchicine halts cellular mitosis by inhibiting microtubule formation. Gastroenteritis, which may be delayed (2 to 24 hours), is followed by multisystem organ failure. Common effects include coagulopathy, bone marrow suppression with granulocytopenia and thrombocytopenia, cardiac dysrhythmias, cardiogenic shock, acute respiratory distress syndrome, hepatic failure, delirium, seizures, coma, and death. If patients survive, alopecia and neuropathy may develop. Mild toxicity is expected if GI symptoms begin >9 hours after ingestion.[19,20]

Podophyllin is an extract of the roots of the mayapple plant (*Podophyllum peltatum*). This extract contains a mixture of toxins including podophyllotoxin, which inhibits topoisomerase II and microtubule formation. Toxicity is characterized by obtundation, coagulopathy, hematologic suppression, renal failure, GI irritation, hepatotoxicity, and death.[9]

Early after ingestion, pursue aggressive GI decontamination because there is no antidote and toxicity can be fatal due to multisystem organ involvement. Due to its delayed onset, observe exposed patients for a prolonged period. In addition to GI decontamination with activated charcoal, treatment usually requires aggressive fluid resuscitation and aggressive supportive care. Colchicine-specific Fab fragments have been used in colchicine-poisoned patients with some success experimentally but are not commercially available.

CALCIUM OXALATE (ELEPHANT'S EAR)

Many common household ornamental plants contain crystalline calcium oxalate. Examples include dumbcane (*Dieffenbachia* spp.), elephant's ear (*Colocasia* spp.), and philodendron (*Philodendron* spp.). The calcium oxalate crystals are needle-shaped and are packaged in raphides that also contain proteolytic enzymes and other chemicals. The contents are extruded when the plant is injured, causing both direct trauma from the crystals and inflammation due to the chemicals' effects.

Ingestion of calcium oxalate–containing plants results in immediate oropharyngeal pain and swelling. This pain usually limits the amount of plant ingested. In serious cases, the swelling can involve upper airway structures and cause respiratory compromise due to obstruction.[21] Ocular exposures to the calcium oxalate–containing plants result in ocular pain, corneal injury, and conjunctivitis. Pain and swelling can last up to 8 days.

Patients with oropharyngeal swelling and pain following ingestion tend to improve with supportive care. Anti-inflammatories may decrease swelling and provide analgesia. Topical treatments such as ice, ice water, and ice cream are soothing and can be given in patients with stable, patent airways. Patients at risk of airway obstruction must be closely monitored and should be quickly intubated if progressing. Consider steroid administration; however, there are no trials demonstrating outcome improvement with steroid use.

CYANOGENIC PLANTS (*PRUNUS* SPECIES)

Several thousand plants, including many common vegetables and fruits, contain cyanogenic compounds, such as amygdalin. Fortunately, the toxins are either sequestered in nonconsumed portions of the foods

(seeds) or exist in quantities that are not clinically significant. Amygdalin is found in the leaves, bark, and seeds of those fruits of the *Prunus* species, including pears, apples, plums, peaches, and apricots. Although the aril (fruit portion) of these plants is nontoxic, ingestion of the other portions of the plants and their seeds can result in the liberation of hydrogen cyanide from amygdalin in the GI tract. Linamarin and lotaustralin are present in cassava (*Manihot esculenta*) and are similarly hydrolyzed to liberate hydrogen cyanide.[9,22] If prepared correctly, the cyanogenic glycosides can be hydrolyzed prior to ingestion, thereby liberating the cyanide prior to consumption.[23,24] Initial effects may be slightly delayed and include GI irritation, followed by signs of tissue hypoxia. Rapid progression of toxicity can occur, and treatment for cyanide poisoning should be initiated immediately.

CAPSAICIN (PEPPERS)

Capsicum peppers contain capsaicin, a phenylpropanoid toxin that causes irritation, burning, and pain upon contact with skin and mucous membranes. This toxin enhances the release of substance P from small unmyelinated nerve fibers, which stimulate nociceptors that cause the sensation of burning or heat. Contact typically occurs as a result of self-inoculation while preparing peppers or exposure to spraying of pepper extracts in self-defense. Decontaminate affected areas by irrigation with copious amounts of water and gentle hand soap. Ocular exposures may require aggressive decontamination and ophthalmologic evaluation. Analgesics may be necessary.

MISCELLANEOUS GI TOXINS

Solanine and chaconine are glycoalkaloids that are present in many common plants and vegetables of the *Solanum* species. Unripe eggplant, green potatoes, and their sprouts contain a small amount of these heat-labile glycoalkaloids. Ingestion may cause GI effects such as vomiting, diarrhea, and abdominal pain, which can be delayed as long as 24 hours. CNS symptoms such as hallucinations, delirium, and obtundation are reported.[25] There is no definitive antidote for solanine or chaconine poisoning, and supportive care is usually sufficient.

Pokeweed (*Phytolacca americana*) contains phytolaccatoxin and similar phytotoxins in the leaves and roots. The mature berries are less toxic. Exposures can occur when foragers mistake the roots for other nontoxics such as parsnips or horseradish. Pokeweed is often prepared in poke salad or pokeroot tea. Toxicity is avoided if prepared by parboiling young greens. Incorrect preparation results in GI upset from direct mucosal irritation. Nausea, vomiting, hemorrhagic gastritis, abdominal pain, and profuse diarrhea may last for 48 hours.[26] Severe intoxications may rarely result in coma and death. Treatment is supportive. A nonconsequential lymphocytosis develops approximately 3 days after ingestion and typically resolves within 2 weeks.

Ackee fruit grows on the *Blighia sapida* tree, and it is a common ingredient in West African and Jamaican cuisine. Unripe ackee fruit contains the heat-stable toxins hypoglycin A and B. Hypoglycin A inhibits free fatty acids from entering the mitochondria, impairs substrate formation for gluconeogenesis, and prevents conversion of glutamate to γ-aminobutyric acid. The resulting clinical syndrome, which is characterized by severe vomiting and hypoglycemia, is Jamaican vomiting sickness. Severe cases develop acidemia, seizures, and encephalopathy.[9,27] Administer IV dextrose or a carbohydrate-heavy meal to hypoglycemic patients. Treat seizures liberally with benzodiazepines. However, seizures may be refractory to benzodiazepines if γ-aminobutyric acid concentrations are critically low. Rarely, chronic toxicity from hypoglycin A can lead to cholestatic hepatitis or fulminant liver failure.[9,28] Admit symptomatic patients for close monitoring and treatment.

Holly (*Ilex* spp.) exposures are in the top 10 plants reported to poison control centers.[2] Although the leaves are nontoxic, the attractive berries contain a mixture of toxins. The most consequential of this mixture are saponins, glycosides that cause abdominal pain, vomiting, and diarrhea. If fewer than six berries are ingested, minimal toxicity should follow.[29] Large ingestions with severe GI upset may result in electrolyte abnormalities. For symptomatic patients, treatment is supportive.

PLANT-INDUCED DERMATITIS

Dermal exposure to a number of plants can result in an undesired dermatitis. These exposures are some of the most commonly reported plant-related concerns reported to poison control centers in the United States.[2] Classification by mechanism of action can guide therapy (**Table 220-3**), but often, exposure to a single plant can result in injury due to multiple mechanisms.

MECHANICAL INJURY

Specialized plant structures can injure the dermis and serve as a nidus for entry of toxins. Needle-shaped crystals, such as calcium oxalate crystal bundles, are found in a number of common plants, including dumbcane (*Dieffenbachia* spp.) and philodendron (*Philodendron* spp.). Needles of pineapples (*Bromeliaceae* spp.) and the hairs of stinging nettles (*Urtica dioica*) directly pierce the dermis, and chemical irritants in these structures cause further dermal injury (see below).

IRRITANT DERMATITIS

Phorbol esters found in the sap of plants of the Euphorbiaceae (spurge) can cause dermal irritation following contact. Symptoms such as erythema and bullae may develop shortly after direct contact. The phorbol esters can penetrate the dermis upon contact. Ocular injuries and GI injury can also occur upon exposure or ingestion. Occasionally, aerosolized irritants can cause dermatitis or respiratory distress. Exposures to poinsettia (*Euphorbia pulcherrima*) are typically well tolerated.[30] Pineapples (*Bromeliaceae* spp.), stinging nettles (*U. dioica*), and dumbcane (*Dieffenbachia* spp.) all introduce irritants such as proteolytic

TABLE 220-3 Plant-Induced Dermatitis

Dermatitis Classification	Mechanism of Injury	Specific Plants
Mechanical injury		
	Calcium oxalate	Dumbcane (*Dieffenbachia maculate*) Philodendron (*Philodendron* spp.)
	Raphides and trichomes	Stinging nettles (*Urtica dioica*) Velvet bean or cowhage (*Mucuna pruriens*) Pineapple (*Bromeliaceae* spp.)
Irritant dermatitis	Phorbol esters	Cow's horn (*Euphorbia grandicornis*) Poinsettia (*Euphorbia pulcherrima*) Manchineel tree (*Hippomane mancinella*)
	Other chemical irritants	Stinging nettles (*U. dioica*) Velvet bean or cowhage (*M. pruriens*) Pineapple (*Bromeliaceae* spp.)
Contact dermatitis		
	Urushiol oleoresins	Ginkgo (*Ginkgoaceae*) Poison ivy, oak, and sumac (*Toxicodendron* spp.) Mango (*Mangifera indica*) Pistachio (*Pistacia vera*) Cashew (*Anacardium occidentale*)
	Miscellaneous antigens	Peruvian lily (*Alstroemeria* spp.) Narcissus and daffodils (*Narcissus* spp.) Tulips (*Tulipa* spp.) Primroses (*Primula* spp.)
Phytophotodermatitis		
	Furocoumarins	Cow parsnip (*Heracleum lanatum)* Wild parsnip (*Pastinaca sativa*) Lime (*Citrus aurantiifolia*)

enzymes and other proinflammatory chemicals such as histamine, acetylcholine, and 5-hydroxytryptamine.[10]

ALLERGIC CONTACT DERMATITIS

Many plants can cause allergic contact dermatitis after repeat exposure. Sensitization occurs after a resin binds to skin proteins and forms an antigen. Reexposure then stimulates a T-cell–mediated immune response.

Poison ivy, poison oak, and poison sumac (*Toxicodendron* spp.) are ubiquitous sources of the antigenic resin urushiol. Ginkgo (*Ginkgoaceae*), mango (*Mangifera indica*), pistachio (*Pistacia vera*), and cashew (*Anacardium occidentale*) are common foods with urushiol. In sensitized individuals, reexposure can result in urticaria and pruritus. Over 12 to 48 hours, symptoms may progress to varying degrees of vesiculobullous formation. Treatment usually consists of drying agents and local topical steroids, but systemic steroids may be necessary in severe cases. Some exposures can result in type I hypersensitivity or anaphylaxis.

Tulips (*Tulipa* spp.) and daffodils (*Narcissus* spp.) contain the glycoside tuliposide A. After hydrolysis, an allergen causes tulip fingers or daffodil itch with chronic reexposure, a painful and pruritic condition.

PHYTOPHOTODERMATITIS

Phytophotodermatitis occurs when furocoumarins are activated by sunlight and produce symptoms that resemble sunburn in the acute phase; erythema and bullae are common. When these symptoms heal, hyperpigmentation persists for months. The mechanism is unknown. Exposure can be directly through the dermis, or furocoumarins can be deposited in the skin following ingestion and subsequent systemic circulation. Many plants, including common foods, can cause phytophotodermatitis, including numerous citrus fruits, celery, carrots, and herbs.[9]

CHAPTER 221

High-Altitude Disorders

Peter H. Hackett
Christopher B. Davis

INTRODUCTION AND EPIDEMIOLOGY

Millions of people annually visit mountainous areas of the western United States at altitudes of >2440 m (>8000 ft). In addition, tens of thousands travel to high-altitude regions in other parts of the world. Adventure travel to mountainous regions is booming.[1] Physicians working or traveling in or near these locations are likely to encounter high-altitude illness or preexisting conditions that are exacerbated by altitude. Although the focus of this chapter is hypoxia-related problems, patients in the mountain environment may require care for associated illnesses such as hypothermia (see chapter 209, "Hypothermia"), frostbite (see chapter 208, "Cold Injuries"), trauma, ultraviolet keratitis, dehydration, and lightning injury (see chapter 218, "Electrical and Lightning Injuries").

High altitude (>2440 m [>8000 ft]) is a hypoxic environment. Because the concentration of oxygen in the troposphere remains constant at 21%, the partial pressure of oxygen (P_{O_2}) decreases as a function of the barometric pressure. In Denver at 1610 m (5280 ft), air pressure is 17% less than at sea level. The air of Aspen, Colorado, 2440 m (8000 ft), has 26% less oxygen than sea level. At 5490 m (18,000 ft), there is half the available oxygen, whereas on top of Mount Everest, there is only one third. Oxygen supplementation prevents symptoms of altitude illness during hypobaric exposure, and therefore, hypoxia, not hypobaria per se, is responsible for illness.

Altitude may be divided into stages according to physiologic effects. *Intermediate altitude*, 1520 to 2440 m (5000 to 8000 ft), produces decreased exercise performance and increased alveolar ventilation without major impairment in arterial oxygen transport. Acute mountain sickness (AMS) occurs at and above 2130 to 2440 m (7000 to 8000 ft) and sometimes at lower altitudes in particularly susceptible individuals. Patients who have limitations in ventilatory response such as some neuromuscular diseases or those with preexisting hypoxemia may become more symptomatic in this range of altitude. *High altitude,* 2440 to 4270 m (8000 to 14,000 ft), is associated with decreased arterial oxygen saturation (Sa_{O_2}); marked hypoxemia may occur during exercise and sleep. Most cases of altitude-related medical problems occur in this elevation range, because of the availability of overnight tourist facilities located at these heights. *Very high altitude,* 4270 to 5490 m (14,000 to 18,000 ft), is uncommon in the United States but is encountered by visitors to the mountainous regions of South America and the Himalayas. Abrupt ascent can be dangerous, and a period of acclimatization is required to prevent illness. *Extreme altitude,* >5490 m (>18,000 ft), is experienced only by mountain climbers and is accompanied by severe hypoxemia and hypocapnia. At this height, progressive physiologic deterioration eventually outstrips acclimatization, and sustained human habitation is impossible. **Because hypoxemia is maximal during sleep, the sleeping altitude is the critical altitude to consider.**

PHYSIOLOGY AND PATHOPHYSIOLOGY OF ALTITUDE ACCLIMATIZATION

Acutely hypoxic individuals become dizzy, faint, and rapidly unconscious if hypoxic stress is sufficient (Sa_{O_2} <65%). Captain Hawthorne Gray, in an attempt to set the record for highest hot air balloon flight in 1927, lost consciousness and died when his balloon rose to >12,200 m (>40,000 ft). However, individuals given days to weeks to acclimatize can tolerate surprising degrees of hypoxemia and function quite well. Although the fundamental process of this acclimatization takes place in the metabolic machinery of cells and mitochondria, acute "stress" responses are critical while allowing cells time to adjust.

VENTILATION

The primary initial adaptation is defense of alveolar P_{O_2} through increased ventilation. The hypoxic ventilatory response is modulated by the carotid body, which senses a decrease in arterial oxygenation and signals the central respiratory center in the medulla to increase ventilation. The vigor of this inborn response relates to successful acclimatization and increased performance. Respiratory depressants or stimulants may affect hypoxic ventilatory drive, as does chronic hypoxia, which eventually blunts the response. A low hypoxic drive may allow extreme hypoxemia to develop during sleep. Initial hyperventilation is attenuated quickly by respiratory alkalosis, which acts as a brake on the respiratory center. As renal excretion of bicarbonate compensates for the respiratory alkalosis, pH returns toward normal, and ventilation continues to increase. The process of maximizing ventilation, termed *ventilatory acclimatization*, culminates after 4 to 7 days at a given altitude. With continuing ascent to higher altitudes, the central chemoreceptors reset to progressively lower values of partial pressure of carbon dioxide, and the completeness of acclimatization can be gauged by the partial pressure of arterial carbon dioxide. Acetazolamide, which forces a bicarbonate diuresis, greatly facilitates this process. An appreciation of the normal values for blood gases and acid-base status with acclimatization at various altitudes is necessary to distinguish abnormalities (**Table 221-1**).

BLOOD

Within 2 hours of ascent to altitude, serum erythropoietin level increases and results in increased red cell mass over days to weeks. This adaptation has no importance during initial acclimatization when acute altitude illness develops; however, excessive red cell mass may develop over a period of weeks to months leading to chronic mountain polycythemia. Shifts in

TABLE 221-1 Blood Gas Concentrations at Various Altitudes

Altitude	Pa_{O2} (mm Hg)	Sa_{O2} (%)	PaC_{O2} (mm Hg)
Sea level	90–95	96	40
5000 ft (1520 m)	75–81	95	35.6
7500 ft (2290 m)	69–74	92–93	31–33
15,000 ft (4570 m)	48–53	86	25
20,000 ft (7000 m)	37–45	76	20
25,000 ft (7620 m)	32–39	68	13
29,000 ft (8840 m)	26–33	58	9.5–13.8

Abbreviations: Pa_{O2} = partial pressure of arterial oxygen; PaC_{O2} = partial pressure of arterial carbon dioxide; Sa_{O2} = arterial oxygen saturation.

the oxyhemoglobin dissociation curve are thought to be minimal at altitude because of balancing physiologic effects. Hypoxia causes an increase in the level of 2,3-diphosphoglyceric acid and shifts the curve to the right. Respiratory alkalosis shifts the curve to the left. Naturally occurring left-shifted hemoglobin is advantageous at high altitude; a given partial pressure of oxygen will yield higher oxygen saturation and facilitate loading of oxygen onto hemoglobin in the pulmonary capillary.

FLUID BALANCE

Peripheral venous constriction on ascent to altitude causes an increase in central blood volume that triggers baroreceptors to suppress secretion of antidiuretic hormone and aldosterone and induces a diuresis. Combined with the bicarbonate diuresis from the respiratory alkalosis, the result is decreased plasma volume and a hyperosmolality (serum osmolality of 290 to 300 mOsmol/L) that results from a reset of the osmolar center of the brain. The hemoconcentration also increases oxygen-carrying capacity of the blood. Clinically, diuresis and hemoconcentration are considered a healthy response, whereas antidiuresis is associated with AMS and may contribute to edema formation.

CARDIOVASCULAR SYSTEM

Stroke volume decreases initially, and increased heart rate maintains cardiac output. Maximum exercising heart rate declines at altitude proportional to the decrease in maximum oxygen consumption (Vo_2max). Cardiac muscle in healthy persons can withstand extreme levels of hypoxemia (partial pressure of arterial oxygen [Pa_{O2}] of <30 mm Hg) without evidence of ST-segment changes or ischemic events. Blood pressure typically increases mildly on ascent secondary to increased sympathetic tone, but labile blood pressure is also possible.

The pulmonary circulation constricts with exposure to hypoxia. Although pulmonary vasoconstriction is advantageous during conditions of regional alveolar hypoxia, such as pneumonia, it poses a disadvantage during the global hypoxia of altitude exposure, increasing to a variable degree pulmonary vascular resistance and pulmonary artery pressure. A hyperreactive response increases susceptibility to high-altitude pulmonary edema.

Cerebral blood flow transiently increases on ascent to altitude (despite the hypocapnic alkalosis), which increases oxygen delivery to the brain. This response, however, is limited by the increase in cerebral blood volume, which may increase intracranial pressure and aggravate symptoms of altitude illness.

EXERCISE CAPACITY

Exercise capacity, as measured by Vo_2max, drops dramatically on ascent to altitude, approximately 10% for each 1000-m (3280-ft) altitude gain above 1500 m (4920 ft). During acclimatization, submaximal endurance increases appreciably after 10 days, but Vo_2max does not. The mechanism of this decrement might be lack of adequate oxygen supply to the muscle cells due to the low driving pressure for diffusion of oxygen from the capillary. Another theory suggests that the CNS limits muscle activity to preserve its own oxygenation.

LIMITATIONS TO ACCLIMATIZATION

There are limits to acclimatization. Even those who are by nature good acclimatizers cannot tolerate the hypoxia of extreme altitude for long. Miners in South America report that they cannot live at altitudes >5800 m (>19,000 ft) because of weight loss, increasing lethargy, poor-quality sleep, weakness, and headache. High-altitude mountaineers cannot survive for more than a few days at >8000 m (>26,200 ft) without supplemental oxygen because of rapid deterioration of physiologic functioning. Considerable weight loss due to loss of fat and lean body mass is unavoidable. Other factors limiting the ability to adapt to extreme altitude include right ventricular strain from excessive pulmonary hypertension, intestinal malabsorption, impaired renal function, polycythemia leading to microcirculatory sludging, and prolonged cerebral hypoxia. Even at more modest altitudes, some individuals acclimatize poorly due to genetic and epigenetic factors. One phenotype is blunted carotid body function that leads to inadequate ventilation at high altitude.

SLEEP AT HIGH ALTITUDE

Sleep stages III and IV are reduced at altitude, whereas sleep stage I is increased. More time is spent awake, with a significant increase in arousals, but with only slightly less rapid eye movement time. Frequent nighttime awakenings are a common source of bitter complaints from skiers and others, but they are innocuous and improve with time at altitude. The typical periodic breathing (Cheyne-Stokes respiration) in those sleeping at >2700 m (>8860 ft) consists of 6- to 12-second apneic pauses interspersed with cycles of vigorous ventilation. Intervals of apnea of >20 seconds have been observed at extreme altitudes. Interestingly, the frequent awakenings are not necessarily related to sleep periodic breathing, and they are not related to AMS either. Quality of sleep and arterial oxygenation during sleep improve with acclimatization and with acetazolamide.

HIGH-ALTITUDE SYNDROMES

High-altitude syndromes are those attributed directly to the hypoxia: acute hypoxia, AMS, pulmonary edema, cerebral edema, retinopathy, peripheral edema, sleeping problems, and a group of neurologic syndromes. Other syndromes occurring at high altitude, which are not necessarily related to hypoxia, include thromboembolic events (which may be attributable to dehydration, prolonged incapacitation, polycythemia, and cold), high-altitude pharyngitis and bronchitis, and ultraviolet keratitis. **Although the different hypoxic clinical syndromes overlap, all share a fundamental mechanism, all are seen in the same setting of rapid ascent in unacclimatized persons, and all respond to the same essential therapy: descent and oxygen.**

ACUTE HYPOXIA

The syndrome of acute hypoxia occurs in the setting of sudden and severe hypoxic insult, such as accidental decompression of a pressurized aircraft cabin or failure of the oxygen system used by a pilot or high-altitude mountaineer. Sudden overexertion precipitating arterial desaturation, acute onset of pulmonary edema, carbon monoxide poisoning, and sleep apnea may result in relatively acute hypoxia as well. Unacclimatized persons become unconscious at an Sa_{O2} of 50% to 60%, a Pa_{O2} of less than approximately 30 mm Hg, or a jugular venous P_{O2} of <15 mm Hg. Acute hypoxia reverses with immediate administration of oxygen, rapid descent, and correction of the underlying cause. Symptoms of acute hypoxia reflect the sensitivity of the CNS to this insult: dizziness, light-headedness, and dimmed vision progressing to loss of consciousness. Hyperventilation increases the time of useful consciousness during acute alveolar hypoxia.

ACUTE MOUNTAIN SICKNESS

AMS is a syndrome characterized by headache along with some combination of GI disturbance, dizziness, fatigue, or sleep disturbance

TABLE 221-2 Lake Louise Acute Mountain Sickness (AMS) Self-Questionnaire*

1. Headache	Score
No headache—0	
Mild headache—1	
Moderate headache—2	
Severe headache, incapacitating—3	
2. GI symptoms	Score
No symptoms—0	
Poor appetite or nausea—1	
Moderate nausea or vomiting—2

(Table 221-2). It occurs in the setting of more gradual and less severe hypoxic insult than in acute hypoxia syndrome. Its incidence varies by location, ease of access to the high-altitude environment, rate of ascent, and sleeping altitude. One study found a 25% incidence of AMS in physicians attending a continuing-education meeting held at 2100 m (6900 ft) in Colorado. Other studies at resorts at altitudes between 2220 and 2700 m (7280 and 8860 ft) claim an incidence between 17% and 40%, and a sleeping altitude of 2740 m (9000 ft) seems to be a threshold for an increase in attack rate.[2] Approximately 40% of trekkers in Nepal on the path to Mount Everest experience AMS, and climbers on Mount Rainier have a very high incidence of 70% because of the rapidity of ascent.

In addition to rate of ascent and sleeping altitude, inherent factors determine individual susceptibility to AMS. Blunted carotid body response and low vital capacity are examples. Age has little influence on incidence, with children being as susceptible as adults, although those >50 years of age tend to have less AMS. Women are just as likely to develop mountain sickness but appear to have less pulmonary edema. Obesity has recently been linked to the development of AMS, possibly due to greater nocturnal oxygen desaturation.[3] Susceptibility to AMS generally is reproducible in an individual on repeated exposures. Persons living at intermediate altitudes of 1000 to 2000 m (3300 to 6600 ft) already are partially acclimatized and do much better than lowlanders on ascent to higher altitudes. There is no relationship between susceptibility to AMS and physical fitness.

PATHOPHYSIOLOGY

AMS is due to hypobaric hypoxia, but the exact sequence of events leading to illness is unclear. Cerebral vasodilation appears to be the initiating event. Vasodilation occurs in the brain in all persons ascending to high altitude, thus increasing cerebral blood flow and blood volume. Whether this is solely sufficient to cause the symptoms of mild AMS is unclear. However, in persons who progress to high-altitude cerebral edema, vasogenic edema is evident as increased T2 signal on MRI.[4] The leaky blood–brain barrier in high-altitude cerebral edema is due either to loss of autoregulation leading to overperfusion, or to increased permeability caused by mediators such as vascular endothelial growth factor or bradykinin. A combination of these two processes is also possible. The fact that dexamethasone so effectively treats AMS also supports the notion of vasogenic edema. An alternative notion is that the trigeminal-vascular system is triggered by hypoxic vasodilation or by noxious agents such as nitric oxide or free oxygen radicals.

CLINICAL FEATURES

The diagnosis of AMS is based on an appropriate setting paired with characteristic symptoms. The setting is rapid ascent of an unacclimatized person to 2000 m (6560 ft) or higher. On arrival the person typically feels light-headed and slightly breathless, especially with exercise. Symptoms develop between 1 and 6 hours later, but sometimes are delayed for 1 or 2 days (especially after a night's sleep). Symptoms of mild AMS are remarkably similar to those of an alcohol hangover. Headaches are usually bifrontal and worsen with exertion, bending over, or performing a Valsalva maneuver. GI symptoms include anorexia, nausea, and sometimes vomiting, especially in children. The chief constitutional symptoms are lassitude and weakness. The person with AMS can be irritable and often wants to be left alone. Sleepiness and a deep inner chill also are common. The Lake Louise AMS self-report questionnaire can be helpful in following the severity of the illness (Table 221-2).

As the illness progresses, headache becomes more severe while vomiting and oliguria develop. Lassitude may progress so that the victim requires assistance in eating and dressing. The onset of ataxia and altered level of consciousness heralds high-altitude cerebral edema. Coma may ensue within 12 hours if treatment is delayed. The diagnosis of AMS can be difficult in preverbal children and should be a diagnosis of exclusion.[5]

Physical findings in mild AMS are nonspecific. Heart rate and blood pressure are variable and usually in the normal range, although postural hypotension may be present. **Presenting percent Sa_{O_2} is typically normal or slightly low for a given altitude, and percent Sa_{O_2} overall correlates poorly with the diagnosis of AMS.** Localized rales are detectable in up to 20% of persons with AMS. Fundoscopy reveals venous tortuosity and dilatation, and retinal hemorrhages are common at altitudes >5000 m (>16,400 ft) and in those with pulmonary and cerebral edema. Facial and peripheral edema sometimes accompanies AMS.

The differential diagnosis in this setting includes hypothermia, carbon monoxide poisoning, pulmonary or CNS infection, dehydration, migraine, and exhaustion. Carbon monoxide poisoning may have a presentation very similar to that of AMS and is not uncommon in mountain towns in the winter. Reduced oxyhemoglobin levels complicate hypoxia from high altitude, and the effects are additive. Hypoxia may trigger a migraine headache in patients with a personal or family history of migraine.[6] Headache from AMS often dissipates within 10 to 15 minutes with supplemental oxygen administration, unlike headaches from other causes. Providers may find this to be a useful diagnostic maneuver.

The average duration of AMS at a Colorado resort (3000 m or 9840 ft) was 15 hours, with a range of up to 94 hours. Half of those affected with AMS chose to self-medicate.[2] At higher sleeping altitudes the illness may last much longer, up to weeks if untreated, and is more likely to progress to pulmonary or cerebral edema. Eight percent of those with AMS at 4270 m (14,000 ft) in Nepal developed cerebral or pulmonary edema or both.[7]

TREATMENT

The goals of treatment (**Table 221-3**) are to prevent progression, treat symptoms, and improve acclimatization. Early diagnosis is essential. Initial

TABLE 221-3 Suggested Treatment Options for High-Altitude Illness

Mild AMS	No further ascent
	Descent to lower altitude or acclimatization at same altitude
	Acetazolamide, 125–250 milligrams PO twice a day, to speed acclimatization
	Symptomatic treatment as necessary with analgesics and antiemetics
Moderate/severe AMS	Immediate descent for worsening symptoms
	Low-flow oxygen if available
	Acetazolamide, 250 milligrams PO twice a day, and/or dexamethasone, 4 milligrams PO every 6 h
	Hyperbaric therapy
High-altitude cerebral edema	Immediate descent or evacuation
	Oxygen 2–4 L/min or titrated to Sa_{02} >90%
	Dexamethasone, 8 milligrams PO, IM, or IV, then 4 milligrams every 6 h
	Hyperbaric therapy if patient cannot descend
High-altitude pulmonary edema	Immediate descent or evacuation
	Oxygen 4 L/min or titrated to Sa_{02} >90%
	Nifedipine, 30 milligrams PO extended release every 12 h if no oxygen or descent*
	Hyperbaric therapy if patient cannot descend
	Measures to minimize patient exertion and keep patient warm
	Dexamethasone if cerebral signs present, 4 milligrams PO every 6 h
Periodic breathing/ insomnia	Acetazolamide, 62.5–125.0 milligrams PO at bedtime as needed

Abbreviations: AMS = acute mountain sickness; Sa_{02} = arterial oxygen saturation.

*Drug therapy is unnecessary if oxygen is available.

clinical presentation does not predict eventual severity, and all persons with AMS must be observed carefully for progression. **The three principles of treatment are (1) do not proceed to a higher sleeping altitude in the presence of symptoms, (2) descend if symptoms do not abate or become worse despite treatment, and (3) descend and treat immediately in the presence of a change in consciousness, ataxia, or pulmonary edema.** Descent is the definitive treatment for all forms of altitude illness. However, descent is not always an option, nor is it always necessary.

Descent and Oxygen Mild AMS is self-limited and generally improves with an extra 12 to 36 hours of acclimatization if ascent is halted. Remarkably, a drop in altitude of only 300 to 1000 m (980 to 3280 ft) usually is effective. Evacuation to a hospital or to sea level is unnecessary except in the most severe cases. To simulate descent, portable hyperbaric bags are being used in various locations to treat high-altitude illness. The patient is inserted into the fabric chamber, and a pressure of 0.9 kg/2.5 cm^2 (2 $lb/in.^2$) is achieved by means of a manual or automated pump, equivalent to a drop in altitude of 1500 m (4920 ft). A valve system creates sufficient ventilation to avoid carbon dioxide accumulation or oxygen depletion.

Oxygen effectively relieves symptoms, but it is generally unavailable in the field or reserved for those with moderate to severe AMS in order to conserve supplies. Oxygen supplementation quickly relieves headache and dizziness. Nocturnal administration of low-flow oxygen (0.5 to 1 L/min) is particularly helpful and efficient. The combination of oxygen and descent provides optimal therapy, especially in more severe illness.

Medical Therapy Pharmacologic treatment offers an alternative to descent or oxygen administration in patients with mild to moderate AMS. Acetazolamide acts by inhibiting the enzyme carbonic anhydrase. In the kidney, acetazolamide reduces reabsorption of bicarbonate, causing a bicarbonate diuresis and metabolic acidosis that stimulates ventilation. As a result, Pa_{O2} is higher. Acetazolamide thus reverses the deleterious effects of hypobaric hypoxia. The drug also maintains cerebral blood flow despite greater hypocapnia.

The treatment regimen for AMS varies: 125 milligrams PO twice daily is effective for some individuals, whereas others may require 250 mg PO twice daily. Side effects are more common with higher doses and include peripheral paresthesias and sometimes nausea or drowsiness. Although acetazolamide contains a sulfhydryl moiety, cross-reactivity in those with sulfa antibiotic allergy is uncommon. Nevertheless, individuals with a history of anaphylaxis to sulfa antibiotics should avoid acetazolamide. Treatment should be continued until symptoms of AMS resolve. It can always be restarted if symptoms return. Because the drug inhibits carbonic anhydrase on the tongue, carbonated beverages such as soda or beer may have an altered flavor.

Symptomatic treatment of AMS is often sufficient. Aspirin, 650 milligrams, acetaminophen, 650 to 1000 milligrams (with or without codeine), or ibuprofen, 600 to 800 milligrams, is effective for headache. Aspirin is effective for prophylaxis of headache in persons who are not exercising.[8] Ondansetron orally disintegrating tablets, 4 to 8 milligrams every 4 to 6 hours, effectively treat nausea and vomiting associated with AMS and should be the first-line antiemetic in this setting.

Dexamethasone, 4 milligrams PO, IM, or IV every 6 hours, is quite effective for mountain sickness, but is best reserved for cases of moderate to severe AMS because of potential side effects. Also dexamethasone does not aid acclimatization and may result in some rebound symptoms when discontinued. A short taper period may prevent rebound. The administration of acetazolamide to speed acclimatization and a brief course of dexamethasone to treat illness is a useful combination. Another useful treatment regimen but one that is not yet validated is a one-time dose of dexamethasone followed by a course of acetazolamide.

Frequent nighttime awakening is a common nuisance at high altitude. Before bedtime, acetazolamide, 62.5 to 125 milligrams, improves sleep oxygenation and reduces apneic periods, thereby improving sleep quality. The newer nonbenzodiazepine sleep agents can also be used. These include zolpidem, 5 to 10 milligrams, zolpidem controlled-release, 6.25 to 12.5 milligrams, or eszopiclone, 1 to 2 milligrams. These drugs are safe at altitude and do not depress ventilation. Diphenhydramine, 25 to 50 milligrams before bedtime, is a safe over-the-counter alternative (**Table 221-4**).

PREVENTION

Graded ascent with adequate time for acclimatization is the best prevention. A recommendation for those visiting moderate-altitude resorts in the western United States is to spend a night at an intermediate altitude of 1500 to 2000 m (4920 to 6560 ft) (Denver or Salt Lake City) before sleeping at altitudes >2500 m (>8200 ft). Mountaineers and trekkers should avoid abrupt ascent to sleeping altitudes over 3000 m (9840 ft) and then allow 2 nights for each 1000-m (3230-ft) gain in camp altitude starting at 3000 m (9840 ft). Other preventative measures include avoiding overexertion, alcohol, and respiratory depressants. Prophylactic acetazolamide benefits those with a history of AMS or those with forced rapid ascent to sleeping altitude above 2500 m. Because the drug prevents AMS by enhancing ventilatory acclimatization, fear of masking serious illness is unwarranted. The drug should be started 24 hours before the ascent and should be continued for the first 2 days at altitude. It can be restarted if illness develops. Acetazolamide reduces the symptoms of AMS by approximately 75% in persons ascending rapidly to sleeping altitudes of >2500 m (>8200 ft). An alternative for those with anaphylaxis to sulfa is dexamethasone, 4 milligrams PO every 12 hours, starting the day of ascent and continuing for the first 2 days at altitude. Conflicting evidence exists on the use of ginkgo biloba for AMS prevention. A few studies indicate that 100 milligrams twice a day started 3 to 5 days before ascent is effective in preventing AMS, but other studies have shown no benefit.[9] Lack of standardization of gingko preparations likely explains conflicting results, and the active ingredient is still unknown. Despite the variable results, ginkgo is a safe option for those who desire a natural alternative.

Preacclimatization Although graded ascent is the most effective means of preventing altitude illness, this strategy is not always feasible. Numerous preacclimatization strategies have been proposed using intermittent exposure either to hypobaric hypoxia by use of hypobaric chambers or normobaric hypoxia through commercially available low-oxygen

TABLE 221-4 Medications for High-Altitude Illnesses

Agent	Indication	Dosage	Adverse Effects	Comments
Acetazolamide	Prevention of AMS	125–250 milligrams PO twice a day beginning 24 h before ascent and continuing during ascent and for at least 48 h after arrival at highest altitude	Common: paresthesias, polyuria, altered taste of carbonated beverages Less common: drowsiness, nausea	Can be taken episodically for symptoms (speeds acclimatization); no rebound effect; pregnancy category C, avoid in breastfeeding
	Treatment of AMS	250 milligrams PO every 8–12 h		
	Pediatric AMS	5 milligrams/kg/d PO in divided doses every 8–12 h		
	Periodic breathing	125 milligrams PO 4 h before bedtime		
Dexamethasone	Treatment of AMS	4 milligrams every 6 h PO, IM, or IV	Mood changes, hyperglycemia, dyspepsia	Rapidly improves AMS symptoms; can be life-saving in HACE, may improve HACE enough to facilitate descent; no value in HAPE; pregnancy category C but preferably avoided in pregnancy or breastfeeding
	HACE	8 milligrams initially, then 4 milligrams every 6 h PO, IM, or IV		
	Pediatric HACE	0.15 milligram/kg every 6 h PO, IM, or IV, not to exceed 16 milligrams/d		
Tadalafil	Prevention of HAPE	10 milligrams PO twice a day starting 1 d prior to ascent and continuing for 2–4 d at maximum sleeping altitude	Headache, hypotension (less than with nifedipine), priapism (rare), visual/hearing change or loss (extremely rare)	More effectively blunts hypoxic pulmonary vasoconstriction than sildenafil; better tolerated than nifedipine; pregnancy category B
Nifedipine	Prevention of HAPE	20–30 milligrams extended-release PO every 12 h	Reflex tachycardia, hypotension (uncommon)	
	Treatment of HAPE	30 milligrams extended-release formulation PO every 12 h		No value in AMS or HACE; not necessary if supplemental oxygen available; pregnancy category C

Abbreviations: AMS = acute mountain sickness; HACE = high-altitude cerebral edema; HAPE = high-altitude pulmonary edema.

tents or breathing masks. The overall goal is to reduce the incidence of altitude illness and to improve exercise performance on ascent to altitude. These strategies vary considerably in their use of hypoxic "dose" (simulated altitude), duration of exposure, and overall number of exposures over a period of days. Although many of these strategies induce physiologic responses suggestive of acclimatization, only a few are able to demonstrate a significant decrease in AMS incidence.[10-12] Short-term exposure to hypoxia of less than 6 hours per day has not been shown to be efficacious in preventing mountain sickness. The most efficient and effective preacclimatization strategy has yet to be determined.

HIGH-ALTITUDE CEREBRAL EDEMA

High-altitude cerebral edema is defined as progressive neurologic deterioration in someone with AMS or high-altitude pulmonary edema. It is characterized by altered mental status, ataxia, stupor, and progression to coma if untreated. Headache, nausea, and vomiting are not always present. Because of raised intracranial pressure, focal neurologic signs, such as third and sixth cranial nerve palsies, may result. High-altitude cerebral edema at intermediate altitudes is all but nonexistent with the rare case likely precipitated by severe hypoxia associated with high-altitude pulmonary edema and/or a preexisting space-occupying cerebral lesion.

High-altitude cerebral edema is usually associated with pulmonary edema. Pathologically, necropsies have described severe, diffuse cerebral edema with multiple small hemorrhages and sometimes thrombosis.

Treatment of high-altitude cerebral edema is oxygen supplementation, descent, and steroid therapy (Tables 221-3 and 221-4). Descent is the highest priority. Acetazolamide may be used as an adjunct, but immediate reversal of the illness is the goal. Improving acclimatization comes later. In acutely ill patients who cannot descend, a combination of steroids, supplemental oxygen, and a hyperbaric bag is optimal therapy but rarely available. Persons remaining ataxic or confused after descent should be admitted to hospital. The possibility of encephalitis or meningitis, stroke, or subarachnoid hemorrhage should be considered in patients whose condition does not improve with treatment. Comatose patients require an advanced airway. Typically the partial pressure of arterial carbon dioxide is already low and the pH high, and hyperventilation could produce cerebral ischemia. Evidence is lacking for the use of hypertonic saline, loop diuretics, or mannitol in high-altitude cerebral edema. Coma may persist for days, even for weeks, after evacuation to lower altitude, yet the patient may still recover. Persistent coma is unusual, however, and mandates exclusion of other possible causes. MRI findings of high-altitude cerebral edema include reversible white matter edema evidenced by increased T2 signal, especially in the splenium of the corpus callosum (**Figure 221-1**).[4] In contrast, hemosiderin depositions in the corpus

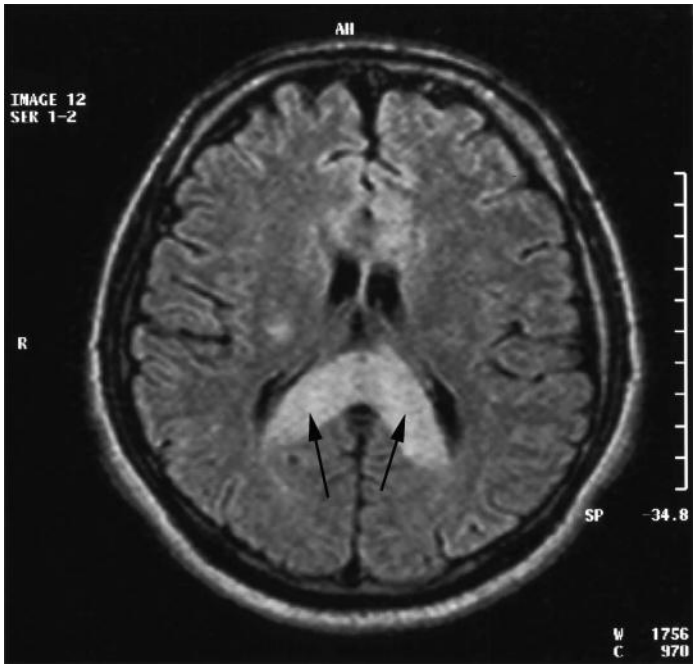

FIGURE 221-1. MRI of a 34-year-old male high-altitude mountaineer with high-altitude cerebral edema. The *arrows* indicate the markedly increased T2 signaling in the splenium of the corpus callosum indicating edema.

callosum may be detected by MRI for years after a case of high-altitude cerebral edema; this may be useful in the setting of diagnostic uncertainty.[13]

HIGH-ALTITUDE PULMONARY EDEMA

High-altitude pulmonary edema is the most lethal of the altitude illnesses. The cause of death is usually lack of early recognition, misdiagnosis, or inability to descend to a lower altitude. The condition is easily reversible with descent and oxygen administration.

The incidence of high-altitude pulmonary edema varies from less than 1 in 10,000 skiers in Colorado to 2% to 3% of climbers on Mount McKinley; an incidence of 15% was reported in some regiments of the Indian army that were airlifted to high altitude during the Indian-Chinese war. Women appear less susceptible than men. Risk factors include heavy exertion, rapid ascent, cold, excessive salt ingestion, use of a respiratory depressant, a previous history indicating inherent individual susceptibility, and pulmonary hypertension. Genetic factors include diminished lung epithelial sodium channel activity, excessive hypoxic pulmonary hypertension, and immunogenetic factors.[14,15] Pulmonary hypertension from any cause greatly predisposes to high-altitude pulmonary edema. As a result, high-altitude pulmonary edema has been reported in patients with intracardiac shunts (atrial septal defect, patent ductus arteriosus, patent foramen ovale), congenital absent pulmonary artery, drug-induced pulmonary hypertension (phentermine), and chronic venous thrombotic disease.[16,17] Preexisting respiratory infection may predispose children to high-altitude pulmonary edema.[18]

PATHOPHYSIOLOGY

High-altitude pulmonary edema is a noncardiogenic, hydrostatic edema; left ventricular function is normal. Left ventricular end-diastolic pressure, wedge pressures, and left atrial pressures are low to normal, cardiac output is low, and pulmonary vascular resistance and pulmonary artery pressure are markedly elevated. The culprit in high-altitude pulmonary edema is high microvascular pressure. Pulmonary hypertension is an essential component, but not all persons with pulmonary hypertension develop high-altitude pulmonary edema. Other factors that play a role include pulmonary venous constriction and uneven arterial vasoconstriction, which leads to overperfusion of some areas of the lung vasculature. Inflammation is not present early in the course of high-altitude pulmonary edema, as measured by the chemical composition of bronchoalveolar lavage fluid, but appears to be a secondary finding later in the illness.[19] Predisposed individuals have a low hypoxic ventilatory response and an abnormal pulmonary circulation response to hypoxia, and tend to experience high-altitude pulmonary edema on repeated exposures to high altitude.

CLINICAL FEATURES

The differential diagnosis of shortness of breath at altitude is broad. This includes pneumonia, pulmonary embolism, myocardial infarction, congestive heart failure, mucous plugging, and bronchitis. Early in the course of high-altitude pulmonary edema, the individual develops a dry cough, decreased exercise performance, dyspnea on exertion, and increased recovery time from exercise. Localized rales, usually in the right mid-lung field, are common. Resting percent Sa_{O2} is often 10 to 20 points lower than normal for a given altitude and will drop further with exertion. Late in the course of the illness, tachycardia, tachypnea, dyspnea at rest, marked weakness, productive cough, cyanosis, and more generalized rales develop. As hypoxemia worsens, altered mental status and eventually coma develop.

Early diagnosis is critical, and decreased exercise performance and dry cough are enough to raise the suspicion of early high-altitude pulmonary edema. Progression of dyspnea with exertion to dyspnea at rest is a hallmark of high-altitude pulmonary edema. The typical victim is strong and fit and may or may not have symptoms of AMS before the onset of high-altitude pulmonary edema. The condition typically worsens at night and is most commonly noticed on or after the second night at a new altitude. Rales are not audible in 15% of persons with high-altitude pulmonary edema at rest but can be elicited immediately after a short bout of exercise. Low-grade fever is common, and tachycardia and tachypnea generally correlate with the severity of illness. On cardiac auscultation, a prominent P_2 and right ventricular heave may be appreciated. ECG may reveal right-axis deviation and a right ventricular strain pattern consistent with acute pulmonary hypertension. Chest radiographic findings progress from interstitial to localized alveolar to generalized alveolar infiltrates as the illness progresses from mild to severe (**Figure 221-2**). The absence of infiltrates should alert the clinician to the possibility of an alternate diagnosis.

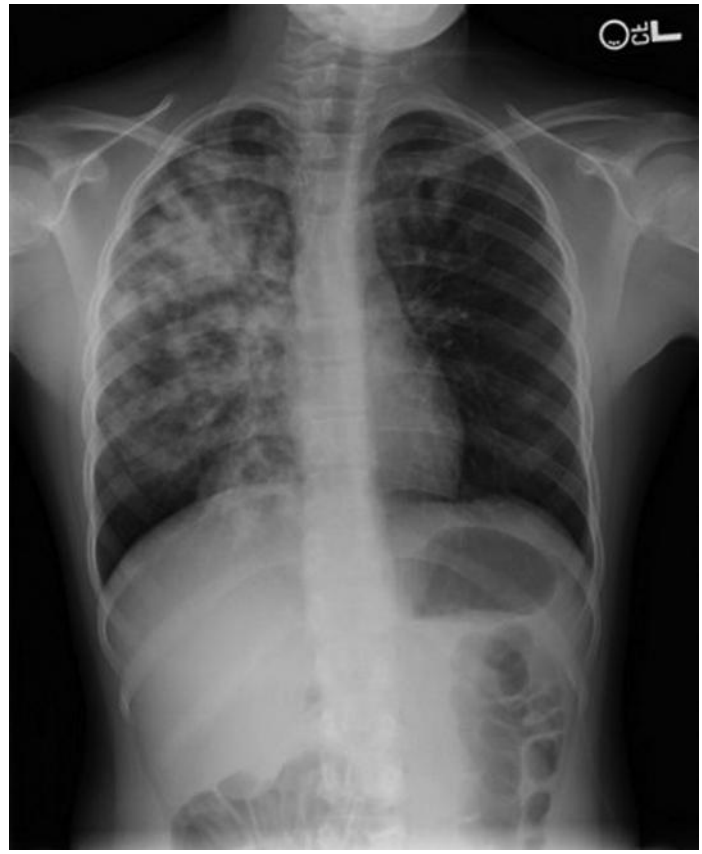

FIGURE 221-2. Chest radiograph of an 11-year-old girl with reentry high-altitude pulmonary edema at 2670 m (8750 ft).

TREATMENT AND PREVENTION

The key to successful treatment of high-altitude pulmonary edema (Tables 221-3 and 221-4) is early recognition, because the condition in its early stage is easily reversible. The optimal therapy depends on the environmental setting, evacuation options, availability of oxygen or hyperbaric units, and ease of descent. **Immediate descent is the treatment of choice, but this is not always possible.** During descent, exertion by the patient must be minimized. Reports of patients dying during descent probably are related to overexertion that offsets the benefit of lower altitude. Oxygen supplementation produces excellent results and can completely resolve the pulmonary edema without descent to a lower altitude, but it may require 36 to 72 hours to do so. In settings such as Colorado ski resorts, for example, keeping the patient at altitude but on oxygen is a practical option. The required quantities of oxygen are rarely available to trekking, mountaineering, and back country skiing groups, however. Oxygen immediately lowers pulmonary artery pressure and improves arterial oxygenation. Its use is lifesaving when descent is not an option; in such cases, rescue groups should make delivery of oxygen to the victim the highest priority.

As in the treatment of AMS and high-altitude cerebral edema, the portable hyperbaric bag is a useful adjunct to therapy when immediate descent is not possible.

Bed rest may be adequate for very mild cases, and bed rest with supplemental oxygen may suffice for moderate illness, as long as the safety of the patient can be ensured by the presence of a medical facility, adequate oxygen, or immediate descent capability should the patient's condition deteriorate.[20] Because cold stress elevates pulmonary artery pressure, the patient should be kept warm. The use of an expiratory positive airway pressure mask increases Sa_{O2} by 10% to 20% in high-altitude pulmonary edema patients by enhancing alveolar recruitment. The mask is lightweight, is well tolerated, and may be a useful adjunct to descent. Continuous positive airway pressure or bilevel positive airway pressure ventilation would likely work as well.

Because oxygen supplementation and descent are so effective, experience with drugs has been limited. Several studies have demonstrated that nifedipine, either as a 10-milligram capsule or 30-milligram extended-release formulation, reduces pulmonary artery pressure by 30% to 50% but increases Sa_{O2} only slightly.[21] Nifedipine, 20 milligrams (slow-release preparation) every 8 hours while ascending, provides effective prophylaxis in those who have previously experienced high-altitude pulmonary edema.[22] Nitric oxide lowers pulmonary artery pressure and redistributes blood away from edematous areas but is rarely available.[23]

The phosphodiesterase-5 inhibitors sildenafil and tadalafil blunt hypoxic pulmonary vasoconstriction.[24] Tadalafil, 10 milligrams PO twice a day 24 hours prior to ascent, effectively prevents high-altitude pulmonary edema in susceptible individuals.[25] These agents may also prove to be useful for treatment of high-altitude pulmonary edema when oxygen is unavailable.

Inhaled salmeterol twice a day reduces the incidence of high-altitude pulmonary edema by 50% in persons with previous repeat episodes of high-altitude pulmonary edema.[26] The mechanism is presumed to be upregulation of the epithelial sodium channel and increased clearance of alveolar fluid, a known effect of β-agonists. Although these agents have not yet been studied for the treatment of high-altitude pulmonary edema, given their likely benefit and safety and ease of use, treatment of high-altitude pulmonary edema with β-agonists is reasonable. **None of these agents is as effective as oxygen administration or descent, which still remain the treatments of choice.**

Hospitalization is warranted for severe illness that does not respond immediately to descent, especially if cerebral edema is present. Intubation, oxygen supplementation with a high fraction of inspired oxygen (FIO_2), and positive end-expiratory pressure ventilation are rarely required. Antibiotics are indicated for coexisting infection when present. Measurement of brain natriuretic peptide level or echocardiography may be needed to exclude a cardiac component of edema in persons with potential heart failure. Patients with high-altitude pulmonary edema who do not make the usual rapid improvement or who develop the condition at <2500 m (<8200 ft) should be evaluated for pulmonary emboli or other anatomic abnormalities, such as congenital absence of a pulmonary artery or intracardiac shunt. Echocardiography with bubble contrast material can assess for the presence or absence of shunting from a patent foramen ovale or other cardiac abnormality.

Adequate discharge criteria are progressive clinical and radiographic improvement and a Pa_{O2} of 60 mm Hg or an Sa_{O2} of >90%. Residual effects such as fibrosis or abnormal pulmonary function tests have not been reported. An episode of high-altitude pulmonary edema is not a contraindication to subsequent ascent, but patients should be counseled regarding the advisability of staged ascent; prophylaxis with acetazolamide along with tadalafil, sildenafil, or nifedipine; and the importance of recognizing early signs and symptoms.

PERIPHERAL EDEMA

Swelling of the face and distal extremities is common at high altitude. Peripheral edema was reported in 18% of trekkers at 4200 m (13,800 ft) in Nepal and was twice as common in women.[7] It often was associated with AMS but not in all cases. The presence of peripheral edema should raise suspicion of altitude illness and prompt a thorough examination for pulmonary and cerebral edema. The problem can be treated with diuretics but will resolve spontaneously with descent. The mechanism is presumably similar to that of fluid retention altitude illness but with edema formation peripherally rather than in the brain and lung.

HIGH-ALTITUDE RETINOPATHY

Retinal abnormalities described at high altitude include retinal edema, tortuosity and dilatation of retinal veins, disc hyperemia, retinal hemorrhage, and, rarely, cotton-wool exudates. Retinal hemorrhages are asymptomatic, except for rarely occurring macular hemorrhages, and are not considered an indication for descent unless vision changes are present. They resolve spontaneously in 10 to 14 days. Hemorrhages are common at sleeping altitudes of >5000 m (>16,400 ft) and occur at lower altitudes in persons with altitude illness.

HIGH-ALTITUDE BRONCHITIS

Many unacclimatized persons exercising at altitudes of >2500 m (>8200 ft) develop a dry, hacking cough. Breathing high volumes of dry, cold air may induce respiratory heat loss, secretions, and bronchospasm. As in cough-variant asthma, fast-acting β-agonists, such as albuterol, delivered by metered-dose inhaler may provide relief from these coughing spasms. Prophylactic use of long-acting β-agonists and inhaled steroids may be useful for prevention of debilitating cough for those staying at altitude for long periods. Those staying at ski resorts or indoors at altitude may find humidifiers helpful. Wearing a silk balaclava or a scarf of similar material across the nose and mouth that is sufficiently porous to allow large-volume ventilation but that traps some moisture and heat may help ameliorate this bothersome high-altitude condition.

CHRONIC MOUNTAIN POLYCYTHEMIA/CHRONIC MOUNTAIN SICKNESS

Monge's disease, also called *chronic mountain sickness*, has been recognized in all high-altitude locations of the world. Both long-term high-altitude residents and lowlanders who relocate to high altitude may develop this condition after variable lengths of residence. Males have a much higher incidence, and incidence increases with age. The disease is characterized by excessive polycythemia for a given altitude, which causes symptoms such as headache, muddled thinking, difficulty sleeping, impaired peripheral circulation, drowsiness, and chest congestion. The diagnosis is based on presence of the characteristic symptoms and a hemoglobin value greater than expected for the altitude, generally over 20 to 22 grams/dL. Any problem causing hypoxemia at sea level causes greater hypoxemia at altitude, and the cause of chronic mountain polycythemia can be traced to problems such as chronic obstructive pulmonary disease and sleep apnea in 50% of patients. "Pure" chronic mountain polycythemia is attributed to idiopathic hypoventilation based on diminished ventilatory drive.

Therapy includes phlebotomy, relocation to a lower altitude, or home oxygen use. Respiratory stimulants such as acetazolamide (250 milligrams PO twice a day) and medroxyprogesterone acetate (20 to 60 milligrams PO per day) also have been used successfully. The response to respiratory stimulants supports the role of hypoventilation in this disorder.

ULTRAVIOLET KERATITIS (SNOW BLINDNESS)

Ultraviolet A and ultraviolet B light penetrate the atmosphere to a greater degree at high altitude because there is less cloud cover, less water vapor, and less particulate matter in the air. Radiation increases roughly 5% for every 300 m (980 ft) gained and is exacerbated by reflection back from

snow. The cornea absorbs ultraviolet radiation of <300 nm (ultraviolet B), and high levels can cause corneal burns in 1 hour. Symptoms may not become apparent for 6 to 12 hours. Severe pain, a foreign-body or gritty sensation, photophobia, tearing, marked conjunctival erythema, chemosis, and eyelid swelling comprise the main symptoms of photokeratitis. Ultraviolet keratitis generally is self-limited and heals within 24 hours, but the condition is sufficiently painful to warrant administration of systemic analgesics. Application of cold compresses also may provide some relief. Prevention cannot be overemphasized, because this condition can be disabling, especially in hazardous terrain. Sunglasses should transmit <10% of ultraviolet B light. Side shields are necessary if one is traveling on snow, and polarizing lenses help by absorbing glare. Makeshift protection can be fashioned by cutting narrow horizontal slits in cardboard, foam, or any available material ("Eskimo sunglasses").

SPECIAL POPULATIONS

INDIVIDUALS WITH ILLNESSES AGGRAVATED BY HIGH ALTITUDE

Chronic Lung Disease Patients with chronic obstructive pulmonary disease ascending to altitude often report increased dyspnea and reduced exercise performance. Patients with hypoxemia, pulmonary hypertension, disordered control of ventilation, and sleep-disordered breathing at sea level may require supplemental oxygen at altitude because of greater alveolar hypoxia. Patients who are oxygen dependent at sea level will need to increase their F_{IO_2}. The required F_{IO_2} can be calculated by multiplying low-altitude F_{IO_2} by the ratio of low-altitude barometric pressure to high-altitude barometric pressure. This will ensure the delivery of the same P_{O2} as at low altitude. Although no data exist to suggest that persons with chronic obstructive pulmonary disease are more likely to develop AMS or high-altitude pulmonary edema, these patients may simply avoid travel to high altitude. In fact, persons with mild to moderate chronic obstructive pulmonary disease already are partially acclimatized and may do well at modest altitude. High altitude per se does not exacerbate asthma, and persons with chronic bronchospasm often report easier breathing at high altitude due to lower air density and/or cleaner air. Patients with allergic asthma do better at high altitude because of reduced allergens.

Arteriosclerotic Heart Disease A healthy heart and cardiovascular system can tolerate even extreme hypoxia remarkably well. Examinations of numerous ECGs, echocardiograms, heart catheterization findings, and exercise test results demonstrate no cardiac ischemia or cardiac dysfunction in healthy persons at high altitude, even when Pa_{O2} is <30 mm Hg. Those with arteriosclerotic disease may not have the same adaptive capabilities and intuitively seem more likely to experience acute cardiac events. Epidemiologic data, however, do not support this supposition. Long-term residence at high altitude reduces morbidity and mortality from arteriosclerotic heart disease,[27] and visitors apparently do not have increased risk of acute myocardial infarction. Ischemia may be provoked with less exercise during the first few days at 2500 m (8200 ft) among persons with coronary artery disease; however, after 5 days of acclimatization, patients perform at their sea-level exercise capacity without increased or early-onset angina.[28] A cohort of individuals who underwent revascularization for acute coronary syndrome 6 months previously were able to perform symptom-limited exercise testing after rapid ascent to 3,454 m without ECG evidence of myocardial ischemia or significant arrhythmia.[29]

Congestive heart failure may worsen in tourists arriving at the moderate altitude of ski resorts; this is related to fluid retention rather than depressed ventricular function from hypoxia. Therefore, patients with congestive heart failure should maintain or increase their diuretic dosage during travel to high altitude, and clinicians may consider administering low-flow oxygen during sleep to patients with congestive heart failure, at least for the first few nights after arrival at altitude. Individuals who have undergone coronary artery bypass grafting have trekked to altitudes of >5000 m (>16,400 ft) without problems.

Ascent to altitude produces a mild increase in blood pressure in normotensive and hypertensive persons secondary to increased sympathetic tone. However, the magnitude of blood pressure response varies significantly and is quite unpredictable. Patients should continue hypertensive medications at altitude, and blood pressure monitoring might be prudent. Occasionally, hypertensive medication dosages may need to be temporarily adjusted. No data suggest that hypertensive patients have a higher risk for any of the altitude illnesses, and in general, hypertension is not a contraindication to altitude exposure.

Neurologic Syndromes of High Altitude Until recently, most neurologic events at high altitude were attributed to high-altitude cerebral edema or AMS. Clearly, this has been a diagnostic oversimplification. Other syndromes now recognized as related to high altitude include altitude syncope, cerebrovascular spasm (migraine equivalent), cerebral arterial or venous thrombosis (infarct), transient ischemic attack, and cerebral hemorrhage. These syndromes are characterized by more focal neurologic findings than in cerebral edema, although differentiation in the field may be difficult. Other symptoms may be due to exacerbation or unmasking of underlying disease. Cortical blindness and various focal neurologic signs, such as transient hemiparesis or hemiplegia, also occur. **Focal neurologic signs should be thoroughly evaluated and not attributed to altitude illness.**

Other symptoms may be due to exacerbation or unmasking of underlying disease, such as previously asymptomatic brain tumors and epilepsy. Presumably, space-occupying lesions become symptomatic because of increased brain volume at altitude. Hyperventilation (hypocapnic alkalosis), which is commonly used to induce seizure activity on electroencephalography, may explain unmasking of seizure disorder at altitude, whereas changes in cerebral blood flow may exacerbate preexisting vascular lesions such as aneurysm or arteriovenous malformation, leading to spontaneous intracerebral hemorrhage.

In the field, it is reasonable to treat neurologic events as if cerebral edema were present, with rapid descent to lower altitude, oxygen supplementation, administration of steroids, and evacuation to hospital if symptoms persist. It is prudent to avoid use of agents that may contribute to hypotension and decrease cerebral perfusion.

Sickle Cell Disease Even the modest cabin altitude of pressurized aircraft (1500 to 2000 m [5000 to 6600 ft]) may cause persons with hemoglobin SC and sickle cell–thalassemia disease to experience vaso-occlusive crisis. Exposure to high altitude thus requires oxygen supplementation for such individuals. Although sickle cell trait is not considered a risk factor for increased altitude-related problems, splenic infarction syndrome during heavy exercise at altitude has been reported in individuals with the trait. Left upper quadrant pain should alert the physician at high altitude to consider splenic infarction syndrome.

Pregnant Women Pregnant women who live at high altitude have an increased prevalence of hypertension, delivery of low-birth-weight infants, and neonatal hyperbilirubinemia in their offspring. However, an increased incidence of pregnancy complications in lowlanders who visit high altitude has not been reported. The normal Pa_{O2} of the fetus is 29 to 33 mm Hg, and the mild maternal hypoxia induced by traveling to resort-type altitudes does not generate significantly more hypoxic stress. Few data exist regarding exercise in pregnant women at altitudes of >2500 m (>8200 ft), so a conservative approach should be used.[30] Pregnant women should avoid altitudes at which Sa_{O2} falls to <85%, such as a sleeping altitude of 3000 m (10,000 ft) or higher.[30] Perhaps of more concern than mild hypoxia is the fact that high-altitude locations are often remote from medical facilities. Patients need to be aware that without access to sophisticated medical care, complications may be associated with more serious consequences. Patients with high-risk pregnancies should be managed at low altitude.

CHAPTER 222

Carbon Monoxide

Gerald Maloney

INTRODUCTION

Carbon monoxide is one of the most common toxic exposures that emergency physicians will encounter. It is the most common cause of fatal poisoning, via either intentional (suicidal) or accidental exposure in the United States, and may be the most common worldwide cause of fatal poisoning.[1] Despite much clinical experience and several randomized trials, there is a great deal of controversy about the ideal approach for management.

EPIDEMIOLOGY

Exact statistics for carbon monoxide poisoning are difficult to determine, mainly due to incomplete reporting. Data from the American Association of Poison Control Centers Toxic Exposure Surveillance System in 2012[2] reported 13,038 exposures, with 54 deaths. However, this information is limited, as many exposures and some deaths are not reported to the local poison control center. It is also unclear how often patients with mild carbon monoxide poisoning are misdiagnosed and thus are not included in the database. Data from the Centers for Disease Control and Prevention paint a much broader picture of exposures than the Toxic Exposure Surveillance System database. The most recent large epidemiologic report from the Centers for Disease Control and Prevention on the subject, which reviewed data on non–fire-related carbon monoxide exposures, revealed 5149 deaths, for an average of 430 deaths per year.[3] Interestingly, the incidence of carbon monoxide exposure has not decreased despite more widespread use of carbon monoxide detectors.[3]

In the past, vehicular emissions were the major source of carbon monoxide poisoning in adults. Currently, nonvehicular sources have become more common as use of catalytic converters has reduced carbon monoxide in vehicular exhaust emissions[4] (**Table 222-1**)

Peak incidence occurs in the fall and winter months, generally due to increased use of space heaters, wood-burning stoves, charcoal burning for heat, or portable generators without adequate ventilation.[3] Additional sources of carbon monoxide exposure include air conditioners, portable generators in camping tents, exhaust on motorboats, and Zamboni machines used in ice rinks.[5-7] Exposures have been reported in persons riding in the back of pickup trucks, as well as in vehicles with an exhaust pipe occluded by snow.

It is believed that carbon monoxide poisoning is probably the most pressing danger from smoke inhalation and is a major contributor to fire-related deaths. Although carbon monoxide poisoning most commonly affects adults in the third to fifth decades, it may be seen across age groups, and it is not uncommon for entire families to be affected.

Another source for carbon monoxide poisoning is methylene chloride, which is found in varnishes and paint strippers, and in Christmas ornaments as a bubbling fluid. Routes of exposure are inhalation or ingestion, and the methylene chloride is metabolized in the liver to carbon monoxide. As a result of ongoing production, persistent elevation of carboxyhemoglobin occurs despite oxygen therapy.[8] Time to peak carbon monoxide levels may be 8 hours or longer.

PATHOPHYSIOLOGY

Carbon monoxide is typically described as a colorless, odorless gas. It is normally present in air at 10 ppm or less, perhaps higher in urban areas. There are multiple industries in which there may be occupational exposure to carbon monoxide. The Occupational Safety and Health Administration set a permissible exposure level of carbon monoxide of 50 ppm averaged over an 8-hour shift (https://www.osha.gov/pls/oshaweb/owadisp.show_document?p_table=STANDARDS&p_id=10366). Toxicity generally begins at levels of 100 ppm.

Carbon monoxide is also an endogenous substance, with production occurring in the body during the normal breakdown of heme. Normal physiologic carbon monoxide levels from this process are ~1% in healthy nonsmokers. This physiologic production can be increased in hemolysis or sepsis. Baseline levels in smokers of up to 10% have been reported.

The most easily quantified physiologic effect seen after carbon monoxide exposure is its binding to hemoglobin. The binding affinity of normal adult hemoglobin for carbon monoxide is approximately 200 times that of oxygen. Binding is higher for fetal hemoglobin, which may account for potentially more severe fetal toxicity.[9] Approximately 85% of carbon monoxide is bound to hemoglobin; the remaining carbon monoxide is dissolved in plasma or bound intracellularly, often to myoglobin. Carbon monoxide binds to hemoglobin to form carboxyhemoglobin. There are mathematical models for predicting the half-life of carboxyhemoglobin; these have been evaluated in both volunteer human models and actual carbon monoxide–poisoned patients. Quoted half-lives of carboxyhemoglobin on room air at normal atmospheric pressure range from 249 to 320 minutes.[7] On 100% oxygen at atmospheric pressure, this is reduced to an average of 74 to 80 minutes.[10] The exception to this is carboxyhemoglobin generated by methylene chloride exposure, which can have a half-life of up to 13 hours due to ongoing metabolic production.[8]

Carboxyhemoglobin does not participate in oxygen delivery to the cells, and as carboxyhemoglobin levels increase, relative anemia and hypoxia occur. Further, carbon monoxide shifts the oxyhemoglobin dissociation curve to the left, impairing oxygen release to the tissues. However, these features alone do not fully explain the physiologic effects of carbon monoxide or its delayed neurologic sequelae. Patients with corresponding levels of hypoxia, or anemia, who are not carbon monoxide poisoned, do not have similar short- and long-term effects seen with carbon monoxide poisoning. This indicates that there is a separate toxicity to carbon monoxide irrespective of the level of carboxyhemoglobin. Carboxyhemoglobin appears to be more a marker for the degree of poisoning than the primary cause of injury itself. The best experimental evidence of this involved dogs that were given carbon monoxide by inhalation to produce carboxyhemoglobin levels of 80%.[11] Exchange transfusion of this blood into healthy dogs produced no symptoms, suggesting that something other than simply the carboxyhemoglobin level is at play in explaining the full range of toxic effects.

As carboxyhemoglobin level rises, there is an increase in body burden of carbon monoxide. Ten to 15% of the carbon monoxide is dissolved unbound into plasma, a large proportion of which ultimately moves into the intracellular compartment. Like hemoglobin, myoglobin has a greater affinity for carbon monoxide than it does for oxygen, and myoglobin will bind to carbon monoxide with approximately 60 times the affinity of oxygen. Carbon monoxide inhibits intracellular cytochrome oxidase, interfering with cellular respiration and adenosine triphosphate generation. This results in a relative uncoupling of oxidative phosphorylation and the generation of elevated lactate levels, resulting in a lactic acidosis. Carbon monoxide also causes endothelial dysfunction and vasodilatation through the release of guanylate cyclase and nitric oxide. Carbon monoxide–induced nitric oxide release may in fact be one of the key factors in the cytotoxic effects of carbon monoxide poisoning. The release of guanylate cyclase and nitric oxide can contribute to hypotension. The combination of relative hypoxia and hypotension can cause ischemia-reperfusion injury in cardiac myocytes, as well as neuronal tissue. The damaged endothelium attracts neutrophils and triggers an inflammatory cascade, resulting in lipid peroxidation and ultimately

neuronal cell death. This complex intracellular process explains many of the clinical effects of carbon monoxide.[7] Rhabdomyolysis, acute myocardial infarction, and neuronal cell death are a result of this cellular toxicity. Cells in the basal ganglia are particularly sensitive to this neurotoxic effect, demonstrated by the globus pallidus lesions sometimes seen on cranial CT imaging.

CLINICAL FEATURES

The clinical presentation of carbon monoxide poisoning is protean, which likely leads to misdiagnosis in many cases (**Table 222-2**). An unconscious patient pulled from a house fire or from a running car in a closed garage does not present a diagnostic dilemma; the patient with "flu-like" symptoms or the elderly person presenting with syncope and ischemic changes on their ECG may be more difficult to diagnose. Given the lack of any predictable clinical toxidrome for carbon monoxide poisoning, a strong clinical suspicion remains the best initial method of detection.

History may be strongly suggestive, such as use of a propane heater in an apartment associated with a headache at home but relieved with exit from the home. Symptoms such as a new-onset seizure, syncope, myocardial infarction, or cardiac arrest may not be helpful. Sometimes, concurrent symptoms in other members of the household, or even pets, can be a clue. However, even within a household, different persons may manifest different symptoms, depending on age, comorbid disease, and proximity to the source of carbon monoxide. Occupational history may help, particularly in cases due to less common causes such as methylene chloride exposure. Exposure to any gas- or propane-powered motors, especially if working inside enclosed facilities, or fumes from methylene chloride, which is used as a varnish or paint stripper, may serve as a clue in patients with nonspecific symptoms. **Carbon monoxide poisoning should be in the differential diagnosis for comatose patients, patients with mental status changes, and those with an unexplained elevated anion gap metabolic acidosis or lactic acidosis.**

Physical exam findings are diverse. The classically touted finding of cherry red oral mucosa is rarely seen in living patients. Vital signs may demonstrate mild fever, tachycardia, tachypnea, hypertension, or hypotension. Severe poisoning may present with respiratory or cardiac arrest. Neurologic findings, which are generally thought of as being one of the hallmark signs for this poisoning, are also variable, ranging from mild headache and confusion to irritability, seizures, focal neurologic deficits, and coma. Retinal hemorrhages have been reported with severe poisoning. Skin findings include bullous lesions, generally seen in patients with prolonged immobility from pressure necrosis, although a direct toxic effect of carbon monoxide on epidermal tissue is also possible. Carbon monoxide poisoning may be obscured by other findings, such as trauma or severe burns. A comatose patient removed from a fire scene should be assumed to have carbon monoxide poisoning until proven otherwise, even in the absence of cutaneous or airway burns.

Although most discussions of carbon monoxide poisoning focus on acute exposure, chronic carbon monoxide poisoning, generally from occupational sources, must also be considered. Symptoms are usually more insidious, such as trouble concentrating, personality changes, or memory loss, and can be difficult to diagnose. Patients with chronic carbon monoxide poisoning are at risk of carbon monoxide–related neurotoxicity and may have long-term neuropsychiatric issues.

TABLE 222-2 Signs and Symptoms of Acute Carbon Monoxide Poisoning

Headache	Visual disturbances
Vomiting	Confusion
Ataxia	Dyspnea/tachypnea
Seizure	ECG changes/dysrhythmias
Syncope	Retinal hemorrhage
Chest pain	Bullous skin lesions
Focal neurologic deficit	

DIAGNOSIS

The diagnosis is best made by measuring carboxyhemoglobin levels. Although carboxyhemoglobin in and of itself may not be the most significant factor in carbon monoxide–mediated injury, obtaining free plasma carbon monoxide is rarely feasible. Thus, carboxyhemoglobin serves as a marker of severity of exposure and can help to stratify patients at risk for delayed sequelae. **Co-oximetry, which measures total hemoglobin as well as oxyhemoglobin, methemoglobin, and carboxyhemoglobin saturation, is the only accurate measurement tool.** Routine arterial blood gas analyzers without co-oximetry calculate, rather than measure, saturation, and will not differentiate the contribution of dyshemoglobinemias to total saturation. As a result, the oxygen saturation may appear artificially high. There is excellent correlation between arterial and venous carboxyhemoglobin levels, and thus, a venous blood gas with co-oximetry is sufficient in most cases.[12]

Interpreting carboxyhemoglobin levels can be challenging and needs to take into consideration time and duration of exposure, time from exposure to presentation, treatment (such as high-flow oxygen) rendered en route, and clinical symptoms. Although a markedly elevated level, such as 50%, is a clear indicator of severe intoxication, a level of 10% in a patient who experienced serious symptoms a few hours earlier presents a dilemma in terms of diagnosis and appropriate disposition. Symptomatology and carboxyhemoglobin levels do not always correlate well: levels as high as 47% have been reported in minimally symptomatic patients, whereas levels as low as 10% have been reported in comatose patients in whom the diagnosis of carbon monoxide poisoning was ultimately confirmed.[13]

Standard pulse oximetry is unreliable in the diagnosis of carbon monoxide poisoning. The wavelengths for carboxyhemoglobin fall into the same range of those for oxyhemoglobin, and standard pulse oximetry does not differentiate the two. As a result, the oxyhemoglobin saturation by pulse oximetry reading will appear artificially high[14] (**Figure 222-1**). The **pulse oximetry gap** is a measure of this discordance. When the pulse oximetry values are compared to the oxygen saturation on an arterial blood gas, the oxygen saturation on the pulse oximeter will be higher than the saturation on the arterial blood gas.

Data on currently available pulse co-oximeters are mixed. Until a large, randomized, and well-designed study looking at the accuracy of these devices in an ED setting can be performed, it is not recommended to rely solely on pulse co-oximeters to exclude carbon monoxide poisoning.[15-17]

Other laboratory and diagnostic testing can be also be informative. Elevated lactate from the interference in the electron transport chain, an unexplained elevated anion gap metabolic acidosis, elevated creatine phosphokinase, or elevated troponin may trigger an investigation for

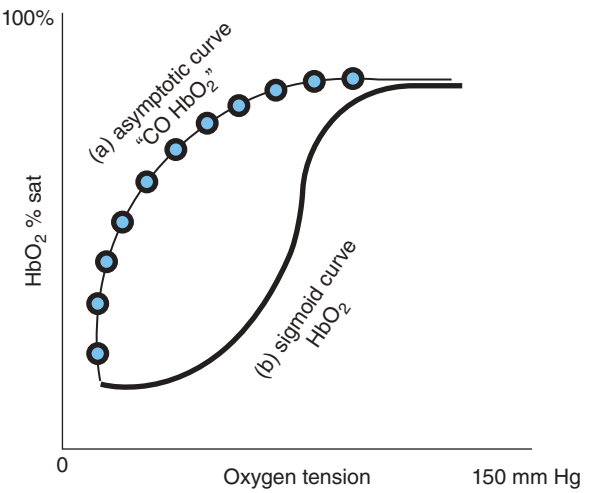

FIGURE 222-1. Carboxyhemoglobin "shift to the left" reshaping of the oxyhemoglobin (HbO_2) dissociation curve. **(A)** Carbon monoxide (CO)–affected HbO_2 dissociation curve (asymptotic) and **(B)** normal HbO_2 dissociation curve (sigmoid).

carbon monoxide poisoning. Concomitant cyanide poisoning may be seen in patients rescued from structure fires. Neuron-specific enolase or S100B,[18] CNS proteins that are released in greater quantities into the plasma when neuronal injury has occurred, and cerebrospinal fluid myelin basic protein are markers for carbon monoxide neurotoxicity. However, these tests may be more useful in determining prognosis than diagnosis and are rarely available for use in ED clinical decision making.

Electrocardiographic findings may range from entirely normal to acute injury patterns, such as ST elevation myocardial infarction. There does not appear to be any classic carbon Monoxide ECG pattern. Few patients with acute myocardial infarction due to carbon monoxide poisoning have occlusive lesions identified at cardiac catheterization.[19]

Radiographic imaging is generally of limited utility and is usually more helpful in establishing an alternative diagnosis. There is, however, one radiographic finding that has been specifically associated with carbon monoxide poisoning, and that is lesions in the globus pallidus. Lesions are generally bilateral and symmetric and are usually noted in severely poisoned patients.[7]

TREATMENT

Initial resuscitation of the carbon monoxide–poisoned patient does not differ from initial resuscitation of any other critically ill patient. **If carbon monoxide poisoning is strongly suspected based on history, immediately provide supplemental oxygen in the highest concentrations available.**

Conditions for the application of hyperbaric oxygen treatment have not been clearly identified. Despite years of experience using hyperbaric oxygen and several clinical trials, identifying individuals who can benefit from HBO is challenging. The most recent comprehensive review on the subject is a Cochrane review from 2011.[20] Six clinical trials were reviewed. Two of the six demonstrated a benefit in terms of decreased neurologic sequelae; the remaining four trials failed to demonstrate a benefit. All studies had various methodologic flaws. The only trials to include sham dives (diving but at room air instead of high-concentration oxygen) were the two positive trials (Weaver and Scheinkestel). These two positive trials were stopped early due to reported clear benefit; however, they did not test multiple hypotheses and had significant heterogeneity in their treatment protocols. The four negative trials were smaller, methodologically heterogeneous, and suffered from problems with long-term follow-up. Given the lack of conclusive evidence-based data, the best guidance comes from consensus recommendations from multiple professional groups (**Table 222-3**). Recommendations consider multiple factors such as carboxyhemoglobin level, comorbid conditions (including pregnancy), stability of the patient, and location of the nearest center with emergency hyperbaric capabilities.

The rationale behind hyperbaric oxygen therapy stems from early studies demonstrating its effectiveness in decreasing carboxyhemoglobin levels. Initial studies on both volunteers and poisoned patients in the 1940s demonstrated that use of hyperbaric oxygen at 2.5 atmospheres of pressure lowered the effective half-life of carboxyhemoglobin to an average of 24 minutes due to a competitive displacement of carbon monoxide from its binding sites by the increased concentration of oxygen.[10] The clinical logic that led to recommendations for routine use centered on the premise that rapid reduction in carboxyhemoglobin levels meant that carbon monoxide was being cleared from the system and that toxicity could be reversed. Neurotoxicity is the endpoint most commonly studied; however, not all studies use the same assessment tools or follow-up periods. Scheinkestel et al[21] were unable to demonstrate any conclusive prevention of delayed neurologic sequelae with use of hyperbaric oxygen, whereas Weaver et al[22] saw a significant reduction in neurologic sequelae (cerebellar dysfunction and cognitive sequelae).

The consensus recommendations for consideration of hyperbaric oxygen therapy are listed in Table 222-3. The decision to initiate hyperbaric oxygen needs to occur in conjunction with a specialist in hyperbaric medicine. The Undersea and Hyperbaric Medicine Society maintains a list of chambers at the following Web site: www.hyperbariclink.com. For complete discussion of hyperbaric oxygen, see the chapter 21, "Hyperbaric Oxygen Therapy."

TABLE 222-3 Commonly Used Indications for Referral for Hyperbaric Oxygen Treatment

Pregnancy with carboxyhemoglobin level >15%
Carboxyhemoglobin >25%
Syncope
Evidence of acute myocardial ischemia
Confusion/altered mental status
Seizure
Coma
Focal neurologic deficit

DISPOSITION

Three distinct categories of carbon monoxide–poisoned patients exist: (1) those with minimal intoxication, with mild or no symptoms throughout their clinical course; (2) those with symptoms attributable to carbon monoxide poisoning but without any high-risk features that suggest a need for hyperbaric oxygen referral; and (3) those with signs of serious toxicity for whom consultation with a specialist in hyperbaric medicine should be considered.

Those with minimal intoxication, who are asymptomatic initially or after a period of brief observation, may be sent home if the exposure is not a suicide attempt and discharge is to a safe environment. If there is a suspected source of carbon monoxide poisoning, contact other potentially exposed persons for ED evaluation, and notify the fire department to measure ambient levels of carbon monoxide at the source site. Once the safety of the discharge destination is established, the patient may be discharged.

Those with more serious symptoms, such as headache or vomiting, or those with an elevated carboxyhemoglobin level but no high-risk features (Table 222-3) should be treated with supplemental oxygen, have pertinent labs checked, and be observed for several hours. After 4 hours of observation, patients may be discharged home if symptoms have resolved, assessment is otherwise benign, and discharge is to a safe environment.

Patients who require referral for possible hyperbaric oxygen therapy need consultation with a hyperbaric specialist and stabilization as best as possible prior to transfer. Critically ill or unstable patients should continue to receive high-concentration normobaric oxygen and should be reassessed prior to transfer.

SPECIAL POPULATIONS

Children may be more susceptible to the effects of carbon monoxide due to a higher percentage of fetal hemoglobin as well as higher metabolic rates.[7] The indications for referral of pediatric patients for HBO therapy are similar to those for adults. HBO has been used in children with a good safety profile.

Pregnant women should be referred to a hyperbaric center at carbon monoxide levels of 15% to 20% because fetal morbidity has been demonstrated at lower levels than usual due to the high affinity of carbon monoxide for fetal hemoglobin.[7]

The elderly, particularly those with serious comorbid disease, are also at higher risk from carbon monoxide poisoning. In patients with known coronary artery disease, even low levels of carboxyhemoglobin (4% to 6%) can cause ECG changes and myocardial ischemia.[7] Some of the elderly may also be at risk due to use of alternate heating sources, particularly during the winter.

PREVENTION

Preventive measures center on education. Educate the public about the dangers of using wood- or coal-burning appliances to heat their homes during the winter and about using adequate ventilation, and review warning signs and symptoms of carbon monoxide exposure. A relatively inexpensive preventative measure is the use of carbon monoxide detectors in the home; some municipalities have even given these away

through the fire department. Local fire departments are generally willing to screen for elevated carbon monoxide levels in homes. Many educational resources are available on the Internet (http://www.cdc.gov/co/guidelines.htm; http://www.carbonmonoxidekills.com; http://www.usfa.dhs.gov/citizens/all_citizens/co/index.shtm).

CHAPTER 223

Type 1 Diabetes Mellitus

Nikhil Goyal
Adam B. Schlichting

INTRODUCTION AND EPIDEMIOLOGY

During 2002–2005, 15,600 people under 20 years of age were newly diagnosed with type 1 diabetes annually in the United States.[1] Classification of diabetes (American Diabetes Association) is shown in **Table 223-1**.[2,3]

PATHOPHYSIOLOGY

Type 1 diabetes is characterized by almost no circulating insulin and the failure of β-cells to respond to insulinogenic stimuli. This accounts for only 5% to 10% of all cases of diabetes and is mostly diagnosed in children and young adults, with peaks before school age and at puberty. Immune-mediated destruction of β-cells causes 90% of these cases, and the remainder have no known cause. Spontaneous ketoacidosis almost always develops in untreated cases, and insulin is required for survival. It is often not possible to clearly classify patients as type 1 or type 2 in the ED.[3]

Chapter 224, Type 2 Diabetes Mellitus, discusses type 2 diabetes mellitus in detail. Hyperglycemia is present in all types of diabetes mellitus and is the main factor responsible for complications. Therefore, maintaining euglycemic control is the cornerstone of management.

DIAGNOSIS

The American Diabetes Association criteria for diagnosis are listed in **Table 223-2**.[2,3] Any one of these can be used to make the diagnosis. Patients with a fasting plasma glucose of 100 milligrams/dL to 125 milligrams/dL (5.6-7.0 mmol/L), a hemoglobin A1C of 5.7% to 6.4%, or a 2-hour plasma glucose of 140 to 199 milligrams/dL (7.8-11.0 mmol/L) as part of an oral glucose tolerance test are classified as having *prediabetes*.[2]

Glycated hemoglobin represents the average blood glucose level over the period of red blood cell half-life. The glycated hemoglobin assay may not be accurate for diagnosis of diabetes in patients with increased red blood cell turnover such as thalassemia, anemia, chronic kidney or liver disease, pregnancy, or in patients who have had heavy bleeding or received a transfusion within the preceding 3 months.[2]

In the ED, it is common to encounter isolated elevations of blood glucose with no established relationship to a meal ("casual plasma glucose," as defined by the American Diabetes Association). Ask about symptoms of hyperglycemia and refer to a primary care physician.

TREATMENT

Type 1 diabetes is characterized by an absolute insulin deficiency, so some form of insulin is required for survival. In addition to insulin, patients with type 1 diabetes may also be treated with prandial injections of pramlintide, a synthetic form of the β-cell–produced hormone amylin, which aids in suppressing glucagon secretion.[4] Patients with type 1 diabetes may also benefit from β-cell transplantation, pancreas transplantation, or combined kidney/pancreas transplantation. Other noninsulin agents are useful in type 2 diabetes and are discussed separately in chapter 224.

INSULIN

Currently, all insulin sold in the United States is of human type and manufactured using recombinant DNA technology (bovine or porcine insulin can still be obtained via special permission from the U.S. Food and Drug Administration). Modern insulin is highly pure and stable, and vials in use can be kept up to 30 days at room temperature. All types of insulin are standardized to a concentration of 100 units/mL ("U100"). When extremely high doses of insulin are required, a concentration of 500 units/mL ("U500") of regular insulin can also be used in consultation with an endocrinologist.

Although unmodified "regular" insulin was the first type of insulin used, many new insulin analogues have now become available (**Table 223-3**, **Figure 223-1**).[5,6] There can be considerable variability in the onset and duration of action depending on the dose (e.g., regular insulin has a longer duration of action with larger doses), site of injection, degree of exercise, and presence of circulating anti-insulin antibodies. Use of insulin analogues and highly pure insulin preparations has reduced the emergence of anti-insulin antibodies.

A physiologic regime of insulin generally starts with half of the daily requirement given as basal insulin (once-daily long-acting, or twice-daily intermediate-acting insulin) and a prandial dose of rapid-acting insulin administered 5 to 30 minutes before a meal.[5] Prandial dosing is most often based on the amount of carbohydrate that is about to be consumed, for example, 1 unit of insulin for each 15 grams of carbohydrate; this is known as "carb counting." Alternatively, some patients may be on a simplified, fixed amount of insulin for each meal.

Methods of Insulin Administration Insulin can be given as intermittent dosing, IV infusion, or continuous subcutaneous infusion using an insulin pump.

Intermittent insulin doses are given with a syringe or pen. The syringe method is the least expensive, but requires care and precision to give the correct dose. Pens provide more accurate dosing.

SC injection is the most common method of insulin administration. Absorption varies due to regional circulatory differences, and frequent use of a single site may lead to fibrosis or lipodystrophy. Therefore, patients are asked to limit injections to one region of the body, but rotate sites within that region.

IV administration of regular insulin leads to almost instantaneous effect on plasma glucose and is the recommended method of administration in hyperglycemic crises—diabetic ketoacidosis and hyperglycemic hyperosmolar nonketotic state.

INSULIN PUMPS (CONTINUOUS SC INSULIN INFUSION)

The use of an insulin pump (**Figure 223-2**) (continuous SC insulin infusion) is common, with estimates as high as 40% of U.S. patients with type 1 diabetes using insulin pumps.[7] An insulin pump is a small device (about the size of a pager) that delivers fixed doses of rapid-acting insulin at a basal rate (generally, 0.5 to 1.5 units/h) by a flexible tube attached to a subcutaneous catheter. **Table 223-4** lists manufacturers of insulin pumps available in the United States. The pump is usually attached to the patient's clothing. However, one manufacturer produces an insulin pump that does not use tubing, but is directly attached to the patient with adhesive.[8] The reservoir needs to be refilled every few days, and the catheter is changed by the patient every 3 days or so.

The basal rate of insulin can be varied throughout the day, for example, increased to counteract an early morning cortisol surge or decreased before exercising. The continuous basal insulin delivery

TABLE 223-1 Etiologic Classification of Diabetes Mellitus

I. Type 1 diabetes (β-cell destruction, usually leading to absolute insulin deficiency)
   a. Immune mediated
   b. Idiopathic
II. Type 2 diabetes (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with insulin resistance)
III. Other specific types, such as
   a. Genetic defects of β-cell function
   b. Genetic defects in insulin action
   c. Diseases of the exocrine pancreas (pancreatitis, trauma, cystic fibrosis, etc.)
   d. Endocrinopathies (Cushing's syndrome, pheochromocytoma, hyperthyroidism, somatostatinoma, glucagonoma, etc.)
   e. Drug- or chemical-induced (interferon-α, β-adrenergic agonists, diazoxide, phenytoin [Dilantin®], glucocorticoids, nicotinic acid, pentamidine, thiazides, thyroid hormone, pyrinuron [Vacor®], etc.)
   f. Infections (congenital rubella, cytomegalovirus, etc.)
   g. Uncommon forms of immune-mediated diabetes
   h. Other genetic syndromes sometimes associated with diabetes (Down's syndrome, Klinefelter's syndrome, Turner's syndrome, etc.)
IV. Gestational diabetes mellitus

eliminates the need for long-acting insulin injection such that the pump delivers all insulin required by the patient in the form of rapid-acting insulin. Rarely, patients requiring exceptionally high doses of insulin using an insulin pump, patients who wish to be disconnected from their pump for extended periods of time, or patients at higher risk of hyperglycemia or diabetic ketoacidosis (e.g., young children) may also inject a once- or twice-daily long-acting insulin.[9,10] **The pump can be manually activated to deliver a bolus for hyperglycemia and for prandial dosing.** Insulin pumps are most appropriate for motivated patients who are mechanically adept, well educated about diabetes and carbohydrate counting, and able to monitor their capillary glucose four to six times a day.

Several models of insulin pumps are also capable of continuous glucose monitoring. These devices measure interstitial glucose concentrations and transmit glucose values to the pump or other display device. Interstitial glucose values are adjuncts to capillary glucose monitoring and still require manipulation of the insulin pump to administer insulin. Interstitial glucose is a proxy for serum glucose and is better for monitoring trends than absolute glucose level. **Capillary or serum glucose levels should be monitored in the ED, and interstitial glucose values should not be relied upon for diagnostic purposes.**

TABLE 223-2 American Diabetes Association Criteria for the Diagnosis of Diabetes

A1C ≥6.5%*	The test should be performed in a laboratory using a method that is NGSP certified and standardized to the DCCT assay.
Or Fasting plasma glucose ≥126 milligrams/dL (7.0 mmol/L)*	Fasting is defined as no caloric intake for at least 8 h.
Or Casual plasma glucose ≥200 milligrams/dL (11.1 mmol/L) **and** symptoms of hyperglycemia	Classic symptoms of hyperglycemia include polyuria, polydipsia, and unexplained weight loss.
Or 2-h plasma glucose ≥200 milligrams/dL (11.1 mmol/L) during an oral glucose tolerance test (OGTT)*	OGTT must be performed as described by the World Health Organization.

Abbreviations: A1C = glycated hemoglobin; DCCT = Diabetes Control and Complications Trial; NGSP = National Glycohemoglobin Standardization Project.

*Should be confirmed by repeat testing unless unequivocal hyperglycemia is present.

Insulin Pump Complications Insulin pump delivery can fail for a variety of reasons (disconnection, empty reservoir, kinked catheter, priming errors), although modern pumps have built-in alarms to detect these conditions.[11] **Because pumps use only rapid-acting insulin, onset of ketoacidosis can be very rapid after pump failure—an hour or less. If the pump is defective or needs to be removed for a procedure such as MRI, give the patient either a dose of rapid-acting insulin or long-acting insulin, especially if the insulin pump is to be interrupted for over an hour.**

Patients being switched from multiple daily injections of insulin to insulin pumps are typically handled as outpatients and will require special attention if presenting to the ED in this transition period. Specific considerations for patients on insulin pumps presenting with hyperglycemia or hypoglycemia are discussed later in this chapter.

Other important complications of insulin pump therapy include cellulitis at the infusion site or lipodystrophy. ED patients with nondiabetes complaints who are incidentally found to have hyperglycemia or hypoglycemia should be allowed to treat themselves (they should have been previously instructed by their endocrinologist) either by administering an insulin bolus through the insulin pump or by consuming carbohydrates.

PRAMLINTIDE

In addition to prandial insulin, patients with type 1 diabetes who are unable to achieve optimal glucose control using insulin or insulin analogues may also be treated with prandial injections of pramlintide, a synthetic form of the hormone amylin, which is produced by β-cells. Amylin promotes satiety, slows gastric emptying, aids in suppressing glucagon secretion,[4] and reduces hemoglobin A1C levels.[12] In initial studies of pramlintide, there was a significant increase in the occurrence of severe hypoglycemia, especially during the first 4 weeks of therapy and when insulin doses were not reduced.[13] **If insulin doses are reduced by about 25% with initiation of pramlintide, the risk of hypoglycemia could be eliminated.**[12,14]

TRANSPLANTS

There are three methods of pancreas transplantation: simultaneous pancreas and kidney, pancreas after kidney, and pancreas transplant alone.[15] In 2010, 350 pancreas transplants and 828 combined kidney/pancreas transplants were performed in the United States.[16] Long-term immunosuppression with medications such as sirolimus and tacrolimus is required.

Another promising modality is islet cell transplantation. One of the most successful protocols is the Edmonton protocol, which has led to insulin independence in type 1 diabetics.[17] Insulin independence is short lived, however; by 2 years post-transplantation, 76% of patients again required the use of exogenous insulin.[17]

GLYCEMIC COMPLICATIONS IN INSULIN-DEPENDENT PATIENTS

The major hyperglycemic emergencies, hyperosmolar hyperglycemic state and diabetic ketoacidosis, are discussed in chapters 227, "Hyperosmolar Hyperglycemic State" and 225, "Diabetic Ketoacidosis," respectively. Here we discuss the common ED presentation of an "abnormal lab value" (i.e., a patient with no acute symptoms of hyperglycemia who was found to have elevated plasma glucose on laboratory or point-of-care testing).

HYPERGLYCEMIA IN PREVIOUSLY DIAGNOSED TYPE 1 DIABETICS

For patients with type 1 diabetes with hyperglycemia noted on multiple ED visits, refer to the primary physician for insulin dose adjustment. In the interim, ask patients to keep a daily record of every meal, every dose of insulin administered (along with type of insulin), and blood glucose

TABLE 223-3 Commonly Used Insulin Preparations, Their Pharmacokinetics and Unique Features*

Category of Insulin or Analogue	Name	Pharmacokinetics			Unique Properties
		Onset (hour)	Peak (hour)	End (hour)	
Rapid acting	Insulin lispro (Humalog®)	0.1–0.25	1.0–1.5	4	Fixed duration of action, regardless of dose Useful in patients allergic to insulin and other analogues[13-15]
	Insulin aspart (NovoLog®)	0.1–0.25	1–2	4–6	More stable than other rapid-acting insulins
	Insulin glulisine (Apidra®)	0.1–0.25	1.0–1.5	3–4	Antiapoptotic; may counteract β-cell destruction[16]
Short acting	Regular insulin (Humulin R®, Novolin R®)	0.25–1.0	2–4	6–8	—
Intermediate acting	NPH (Humulin N®, Novolin N®)	2–4	6–7	10–20	Inexpensive
	Insulin detemir (Levemir®)	1–3	9–?	6–24	Action is relatively constant with gentle peak
Long acting	Insulin glargine (Lantus®)	1.5	No peak	24+	Cannot be mixed with other insulins in same syringe
Mixtures	70/30 Humulin®/Novolin® (70% NPH, 30% regular)	0.5–1.0	3–12	10–20	—
	50/50 Humulin®/Novolin® (50% NPH, 50% regular)	0.5–1.0	2–12	10–20	—
	75/25 Humalog® (75% NPL, 25% lispro)	0.2–0.5	1–4	10–20	—
	50/50 Humalog® (50% NPL, 50% lispro)	0.2–0.5	1–4	10–20	—
	70/30 NovoLog Neutral® (70% protamine aspart, 30% aspart)	0.2–0.5	1–4	10–20	—

Note: All brand names are copyrighted by their respective owners.

Abbreviations: NPH = neutral protamine Hagedorn; NPL = neutral protamine lispro.

*Ultralente and Lente insulins are no longer available in the United States.

levels four times a day (after rising in the morning, before lunch, before dinner, and at bedtime).

If an insulin dose adjustment is made in the ED, the basic regime should be a once- or twice-daily dose of long- or intermediate-acting insulin, combined with prandial doses of rapid-acting insulin. The magnitude of increase in the basal insulin dose should be tailored to the degree of hyperglycemia in the patient. **The total daily dose of insulin is estimated at 0.2 to 0.4 units/kg/day,** with half given as basal insulin such as insulin glargine and half to be given in divided doses preprandially.

A conservative supplemental prandial dose of rapid-acting insulin can be calculated as follows: 1 unit per 50 milligrams/dL above target

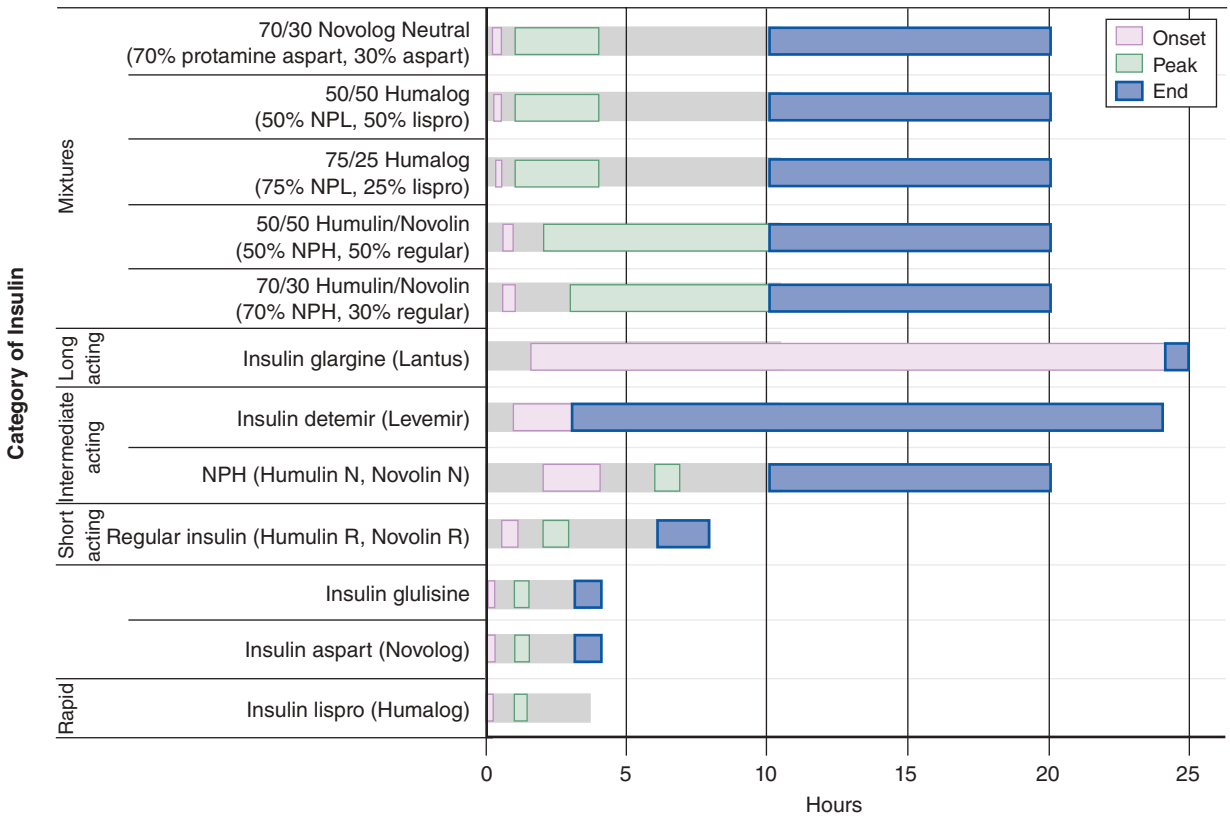

FIGURE 223-1. Insulins: onset, peak, and duration of action. NPH = neutral protamine Hagedorn; NPL = neutral protamine lispro.

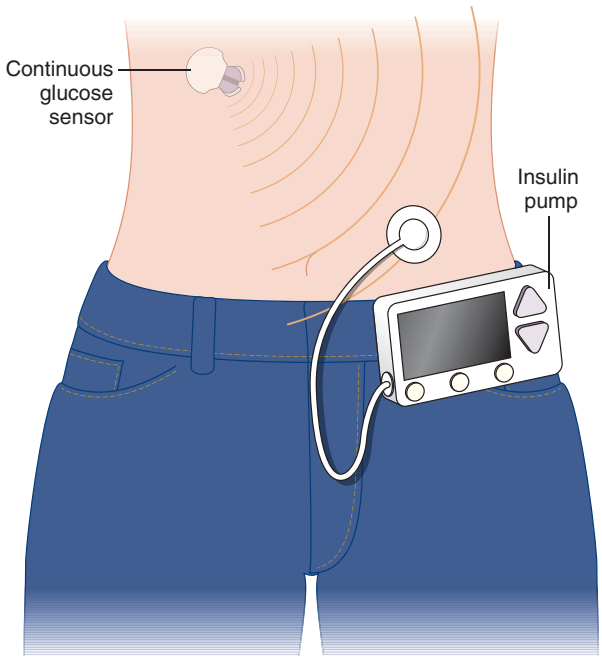

FIGURE 223-2. Schematic illustration of insulin pump.

glucose level for type 1 diabetics, and 1 unit per 30 milligrams/dL above target glucose level for type 2 diabetics.[18]

If the patient is using neutral protamine Hagedorn insulin, then inspect the neutral protamine Hagedorn vial; if frosting is noted on the sides of the bottle, this may indicate denaturation, which renders the insulin ineffective and can lead to diabetic ketoacidosis. Give a new prescription and discard the old vial.

Patients Using Insulin Pumps At this time, there are no published guidelines for the ED management of patients with insulin pumps who present to the ED with diabetic emergencies. **We recommend that patients using insulin pumps who present to the ED with either hyperglycemia or hypoglycemia should be treated the same as patients who are on multiple daily doses of insulin, and the insulin pump should not be disabled.**

Hyperglycemia in Patients Using Insulin Pumps For treatment of hyperglycemia, have the patient give a bolus of rapid-acting SC insulin using the pump (see insulin dosing as previously described).

Once the patient has been stabilized, ask about dietary indiscretions and search for infections. Ask specific questions about the insulin pump: when was the insulin reservoir filled; when was the infusion set last changed; is the insertion site of the infusion set periodically changed? Examine the device thoroughly to ensure the pump is on, the reservoir is not empty, no alarms are indicated, the tubing is not kinked, and the infusion site is well attached to the skin. The patient or caregiver may provide useful information on operation of the pump, pump diagnostics, and how to disconnect it if necessary. All pumps have a toll-free telephone number for 24-hour technical support from the manufacturer (**Table 223-4**). If there is suspicion for pump malfunction, consult endocrinology for consideration of replacement of the insulin pump with long-acting basal insulin.

TABLE 223-4 Manufacturers of Insulin Pumps Available in the United States With Their 24-Hour Phone Numbers

Manufacturer	Website	Telephone Number
Animas	http://www.animas.com	(877) 937-7867

Diabetic Ketoacidosis in Patients Using Insulin Pumps In the case of diabetic ketoacidosis in a patient on an insulin pump, assume a problem with the pump, disconnect the pump, and start an IV insulin infusion and follow protocols for diabetic ketoacidosis treatment. Once the diabetic ketoacidosis has resolved, give a dose of long-acting insulin 1 hour before stopping the insulin drip unless the insulin pump is to be re-initiated—in that case, re-start pump therapy 1 hour before stopping the IV insulin drip. In order to re-initiate pump therapy, make sure that the pump is working appropriately by running diagnostics on the device, that the insulin reservoir is filled with fresh insulin, and that a new SC insulin infusion catheter has been placed. See chapter 225, for further discussion of transition of insulin dosing in diabetic ketoacidosis.

Check serum glucose levels every 30 to 60 minutes.

HYPOGLYCEMIA IN INSULIN-DEPENDENT PATIENTS

Hypoglycemia (plasma glucose <70 mg/dL) is a complication of intensive insulin therapy and is the major adverse effect of tight glycemic control. Apart from insulin administration, diabetics are prone to hypoglycemia because the surge of glucagon is absent in type 1 diabetes, and epinephrine secretion can be blunted as a result of neuropathy, age, or autonomic dysfunction due to frequent hypoglycemic episodes in the past.

Older insulin regimens used once- or twice-daily injections of neutral protamine Hagedorn or Lente insulin as the basal insulin and regular insulin as the prandial dose. Often premixed combinations (70/30, 75/25, 50/50) were used. These schedules mandated fixed meal times and activity schedules, so it was not unusual to develop hypoglycemia with missed meals and unusual stress. Use of modern physiologic regimes of insulin administration has significantly reduced the incidence of hypoglycemia. However, many patients remain on premixed dosing due to familiarity, or financial or insurance coverage limitations.

Determine the cause of hypoglycemia. Common causes include inadequate intake of food, inaccurate administration of insulin, infection, renal failure, acute coronary syndrome, unusual physical or mental stress, and so forth. Identify the timing and administration of insulin in relation to meals. There is a great variation in the pattern of hypoglycemic signs and symptoms from patient to patient; however, individual patients tend to experience the same pattern from episode to episode. Common neuroglycopenic symptoms include drowsiness, confusion, dizziness, tiredness, inability to concentrate, and difficulty speaking. Adrenergic symptoms such as tremor, sweating, anxiety, nausea, palpitations, feelings of warmth, and shivering are also seen, as are other symptoms such as hunger, weakness, and blurred vision.[19]

***Hypoglycemic unawareness* or *hypoglycemia-associated autonomic failure* occurs when diabetic patients have deficient counterregulatory hormone excretion, resulting in a lack of symptoms of hypoglycemia.**[3] This results in frequent episodes of hypoglycemia and profound hypoglycemic episodes. β-Blocker medication may also contribute to this condition, as the drug masks typical sympathetic symptoms of hypoglycemia.

Treatment of Hypoglycemia Glucose is the preferred treatment, although any glucose-containing carbohydrate may be used. The initial dose is 15 to 20 grams (PO, PR, or IV) that can be repeated if hypoglycemia persists after 15 minutes. In comatose patients, the IV or PR route is obviously necessary.

Pure fructose does not cross the blood–brain barrier, and protein has a negligible contribution to serum glucose—both are ineffective in treating hypoglycemia. Rectal syrup or honey is also an effective treatment. Once hypoglycemia has resolved, have the patient eat a meal or carbohydrate snack. **Table 223-5** lists the glucose content of commonly used oral agents.

Glucagon emergency kits are available for caregivers or family members of patients with type 1 diabetes for emergency situations. One milligram IM glucagon stimulates glycogenolysis and is usually effective in 10 to 15 minutes. Once the patient is alert enough to swallow,

TABLE 223-5 Glucose Content of Agents Available at Home

Agent	Dose/Route	Glucose Content
Fruit juice	1 cup PO	Variable depending on type of juice and manufacturer
		6 oz Mott's® apple juice: 21 grams sugar
Honey	1 tbsp PO/PR	17 grams sugar
Cake icing	2 tbsp PO	24 grams sugar
Sugar-containing soda	12 oz (one can) PO	(non-diet) Pepsi® = 41 grams sugars
		(non-diet) Sprite® = 38 grams sugars
		(non-diet) Coke® Classic = 40.5 grams sugars
Glucose tablets (commercially available)	Four tablets PO	16 grams carbohydrates

give oral glucose immediately. **Glucagon is not effective in glycogen-depleted patients**, and glucagon may induce nausea and vomiting, which can make it difficult to consume oral glucose subsequently.

Patients with a significant overdose of a long-acting agent should be admitted for monitoring of glucose levels. Most patients can be discharged if caregivers and family members can monitor symptoms and capillary glucose levels.

Hypoglycemia in Patients Using Insulin Pumps Treat hypoglycemia just as in other patients. **Do not discontinue the pump, as diabetic ketoacidosis can rapidly develop.** Please see section *General Considerations* for patients using insulin pumps, under *Hyperglycemia* (earlier).

If a patient on an insulin pump is to be made NPO, the insulin pump should *not* be removed and glucose levels should be checked every 30 to 60 minutes. If the patient has hypoglycemic episodes while NPO, the pump basal rate can be reduced, but this is best done in consultation with the endocrinologist.

SPECIAL CONSIDERATIONS

UNDIAGNOSED DIABETIC

A long asymptomatic period is common for type 2 diabetes, but type 1 diabetes typically has a short symptomatic period before the disease becomes overt. If the patient is newly identified with severe and symptomatic hyperglycemia (>250 to 300 milligrams/dL or 13.8-16.7 mmol/L), insulin should be administered in the ED. Insulin can be given even if it is not known at the time whether the patient has type 1 or type 2 diabetes. Patients with severe or symptomatic hyperglycemia should be given insulin and admitted or placed in an observation unit for further glucose control and education.

A low dose of regular or rapid-acting insulin (1 unit SC for every 30 milligrams/dL above glucose of 250 to 300 milligrams/dL) may be given to reduce hyperglycemia and a long-acting insulin (e.g., 0.1 to 0.2 units/kg of insulin glargine) should be given in the ED to prevent diabetic ketoacidosis.

For patients without severe and symptomatic hyperglycemia, regular or rapid acting insulin can be given to reduce the glucose to 250 milligrams/dL or so. Normoglycemia does not necessarily need to be achieved in the ED. Then the patient may be discharged with a prescription for metformin[3,20] and referral to their physician or clinic within 24 hours for further care. For further discussion of type 2 diabetes care and noninsulin antidiabetic agents such as metformin, see chapter 224.

GLUCOCORTICOID-INDUCED DIABETES

The American Diabetes Association defines glucocorticoid-induced hyperglycemia as an "other specific type" of diabetes. Patients receiving glucocorticoids are at risk of developing hyperglycemic crises, including hyperosmolar hyperglycemic nonketotic syndrome and diabetic ketoacidosis.

Patients with type 1 diabetes who are started on glucocorticoids before discharge from the ED will likely develop hyperglycemia. They should be informed about warning signs of hyperglycemia and advised to seek close follow-up with their primary physician, with frequent monitoring of blood glucose at home and additional prandial doses of insulin. Routine increase in basal insulin dosage is not indicated.

Although previously undiagnosed diabetics may develop hyperglycemia while on glucocorticoid therapy, the hyperglycemia will often resolve spontaneously once the glucocorticoid course is completed. If hyperglycemia is persistent or symptomatic, medication may be required after failure of dietary modification and exercise.

FALSELY ELEVATED CAPILLARY GLUCOSE

Peritoneal dialysis solutions using icodextrin interfere with many point-of-care capillary glucose measurement systems. These often result in falsely elevated readings, and there have been many reports of severe hypoglycemia due to insulin administration in response to such readings. **Obtain a central laboratory plasma glucose measurement for all peritoneal dialysis patients.**

"DEAD IN BED" SYNDROME

First described in 1991, the phenomenon of "dead in bed" syndrome can occur in typically young adults with uncomplicated type 1 diabetes who go to sleep in normal health and unexpectedly die, only to be found later in an undisturbed bed, without evidence of terminal struggle or seizure.[21,22] On autopsy, patients are found to be hypoglycemic but typically have no other pathologic findings. Several theories regarding the etiology of this phenomenon have been proposed, most of which implicate a terminal arrhythmia as a result of a hypoglycemia-induced prolonged QT_c,[23] possibly worsened by undiagnosed autonomic neuropathy.[21] The occurrence of dead in bed syndrome should reinforce to the emergency physician the lethal effects of hypoglycemia and the importance of avoiding hypoglycemia and hypoglycemic unawareness. By seeking consultation from endocrinology for young patients with type 1 diabetes presenting with hypoglycemia or instructing the patient to decrease their insulin dose until they follow up with their endocrinologist, it may be possible to decrease the risk of dead in bed syndrome.

CHAPTER 224

Type 2 Diabetes Mellitus

Mohammad Jalili
Mahtab Niroomand

INTRODUCTION AND EPIDEMIOLOGY

Type 2 diabetes mellitus (T2DM) is a complex, chronic metabolic disorder characterized by hyperglycemia and associated with a relative deficiency of insulin production, along with a reduced response of the target tissues to insulin. It is a major public health issue and an important contributor to morbidity and mortality all over the world.[1] The top three countries with the highest number of diabetic patients are, in decreasing order, India, China, and the United States.[2] Epidemiology is summarized in **Table 224-1**.

T2DM is more common among women than men, and its prevalence increases by age. The prevalence of T2DM among youth is rising dramatically. Investigators attribute this rise to patterns of obesity and lack of physical activity. Native Americans, blacks, and Americans of Mexican or Japanese ethnicity are more commonly affected by T2DM than non-Hispanic whites (**Figure 224-1**).

TABLE 224-1 Epidemiology of Type 2 Diabetes Mellitus (T2DM)

T2DM Epidemiology Fact Sheet
Prevalence of T2DM can vary depending on geography, age, sex, and race/ethnicity.
In up to 30% of the affected people, the disease is undiagnosed.
Prevalence of T2DM is rising globally, with a greater increase in the developing countries.
There is an alarming trend toward increasing prevalence of T2DM among youth.
T2DM patients show a greater risk of mortality than nondiabetic subjects.
Diabetes is the leading cause of blindness, end-stage renal disease, and nontraumatic lower limb amputations.

Diabetes reduces the life expectancy of its victims by approximately 10 years. Mortality and morbidity increase because of increased risk of cardiovascular disease, heart disease and stroke, visual impairment, renal disease, and amputations. The utilization of health care, including emergency care, is higher in patients with diabetes compared with that of nondiabetic subjects. The relative risk is estimated to be 1.23 (95% confidence interval [CI], 1.08–1.39) before the diagnosis and 2.41 (95% CI, 2.18–2.66) after diagnosis is made.[3]

PATHOPHYSIOLOGY

T2DM is a complex heterogeneous metabolic disorder, characterized by chronic elevation of plasma glucose levels. The pathogenesis is complex and involves interaction of both genetic (usually polygenic) and environmental (often lifestyle-related) factors. The most important pathophysiologic features of T2DM are *decreased insulin sensitivity* (insulin resistance) and *impaired insulin secretion* (**Figure 224-2**).

It is generally believed that, in T2DM, fasting hyperglycemia is caused by increased production of glucose by liver, which is not suppressed because of hepatic resistance to insulin action. Normally, after meals, glucose uptake in peripheral tissues increases and glucose production by gluconeogenesis and glycogenolysis decreases. Insulin acts both directly and indirectly to inhibit gluconeogenesis and glycogenolysis. In T2DM, owing to hepatic resistance to insulin, the liver is programmed to both overproduce and underuse glucose.

However, postprandial hyperglycemia results from several mechanisms: abnormal insulin secretion by pancreatic β cells in response to a meal, impaired regulation of hepatic glucose production, and reduced glucose uptake by peripheral tissues, particularly the skeletal muscle, that are insulin sensitive.[4]

Insulin resistance is the diminished tissue response to insulin at one or more sites in the complex pathways of hormone action and requires higher than normal plasma insulin levels to maintain normoglycemia. The major sites of insulin resistance in T2DM are the liver, skeletal muscle, and adipose tissue.

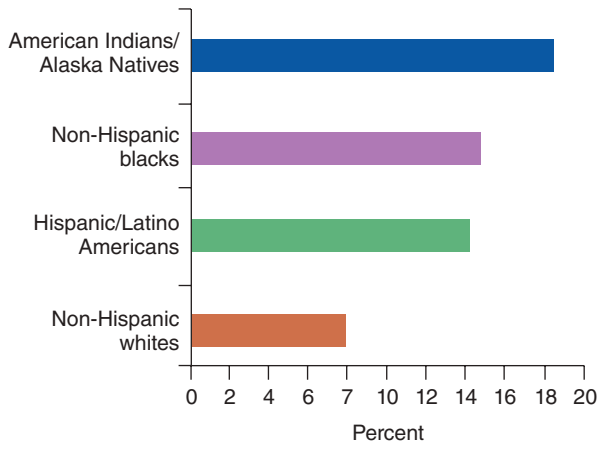

FIGURE 224-1. Estimated age-adjusted total prevalence of diabetes in people age 20 years or older, by race/ethnicity—United States, 2005. [Reproduced from the Centers for Disease Control and Prevention: National diabetes fact sheet: general information and national estimates on diabetes in the United States, 2005. Atlanta, GA: U.S. Department of Health and Human Services, Centers for Disease Control and Prevention, 2005.]

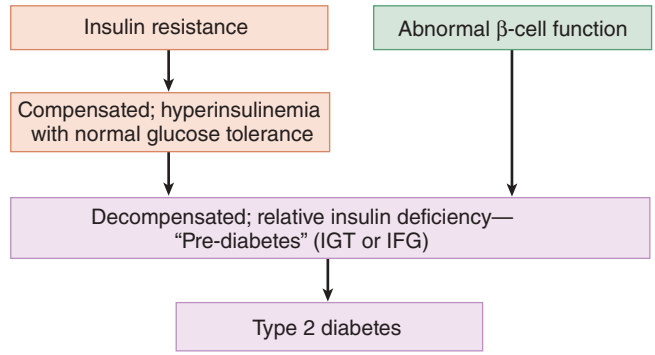

FIGURE 224-2. Pathophysiology of type 2 diabetes mellitus. IFG = impaired fasting glucose; IGT = impaired glucose tolerance.

Insulin secretion is usually impaired and generally insufficient to compensate for insulin resistance.[2] The mechanism behind impaired insulin release in T2DM is complicated and includes glucotoxic and lipotoxic effects, as well as deposition of amyloid within islet cells. *Glucotoxic effect* refers to increased exocytosis of insulin due to increased cytosolic calcium concentration, which occurs when β-cell metabolism of glucose generates adenosine triphosphate that closes adenosine triphosphate–sensitive K^+ channels and leads to depolarization of the membrane and hence opening of voltage-dependent Ca^{2+} channels. Exposure to increased levels of free fatty acid, as frequently found in diabetic patients, may also impair β-cell function, leading to impairment of insulin secretion (lipotoxic effect).[5]

The **incretin hormones** *glucagon-like peptide-1* (GLP-1) and *glucose-dependent insulinotropic polypeptide*, secreted by intestinal L cells following glucose intake, stimulate pancreatic β cells and are responsible for 50% to 70% of total insulin secretion. In people with T2DM, the incretin system is functionally impaired,[6,7] leading to hyperglycemia.

Chronic hyperglycemia is the cornerstone of **microvascular complications**. The causative role of chronic hyperglycemia in the development of **macrovascular complications** is less well defined, and other factors such as dyslipidemia and hypertension that often accompany T2DM may also play an important part in these complications.[8]

The increased prevalence of **infection** is primarily attributed to phagocyte dysfunction, including impaired adherence, chemotaxis, phagocytosis, bacterial killing, and respiratory burst.[9] Other abnormalities include nonenzymatic glycation of immunoglobulins and reduced T-lymphocyte populations.

CLINICAL FEATURES

The classic symptoms, which are usually mild and nonspecific, include fatigue, weakness, polyuria, polydipsia, polyphagia, and blurred vision. Most patients with T2DM are overweight, beyond their 30s, and suffer from other comorbid conditions such as hypertension, cardiovascular disease, dyslipidemia, and polycystic ovary syndrome. Clues in the patient's past medical history that are suggestive of diabetes mellitus include frequent superficial infections and slow healing of skin lesions after minor trauma.

Acute complications include diabetic ketoacidosis, hyperosmolar hypertonic nonketotic state, and hypoglycemia. Diabetic ketoacidosis and hyperosmolar hypertonic nonketotic state are covered elsewhere in this book (see chapters 225 and 227), and hypoglycemia, which in most cases is actually a complication of the treatment of diabetes, is discussed separately at the end of this chapter in the "Hypoglycemia" section.

Chronic complications are categorized as microvascular, macrovascular, and nonvascular complications (**Table 224-2**). One of the chronic complications of diabetes may be the reason for the patient presentation to the ED or may be found during review of systems and physical examination. A brief

TABLE 224-2 Chronic Complications of Type 2 Diabetes Mellitus

Vascular Complications
Microvascular complications

Cataract/glaucoma
Other: Obstructive sleep apnea, depression, fractures, hearing impairment, cognitive impairment, nonalcoholic fatty liver disease and hepatocellular carcinoma, periodontal disease

review of the manifestations of the involvement of various organ systems by diabetes will be presented here.

CARDIOVASCULAR COMPLICATIONS

Diabetes-related atherosclerosis (macrovascular complication) affects all major vascular territories, notably the coronary, cerebral, and peripheral arteries. In individuals with diabetes, the risk of coronary artery disease is two- to fourfold of nondiabetics, and the prognosis is worse than in nondiabetics. Diabetes blunts the cardiovascular benefit of female gender. **"Silent ischemia" (the absence of chest pain despite myocardial ischemia) is common in diabetic patients. It is also common for myocardial infarction to present with atypical or less impressive symptoms such as weakness, fatigue, and confusion.** Patients may suffer from pain in unusual locations or with lower than expected severity. This may explain the increased incidence of medically unrecognized acute myocardial infarction in diabetics compared with nondiabetics (40% vs 25%). The risk of heart failure is increased two to five times in individuals with diabetes (age- and risk factor–adjusted hazard ratio of 1.82 in men and 3.73 in women, according to the Framingham Heart Study). *Diabetic cardiomyopathy* refers to changes in myocardium, distinct from ischemic myocardial injury, which render it more susceptible to ischemia and less able to recover after an ischemic insult.

The incidence of peripheral arterial disease is increased in diabetic patients by a factor of two to four. Diabetes also affects the distribution of atherosclerosis in the lower limb, affecting tibial and peroneal arteries, as well as femoral and popliteal arteries. Claudication, critical limb ischemia and tissue loss, and, finally, amputation are the manifestations of this disorder.

RENAL COMPLICATIONS

Diabetic nephropathy is a major cause of morbidity and mortality. It affects 5% to 40% of patients with T2DM and is present in approximately 7% of the cases at the time of diagnosis. Although this complication is more common in type 1 diabetes, due to the fact that the overwhelming majority of diabetics are type 2, >80% of diabetic patients in renal replacement programs have this form of the disease. Clinically, diabetic nephropathy is characterized as a triad of hypertension, proteinuria (mainly albuminuria), and ultimately renal impairment. Other renal conditions associated with diabetes include urinary tract infections and papillary necrosis. Patients with **renal papillary necrosis** may be asymptomatic and not notice the sloughed papillary tissue excreted in their urine, or they may present with flank pain, hematuria, fever, and chills, symptoms similar to acute pyelonephritis. Urinalysis reveals necrotic fragments of renal papilla, along with red blood cells, white blood cells, and bacteria.

NEUROLOGIC COMPLICATIONS

Diabetics have a threefold increase in the risk of stroke, and diabetes increases the risk of recurrent stroke and stroke-related dementia. Diabetic neuropathy is a set of heterogeneous clinical syndromes, affecting various regions of the nervous system, singly or combined. Clinical manifestations of diabetic neuropathy can be nonspecific and mimic those seen in many other diseases. **Diabetic neuropathy** is a diagnosis of exclusion and should be labeled as such only after other forms of neuropathy, such as chronic inflammatory demyelinating polyneuropathy, B_{12} deficiency, hypothyroidism, and uremia, have been excluded. In most patients, this disorder is silent and goes undetected for long times, and less than half of patients with T2DM will develop symptomatic polyneuropathy in the 10 years after diagnosis. Neurologic disturbances in diabetes have been classified as subclinical neuropathy, diffuse clinical neuropathy, and focal neuropathy. Most common forms of diffuse neuropathies include chronic sensorimotor distal symmetric polyneuropathy and the autonomic neuropathies. Focal neuropathies consist of mononeuropathies and entrapment syndromes.

The most frequent symptoms of neuropathy are burning pain, electrical or stabbing sensations, paresthesia, hyperesthesia, and deep aching pain. Up to half of the patients are asymptomatic, and presence of neuropathy is discovered only on physical examination or when the patient presents with a painless foot ulcer. Physical examination usually reveals that perception of vibration, pressure, pain, and temperature is lost, more commonly in the feet and lower limbs with a symmetric stocking and glove pattern. The most significant morbidity associated with this type of neuropathy is foot ulceration.

Diabetic mononeuropathies usually have a sudden onset and are associated with pain. They may affect a large peripheral nerve such as ulnar, median, peroneal, or medial plantar nerves (as a result of entrapment) or an isolated cranial nerve, especially the third, fourth, or sixth cranial nerve (due to microvascular infarct). It may be difficult in the ED to differentiate the signs and symptoms of diabetic mononeuropathy from a transient ischemic attack or cerebrovascular accident, and imaging and other modalities are needed for diagnosis. The incidence of carpal tunnel syndrome is increased in diabetics.

Autonomic neuropathy may cause dysfunction of every part of the body and represents various clinical entities such as resting tachycardia, exercise intolerance, orthostatic hypotension, diarrhea, constipation, gastroparesis diabeticorum, erectile dysfunction, and neurogenic bladder. **Gastroparesis** is clinically manifested as nausea, vomiting, bloating, and easy satiety. Autonomic diarrhea is defined as at least 3 weeks of increased stool frequency and/or liquidity.

Proximal motor neuropathy with resultant weakness of the proximal muscles of the lower limbs and spontaneous or percussion-provoked muscle fasciculation may also be seen in diabetic patients. This disorder is believed to occur secondary to a variety of other diseases. These diseases are in turn more common in patients with diabetes mellitus than in the general population, and so proximal motor neuropathy may not be a primary component of diabetic neuropathy. Proximal motor neuropathy primarily affects the elderly and may begin, gradually or abruptly, with pain in the thighs and hips or buttocks.

INFECTIOUS COMPLICATIONS

Many common infections (such as pneumonia, soft tissue infections, and urinary tract infections) occur with greater frequency and severity in patients with diabetes. Infectious agents in these cases are usually similar to those seen in the nondiabetic population, but some organisms are more commonly encountered in these patients (*Staphylococcus aureus* and *Mycobacterium tuberculosis* in pneumonia, and *Candida* species in urinary tract infections). Still, there are several rare infections that almost exclusively occur in diabetics. This includes malignant otitis externa, emphysematous cholecystitis and pyelonephritis, and rhinocerebral mucormycosis. **Rhinocerebral mucormycosis** is an invasive fungal infection of the nasal and paranasal sinuses, sometimes

involving the palate and adjacent tissues. The onset is sudden and rapidly progressive. Patients present with periorbital or perinasal pain, blood-tinged nasal discharge, unilateral headache, increased tearing, swelling of eyelids and conjunctiva, and decreased vision. Physical signs can include black eschar on the nasal mucosa or hard palate due to ischemia, proptosis, and, if the infection progresses, cranial nerve involvement or seizures. Patients with **malignant otitis externa** usually present with unilateral otalgia, decreased hearing, purulent ear discharge, and, sometimes, fever. Examination reveals a tender, inflamed external auditory canal with a mass of granular-appearing tissue. The infection can progress and involve the mastoid, temporal bone, or base of the skull, leading to osteomyelitis, meningitis, venous sinus thrombosis, or subdural emphysema. MRI or CT can define the extent of anatomic involvement. This infection is frequently due to *Pseudomonas aeruginosa*, but staphylococci, fungi, and other gram-negative organisms also have been isolated. **Emphysematous cholecystitis** may manifest as fever and abdominal pain. Abdominal radiographs may reveal gas within the gallbladder and biliary tree. Unexplained fever in diabetic patients, with or without abdominal pain, should be evaluated with US to search for cholecystitis. The causative agents are most frequently a *Clostridium* species in addition to streptococci, *Escherichia coli*, and *Pseudomonas*. **Emphysematous pyelonephritis** is a rare, life-threatening infection with gas production in renal parenchyma and around the kidney. Signs and symptoms include fever, clinical toxicity, flank pain, and, sometimes, a palpable mass.

FOOT AND LOWER EXTREMITY COMPLICATIONS

Diabetic foot ulceration results from interaction of many factors, including peripheral neuropathy, excessive plantar pressure, repetitive trauma, peripheral vascular disease, and wound-healing disturbances.[10,11] Ulcers act as a portal of entry for bacteria, resulting in cellulites and abscess formation. Aerobic gram-positive cocci (especially *S. aureus*) are the predominant pathogens in diabetic foot infections. Gram-negative rods may be encountered in patients with chronic wounds or those who have recently received antibiotic therapy. Those with foot ischemia or gangrene may be infected with obligate anaerobic microorganisms.[12]

Foot complaints in a diabetic require a thorough foot examination. Ulcer characteristics, including dimensions, depth, appearance (erythema, swelling, and purulence), and location, should be described. Hair and nail growth, calluses, corns, foot deformities, sensation, and vascular status (palpation of pedal and popliteal pulses) should be assessed. It is sometimes difficult to distinguish between lower extremity ulcers resulting from vascular insufficiency and those due to diabetes. **Venous ulcers** are typically present above the malleoli with irregular borders. **Arterial ulcers** are often found on the toes or the shins, with pale, "punched-out" borders. These ulcers are typically painful in the absence of coexisting neuropathy. **Diabetic ulcers**, on the other hand, usually occur at areas of increased pressure (e.g., sole of the foot) or friction (due to footwear).[13] **Any ulceration found should be unroofed and probed using a blunt-ended rigid sterile probe to determine the depth.** The ability to probe to bone through the ulcer suggests the strong possibility of osteomyelitis and deep-space soft tissue infection. Purulence or inflammation suggests infection, and both aerobic and anaerobic cultures should be taken from purulent drainage or material curetted from the base of the wound. Such specimens are preferable to wound swab specimens, which are often contaminated with colonizing bacteria and often do not identify the infected organism(s).

The diagnosis of **osteomyelitis** in patients with diabetic foot ulcer remains a challenge. When the wound can be probed to the underlying bone, presence of osteomyelitis is almost certain. Radiographs, although not very sensitive, should be obtained in patients with deep or long-standing ulcers to exclude osteomyelitis, subcutaneous gas, foreign bodies, and Charcot joints. MRI can identify osteomyelitis if radiographs are negative but clinical suspicion is high. **Table 224-3** shows the diagnostic utility of physical examination, laboratory, and basic radiographic testing in the diagnosis of osteomyelitis in patients with diabetic foot ulcer.

TABLE 224-3 Diagnostic Accuracy of Physical Examination, Laboratory, and Imaging Investigations for Lower-Extremity Osteomyelitis in Patients with Diabetic Foot Ulcers*

Finding	Positive LR (95% CI)	Negative LR (95% CI)
Ulcer area >2 cm^2	7.2 (1.1–49)	0.48 (0.31–0.76)
Positive "probe-to-bone" test	6.4 (3.6–11)	0.39 (0.20–0.76)
Erythrocyte sedimentation rate (with a cutoff of 70 mm/h)	11 (1.6–79)	0.34 (0.06–1.90)†
Plain radiograph	2.3 (1.6–3.3)	0.63 (0.51–0.78)
MRI	3.8 (2.5–5.8)	0.14 (0.08–0.26)

Abbreviations: CI = confidence interval; LR = likelihood ratio.

*Bone biopsy is considered the gold standard.

†95% CI crosses 1.0.

OPHTHALMOLOGIC COMPLICATIONS

Ocular complications of diabetes are summarized in **Figure 224-3**.

Retinopathy is divided into proliferative and nonproliferative forms. In the nonproliferative stage, changes in retinal vessels (vasodilation, microaneurysm formation, and leakage) occur and lead to accumulation of lipid in the outer plexiform layer (hard exudates) and hemorrhage in different layers of the retina (flame-shaped hemorrhage in the nerve fiber layer; dot-and-blot hemorrhage in deeper layers of the retina). Microinfarctions of the retina result in cotton-wool spots (soft exudates). In severe forms of the nonproliferative stage, venous tortuosity and beading occur. The proliferative stage is characterized by formation of new abnormal blood vessels (neovascularization) across the retinal surface and optic disc. These fragile new blood vessels may bleed into the vitreous, causing a vitreous hemorrhage. **Ocular hemorrhage in diabetic retinopathy after thrombolytic therapy is extremely uncommon,[14] and retinopathy should not be considered a contraindication. The indications and potential complications of thrombolytic therapy should be discussed with the patient before its administration.** Neovascularization can also affect the iris (rubeosis iridis), leading to severe glaucoma. Traction retinal detachment may result from contraction of the fibrous tissue that accompanies neovascularization.

Other ocular manifestations of diabetes include recurrent styes, blepharoconjunctivitis, and xanthelasma, fatty deposits in the subcutaneous tissue of the lids. Impaired corneal sensitivity can predispose to bacterial corneal ulcers, neurotropic ulcers, and difficulties with contact lenses. Cataracts and open- and narrow-angle glaucoma are more common in diabetics.

DERMATOLOGIC COMPLICATIONS

Skin manifestations of diabetes generally appear in patients with known diabetes, but they may also be the first presenting sign of diabetes or even precede the diagnosis by many years.[15] Protracted wound healing and skin ulcerations are the most common skin manifestations. Dermatologic complications of diabetes can be grouped as noninfectious (such as acanthosis nigricans, necrobiosis lipoidica, diabetic dermopathy, scleredema, and granuloma annulare), infectious (e.g., erythrasma, necrotizing fasciitis, and mucormycosis), and resulting from treatment of diabetes (e.g., lipoatrophy, lipohypertrophy, and various skin reactions as adverse effects of oral antidiabetics).

Common infections include cellulitis, furuncles and carbuncles, and candidiasis. Serious infections usually develop due to the combination of poorly controlled serum glucose, vascular insufficiency, and tissue hypoxia. Serious and rapidly progressive infections in diabetics include **necrotizing fasciitis** and **Fournier's gangrene**. See chapter 152, "Soft Tissue Infections" for further discussion. **Table 224-4** summarizes the cutaneous manifestations of diabetes.

PRINCIPLES OF EVALUATION

Look for diabetes in the presence of symptoms suggestive of hyperglycemia, detailed above, in the undiagnosed diabetic. It is reasonable to check the glucose level in patients with certain presentations such as

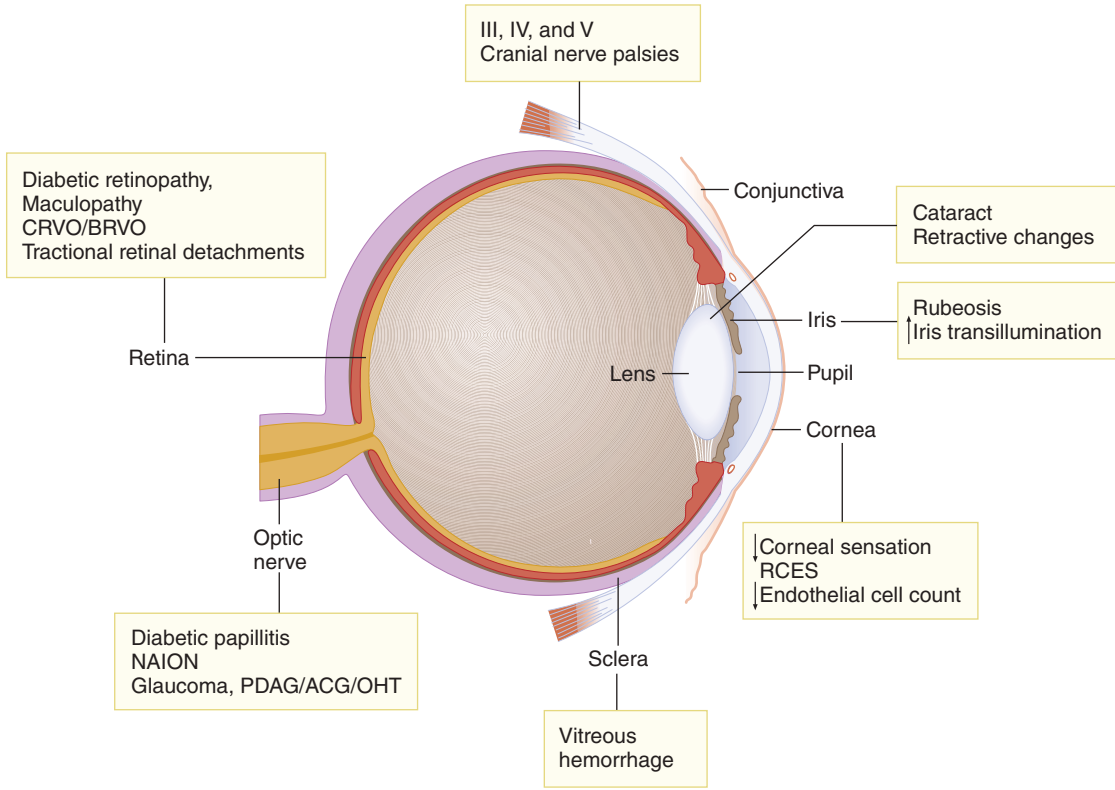

FIGURE 224-3. Common eye abnormalities in diabetes. ACG = angle-closure glaucoma; BRVO = branch retinal vein occlusion; CRVO = central retinal vein occlusion; NAION = nonarteritic ischemic optic neuropathy; OHT = ocular hypertension; POAG = primary open-angle glaucoma; RCES = recurrent corneal erosion syndrome.

unexplained cellulitis, foot ulcers, frequent candidal infections, and unexplained neuropathy.

When evaluating a patient with established diabetes mellitus in the ED, in addition to complaint-directed history and physical examination, special attention can be given to diabetes-related aspects. Assessment can include questions about prior diabetes care, presence or absence of diabetes complications and diabetes-related comorbidities, and assessment of the patient's knowledge about the disease. Elements of the history and physical examination relative to T2DM are presented in **Tables 224-5 and 224-6**.

TABLE 224-4 Cutaneous Manifestations of Diabetes Mellitus

Noninfectious	
Acanthosis nigricans	Hypertrophic, hyperpigmented, velvety plaques in body folds such as the neck, axillae, and groin.
Diabetic dermopathy ("shin spots")	Four to five dull red macules or papules, 5–12 mm in diameter, predominantly on the lower extremities, with a hyperpigmented scar.
Necrobiosis lipoidica	Oval violaceous patch with a red border and a yellow-brown central area, which then atrophies; prominent telangiectasias; may ulcerate.
Scleredema adultorum of Buschke	Asymmetric nonpitting induration of the skin, predominantly on the posterolateral aspects of the neck, shoulders, and upper back.
Granuloma annulare	A ring of small, firm, flesh-colored or red papules, most frequently found on the lateral or dorsal surfaces of the hands and feet.
Yellow skin (carotenodermia)	Skin of patients with diabetes may appear yellowish, secondary to deposition of carotenoids in the elastic tissue of the skin.
Diabetic bullae	Unilateral or bilateral tense, serous blisters of varying sizes from 0.5–3.0 cm, on the planter surfaces and margins of the feet.
Acrochordons (skin tags)	Soft tissue fibromas with a predilection for eyelids, neck, and axilla.
Infectious	
Necrotizing fasciitis	Typically of mixed bacterial origin, most common organisms: *Streptococcus pyogenes, Staphylococcus aureus,* anaerobic streptococci, and *Bacteroides.*
Malignant external otitis	Tenderness of the pinna and periauricular area, swollen external auditory canal, purulent discharge; *Pseudomonas aeruginosa.*
Erythrasma	Pruritic red-brown patch in the axilla or groin; *Corynebacterium minutissimum.*
Rhinocerebral mucormycosis	Fever, facial cellulitis, periorbital edema, proptosis, and blindness, facial numbness, black eschar in nasal mucosa or palate; mortality up to 50%.
Complications of diabetes treatment	
Lipoatrophy	Loss of subcutaneous fat at the insulin injection site.
Lipodystrophy	Localized hypertrophy of subcutaneous fat.
Skin reaction to oral hypoglycemic agents	Pruritus, erythema multiforme, erythema nodosum, urticaria, morbilliform rash, lichenoid eruptions, and photosensitivity.

TABLE 224-5 Elements of the Medical History in Patients with Type 2 Diabetes Mellitus

Key Elements of Medical History	
Past medical history	Cardiovascular disease, hypertension, dyslipidemia, foot lesion, ophthalmologic diseases, nephropathy, neuropathy, cerebrovascular disease
Prior diabetes care	Type of treatment and recent changes in the regimen; prior glycated hemoglobin A levels; blood sugar self-monitoring results; frequency, severity, and cause of hyper- or hypoglycemic episodes; diet and exercise history
Drug history	Oral hypoglycemic agents, insulin, diuretics, β-adrenergic agonists, β-adrenergic blockers
Social history	Smoking, substance abuse
Review of systems	Skin: dryness, pruritus, color changes, ulcers Weight loss GI: constipation, diarrhea, nausea, gastric fullness GU: urinary retention/incontinence, changes in amount of urine, and sexual dysfunction (impotence) Visual changes Numbness, dizziness, and weakness Chest pain

DIAGNOSIS

Diagnosis of diabetes can be done in three ways: by a fasting plasma glucose; a random glucose; or 2 hours after an oral glucose tolerance test (OGTT). An oral glucose tolerance test is reserved for patients in whom diabetes is strongly suspected despite a normal or impaired fasting glucose.[16] A hemoglobin A_{1c} (HbA_{1c}) level ≥6.5 can also diagnose diabetes, and HbA_{1c} is used to monitor the effectiveness of treatment.

Current criteria for the diagnosis of diabetes are summarized in **Table 224-7**. Impaired fasting glucose and impaired glucose tolerance are usually referred to as *prediabetes* and denote hyperglycemia not sufficient to meet diagnostic criteria for diabetes but significant for being risk factors for future diabetes and for cardiovascular disease.[17]

TREATMENT

Treatment of T2DM can be discussed under three topics: the day-to-day prevention of hyperglycemia (long-term management of hyperglycemia); prevention and management of chronic complications; and acute therapy of severe hyperglycemia and life-threatening metabolic decompensation (i.e., hyperosmolar hypertonic nonketotic state and diabetic ketoacidosis). Diabetic ketoacidosis and hyperosmolar hypertonic nonketotic state are discussed elsewhere in this book (see chapters 225 and 227, respectively).

TABLE 224-6 Elements of the Physical Examination in Patients with Type 2 Diabetes Mellitus

Key Elements of Physical Examination	
General	Height, weight, and body mass index
Vital signs	Blood pressure (including orthostatic measurement)
Head, eye, ear, nose, and throat examination	Funduscopy (to look for hemorrhage or proliferative retinopathy); visual acuity; intraocular pressure; thyroid palpation
Skin	Intertriginous areas (to look for acanthosis nigricans), insulin injection sites, lancet puncture sites, nonhealing wounds, cellulitis, tinea
Cardiovascular	Auscultation of the carotid arteries and abdomen for bruits; assessment of peripheral pulses (especially dorsalis pedis and posterior tibial pulses)
Foot examination	Signs of skin breakdown on the feet, signs of infection, determination of proprioception and vibration, monofilament sensation, presence/absence of patellar and Achilles reflexes

TABLE 224-7 Diagnostic Criteria for Diabetes

Test	Impaired Fasting Glucose (milligrams/dL)	Impaired Glucose Tolerance (milligrams/dL)	Diabetes* (milligrams/dL)
Fasting plasma glucose†	100–125 (5.5–6.9 mmol/L)	—	≥126 (≥6.9 mmol/L)
2-h OGTT	—	140–199 (7.8–11 mmol/L)	≥200 (≥11 mmol/L)
Random‡ plasma glucose concentration	—	—	≥200 (≥11 mmol/L) plus symptoms of diabetes#
$HgbA_{1c}$	5.7–6.4%		≥6.5%

Abbreviations: $HgbA_{1c}$ = hemoglobin A_{1c}; OGTT = oral glucose tolerance test (75-gram glucose load).

*In the absence of unequivocal symptoms of hyperglycemia, these criteria should be confirmed on a subsequent day.

†Fasting is defined as no caloric intake for at least 8 hours.

‡Random is defined as any time of the day without regard to time since last meal.

#The classic symptoms of hyperglycemia include polyuria, polydipsia, and unexplained weight loss.

The American Diabetes Association recommends that the goal of treatment in nonpregnant adults should be an HbA_{1c} value <7%. Other guidelines, such as that of the American College of Endocrinology, have recommended lower levels.[17] With respect to fasting, premeal, and postprandial targets, the American Diabetes Association suggestions are summarized in **Table 224-8**.[18]

NEWLY DIAGNOSED DIABETIC IN THE ED

The consensus statement on management of T2DM by the American Diabetes Association and the European Association for the Study of Diabetes recommends metformin in combination with lifestyle changes, as well as timely augmentation of therapy with additional agents (including other oral antidiabetic agents and insulin) to achieve recommended levels of glycemic control. This should be done in conjunction with the control of the symptoms of acute hyperglycemia and treatment of the underlying or exacerbating conditions. **Metformin can be safely initiated at a dose of 500 milligrams per day for patients whose T2DM has been newly diagnosed in the ED, provided that the serum creatinine level is ≤1.4 milligrams/dL.** The dose can be increased as needed in 500-milligram increments each week to a maximum of 2 grams per day. If admission is not warranted and exacerbating factors have been sought and effectively addressed, however, the initiation of pharmacotherapy can also be left to the primary care physician at 24- to 48-hour follow-up.

ACUTE THERAPY OF SEVERE HYPERGLYCEMIA

Acute hyperglycemia is defined as a blood glucose level of >300 milligrams/dL (>16.7 mmol/L). In this situation, the patient may have excessive urine output, weight loss, fatigue, blurred vision, or prominent neuropathic symptoms. Older patients may develop volume depletion, with acute mental status changes, hypovolemic shock, and acute renal insufficiency. Common precipitants include drug interaction with glucose-altering

TABLE 224-8 Glycemic Goals

Parameter	American Diabetes Association Recommended Target
Premeal plasma glucose	70–130 milligrams/dL (3.8–7.2 mmol/L)
Postprandial plasma glucose	<180 milligrams/dL (<10 mmol/L)
Hemoglobin A_{1c}	<7.0%

medications (most commonly, corticosteroids, sympathomimetics, diuretics, anticonvulsants, salicylates, and β-adrenergic receptor agonists), infections, acute illnesses such as acute coronary syndrome or CNS ischemia, or changes in or noncompliance with the prescribed drug regimen. Volume repletion, IV regular insulin, correction of electrolyte imbalance, and specific therapies directed toward any identified underlying cause of hyperglycemia are the components of treatment.

Regular human insulin is administered IV because absorption of SC insulin in a volume-depleted patient can be erratic. SC administration of insulin in non–volume-depleted patients is acceptable. Insulin lispro is an excellent alternative to regular human insulin. However, insulin lispro does not currently have U.S. Food and Drug Administration approval for IV administration, although many clinicians do use it. Typically, an initial bolus dose of 0.1 to 0.15 unit/kg IV or SC of regular human insulin or insulin lispro is given, which may be repeated in 1 to 2 hours if glucose levels have not fallen at least 50 milligrams/dL (2.8 mmol/L).

Patients should have a rapid therapeutic response to insulin, and, with improved glycemic control, many patients may become more responsive to oral therapies and may be able to switch to oral agents alone after using insulin initially. When initial therapy with insulin can be discontinued because of recovery from an acute illness or marked improvement of metabolic control, a standard oral therapy approach may be instituted.

MANAGEMENT OF HYPERGLYCEMIA IN ED OBSERVATION OR ED BOARDING

With many admitted patients boarding in the ED for longer periods, EPs frequently encounter patients with random blood glucose of 140 mg/dL (7.8 mmol/L) or higher on routine lab tests. The patient may or may not be a known diabetic. Stress and decompensation of diabetes may contribute to the pathophysiology of this problem, or it may be iatrogenic, resulting from either inadvertent cessation of antihyperglycemic medications or administration of hyperglycemia-inducing drugs such as glucocorticoids or vasopressors. Whatever the mechanism, emergency physicians may be called upon to control the patient's blood glucose. There is some evidence that in patients who are later admitted, paying careful attention to high blood glucose levels in the ED leads to better glycemic control in the hospital.

In critically ill patients, insulin infusion is usually required. The goal is to maintain blood glucose in the range of 140 to 180 mg/dL (7.8 to 10 mmol/L). More stringent control (with blood glucose <110 mg/dL [<6 mmol/L]) may actually increase mortality and is not recommended.

In patients who are not in a critical condition, subcutaneous insulin with a premeal glucose target of less than 140 mg/dL (7.8 mmol/L) and random blood glucose of less than 180 mg/dL (10 mmol/L) is recommended. In most patients with T2DM admitted for an acute illness, oral hypoglycemic agents should be discontinued and insulin substituted. However, writing orders for sliding scale insulin for admitted patients can lead to undesirable levels of hypoglycemia and hyperglycemia. Sliding scale insulin should not be used for more than 12 to 24 hours, and scheduled subcutaneous insulin therapy, consisting of basal (long- or intermediate-acting) insulin, in combination with bolus/prandial (rapid- or short-acting) insulin, should be substituted. A total dose of 0.2 to 0.5 U/kg/d is usually required based on the age and renal function of the patient. Half of this dose is administered as basal once or twice a day, and the remaining is given in three equally divided doses before each meal (only if the patient is eating). If the desired target blood glucose is not achieved, correction insulin should also be added to the scheduled insulin regimen.[19]

DISPOSITION AND FOLLOW-UP

Guidelines for admission considerations are listed in **Table 224-9**. Diabetic patients may need admission for conditions that in nondiabetics are usually treated on an outpatient basis.

Patients who present with new-onset T2DM without evidence of metabolic decompensation, acute hypoglycemia, or hyperglycemia and do not meet the aforementioned criteria for admission should see their primary care provider within 24 to 48 hours as a general rule to arrange for education, dietary evaluation, and initiation or refinement of appropriate therapy for glycemic control. Metformin can be safely initiated at a dose of 500 milligrams/d for patients whose T2DM has been newly diagnosed in the ED, provided that the serum creatinine level is ≤1.4 milligrams/dL. General discharge instructions for all diabetic patients, new or established, are detailed in **Table 224-10**.

TABLE 224-9 Disposition/Guidelines for Hospital Admission

Inpatient care for type 2 diabetes mellitus is generally appropriate for the following clinical situations:
Life-threatening metabolic decompensation such as diabetic ketoacidosis or hyperglycemic hyperosmolar nonketotic state
Severe chronic complications of diabetes, acute comorbidities, or inadequate social situation
Hyperglycemia (>400 milligrams/dL [>22 mmol/L]) associated with severe volume depletion or refractory to appropriate interventions
Hypoglycemia with neuroglycopenia (altered level of consciousness, altered behavior, coma, seizure) that does not rapidly resolve with correction of hypoglycemia
Hypoglycemia resulting from long-acting oral hypoglycemic agents
Fever without an obvious source in patients with poorly controlled diabetes

ANTIDIABETIC PHARMACOTHERAPY

There are five classes of antidiabetic agents: insulin and four classes of oral antidiabetic agents. Oral agent classification is based on mechanism of action: agents that cause insulin sensitization primarily in the liver, agents that cause insulin sensitization primarily in peripheral tissues, agents that promote secretion of insulin, and agents that slow the absorption of carbohydrates (**Tables 224-11 and 224-12**). Combined formulations are available that mix drugs from different classes of antihyperglycemic agents (metformin plus a thiazolidinedione or a secretagogue).

METFORMIN

Metformin is the only biguanide available in the United States (phenformin and buformin, other drugs of this class, are still available in some countries). Its precise mechanism of action is unknown. It has been suggested that metformin activates adenosine monophosphate–activated protein kinase and hence reduces hepatic insulin resistance. The resulting effect is decreased gluconeogenesis and glucose production in the liver. Some effect on improving insulin sensitivity in peripheral tissues has inconsistently been suggested. Metformin is usually started at a dose

TABLE 224-10 Discharge Instructions and Follow-Up Care

Follow a healthy diet.
Self-monitor blood glucose regularly.
Take insulin or oral hypoglycemic agents as directed.
Reduce weight where appropriate.
Cease smoking where appropriate.
Exercise regularly in the absence of contraindications, such as foot ulcers.
Practice good general foot care (check regularly for minor trauma and hot spots, keep nails trimmed properly, and wear well-fitted shoes). Wear a Medic-Alert bracelet or necklace.
Be able to recognize symptoms of high blood sugar, such as frequent urination, thirst, dizziness, headache, nausea or vomiting, abdominal pain, lethargy, or blurry vision.
Be able to recognize symptoms of low blood sugar, including fatigue, headache, drowsiness, agitation, pale or moist, visual changes, or loss of consciousness.
Know how to help yourself or others with low blood sugar by self-administering or giving an awake person (who can swallow without gagging or choking) candy, fruit juice, or sugar or by calling an emergency phone number (e.g., 911) if the affected person is not able to respond.

TABLE 224-11 Oral Antidiabetic Agents' Classification According to Their Mechanism of Action

Mechanism of Action	Class	Examples
Insulin sensitizers with primary action in the liver	Biguanides	Metformin
Insulin sensitizers with primary action in peripheral tissues	Thiazolidinediones (glitazones)	Pioglitazone, rosiglitazone
Insulin secretagogues	Sulfonylureas	Glyburide, chlorpropamide, glipizide
	Glinides	Repaglinide, nateglinide
Carbohydrate absorption slowing agents	α-Glucosidase inhibitors	Acarbose, miglitol

of 500 milligrams once daily (with a meal) and can be titrated upward slowly to a maximum dose of 2 grams/d. Due to its short duration of action, metformin is generally taken at least twice daily. The most common adverse effects are GI: nausea, diarrhea, crampy abdominal pain, metallic taste, and dysgeusia. **Another rare side effect of metformin is lactic acidosis, which almost exclusively occurs in patients with renal insufficiency. Metformin is eliminated by the kidney in unchanged form and so is contraindicated in patients with an estimated glomerular filtration rate of <40 mL/min.** In those with a glomerular filtration rate between 40 and 60 mL/min, half the recommended dose should be given. Because metformin does not increase insulin levels, it is not associated with a significant risk of hypoglycemia. Other contraindications include congestive heart failure requiring drug therapy, hepatic insufficiency, any form of acidosis, severe hypoxemia, and alcohol abuse. **Take care when administering metformin simultaneously with nephrotoxic agents such as contrast dye. Withhold metformin for 48 hours *after* IV contrast administration.**

GLITAZONES

Glitazones (thiazolidinediones) work through binding and modulation of the activity of peroxisome proliferator-activated receptors. This nuclear receptor influences the differentiation of fibroblasts into adipocytes and lowers free fatty acid levels. Thus, thiazolidinediones improve insulin sensitivity and reduce free fatty acid levels. Pioglitazone and rosiglitazone have replaced the first drug of this class, troglitazone, because they are believed to be safer. thiazolidinediones are well tolerated, and their only significant adverse effects are weight gain and fluid retention. Liver function should be assessed before beginning thiazolidinedione therapy. This class of drugs is contraindicated in the presence of active hepatocellular disease and in patients with unexplained serum alanine aminotransferase levels >2.5 times the upper limit of normal. Thiazolidinediones can affect bone turnover in animals, and an observational study has recently shown bone loss in older female diabetics who are treated with thiazolidinediones.[20] Thiazolidinediones may lead to macular edema, as well as increased risk of bone fracture and bladder cancer.[21]

SULFONYLUREAS

Sulfonylureas are the oldest class of oral antidiabetic agents.[3] They bind to the sulfonylurea receptor, a subunit of the adenosine triphosphate–sensitive potassium channel on plasma membrane of pancreatic β cells, causing a series of reactions, thereby leading to insulin secretion (exocytosis of insulin granules). Drugs in this class can be divided into first- and second- generation agents. First-generation sulfonylureas include chlorpropamide, tolbutamide, tolazamide, and acetohexamide. The second generation of this class includes drugs with higher potency and fewer adverse effects and drug–drug interactions (namely, glipizide, glyburide, gliclazide, and glimepiride). **Hypoglycemia** is the major adverse effect of sulfonylureas (highest risk seen with glyburide), and other side effects like allergic reactions, GI intolerance, hyponatremia, or alcohol flushing are very rare and drug dependent.[3]

REPAGLINIDE

Repaglinide is an insulin secretagogue, structurally distinct from the sulfonylureas. It binds to pancreatic β cells and stimulates insulin release. Repaglinide is absorbed more rapidly and so produces faster and briefer stimulus to insulin secretion. However, it has a prolonged effect on fasting glucose. The maximum dose of this drug is 2 milligrams taken with each meal. Repaglinide has an almost completely biliary elimination, and therefore, it can be used safely in patients with renal insufficiency.

NATEGLINIDE

Nateglinide, a phenylalanine derivative, has an even shorter duration of action than repaglinide. It has a specific effect on postprandial glucose and almost no effect on fasting glucose. This drug is used as 120-milligram tablets taken with each meal.

ACARBOSE AND MIGLITOL

Acarbose and miglitol inhibit the final step of carbohydrate digestion at the brush border of intestinal epithelium through competitive inhibition of α-glucosidases. This action delays the absorption of carbohydrates and consequently decreases the postprandial glucose peak and insulin response to the meal. They have only a modest effect on blood glucose reduction and commonly cause flatulence. Their advantage is lowering postprandial glucose without increasing weight or hypoglycemic risk.

TABLE 224-12 Some Properties of Classes of Antihyperglycemic Agents

Parameter	Secretagogues	Metformin	a-Glucosidase Inhibitors	Thiazolidinediones	Insulin
Mechanism of action	Potentiate insulin secretion	Suppresses liver glucose production	Delay intestinal carbohydrate absorption	Improve insulin sensitivity (fat, liver, and muscle)	Suppresses glucose production; enhance glucose uptake
Hemoglobin A_{1c} reduction (%)	1.5–2.0	1.5–2.0	0.5–1.0	0.75–2.0	Limited by hypoglycemia only
Adverse effects	Hypoglycemia, weight gain	Nausea, diarrhea, lactic acidosis	Flatulence, diarrhea	Edema, congestive heart failure, weight gain, anemia	Hypoglycemia, weight gain
Nonglycemic effects	None	Reduces CV risk markers; limits weight gain	Reduce CV risk markers	Reduce CV risk markers	Reduces CV risk markers
Evidence for benefit					
Microvascular	Strong	Strong	None	None	Strong
Macrovascular	None	Moderate	Weak	Weak	Moderate

Abbreviation: CV = cardiovascular.

INSULIN

Decreased secretion of insulin due to declining β-cell function eventually makes oral antidiabetic agents ineffective in achieving glycemic control and leads to the need for insulin therapy. Insulin can be used to supplement endogenous production of insulin both in the basal and postprandial state. Traditionally, insulin has been used for the treatment of T2DM when nutritional therapy and oral agents have failed to control blood glucose levels. There is, however, an increasing trend toward the initiation of insulin at an earlier stage of the disease. Besides when therapy with oral agents fails to achieve the glycemic target, insulin may be used in the treatment of T2DM in several other situations: during the perioperative period in a diabetic patient, for treatment of acute hyperglycemic crises, and even as the initial therapy in severe hyperglycemia. There are several formulations of insulin available, with different pharmacokinetics. See chapter 223, "Type 1 Diabetes Mellitus" for detailed discussion of insulins.

INCRETIN ANALOGUES

In humans, *glucagon-like peptide*, GLP-1, mediates the process by which oral glucose has a greater stimulatory effect on insulin secretion than parenteral glucose (the so-called *incretin effect*). GLP-1, among other antihyperglycemic actions, enhances endogenous insulin secretion in response to oral caloric intake. GLP-1 analogues (also referred to as *incretin analogues* or *incretin mimetics*) are used in the treatment of diabetes. An important feature of incretin-related therapies is that this class of drugs increases insulin secretion only in the presence of hyperglycemia. **Exenatide** (Byetta™) is a synthetic peptide with 53% amino acid similarity to GLP-1 and is indicated for therapy of T2DM patients who do not achieve adequate glycemic control on metformin, sulfonylurea, thiazolidinedione, or a combination of the two. Exenatide may be used with metformin or in combination with both metformin and a sulfonylurea.[22,23] It has also been used in combination with insulin to enhance glycemic control. Exenatide exerts its HbA_{1c}-lowering and weight reduction effects through several mechanisms: It suppresses glucagon secretion, slows gastric emptying, reduces food intake, and promotes β-cell proliferation. Exenatide is administered at a dose of 5 to 10 micrograms twice daily as SC injection in the abdomen, thigh, or arm. Dose adjustment is necessary in patients with end-stage renal failure (creatinine clearance of <30 mL/min). It is contraindicated in the presence of medullary thyroid cancer.

Liraglutide (Victoza®) is a GLP-1 receptor agonist that is injected at a dose of 0.6 to 1.2 milligrams once a day, so some prefer it over exenatide. It is contraindicated in the presence of medullary thyroid cancer or in those with multiple endocrine neoplasia. Pancreatitis is a reported adverse effect.

Dipeptidyl peptidase IV inhibitors are a distinct yet similar class of medications. These agents prolong the action of native GLP-1 by inhibiting its metabolism by dipeptidyl peptidase IV. They are administered orally. Saxagliptin, sitagliptin, and vildagliptin are available preparations. A safety alert was issued for saxagliptin in February 2014 due to possible association with heart failure.

AMYLIN ANALOGUES

Amylin is a neuroendocrine peptide that is normally cosecreted with insulin from the pancreatic β cells. It has a complementary action for insulin in regulating plasma glucose. In T2DM, secretion of amylin diminishes and is delayed in advanced stages of the disease. Pramlintide is the synthetic analogue of amylin with several metabolic effects: It (1) suppresses endogenous secretion of glucagon, especially in the postprandial state, thereby decreasing postprandial hepatic glucose production; (2) reduces the rate of gastric emptying; (3) decreases appetite and induces satiety; and (4) reduces postprandial glucose levels.[24] **Pramlintide** is used as a 120-microgram SC injection at mealtime in patients with type 1 diabetes as well as patients with T2DM who are treated with insulin, but who are very vigilant with insulin dosage and blood glucose monitoring. It carries a Food and Drug Administration black box warning; if given with insulin therapy, it can induce severe hypoglycemia, especially within 3 hours of insulin administration.

PREVENTION AND MANAGEMENT OF CHRONIC COMPLICATIONS

Emergency physicians can reinforce patient education and provide access to additional resources as necessary (**Table 224-13**). Interventions that may be initiated or augmented in the ED for chronic complications are briefly discussed below.

CARDIOVASCULAR COMPLICATIONS

Angiotensin II receptor blockers and angiotensin-converting enzyme inhibitors are the preferred antihypertensive agents in patients with T2DM. Although β-blockers may potentially mask hypoglycemic symptoms, they are safe in most patients with diabetes. Central adrenergic antagonists and α-adrenergic blockers may worsen orthostatic hypertension in those with autonomic neuropathy. For treatment of hypertension in diabetic patients, nondihydropyridine calcium channel blockers (i.e., verapamil and diltiazem) are preferred over the dihydropyridine group (i.e., amlodipine and nifedipine).

When acute coronary syndrome occurs in the setting of diabetes, the management is very much the same as in nondiabetic patients. Although proliferative retinopathy is considered a relative contraindication to thrombolytic therapy by some, the risk of intraocular bleeding is thought to be very low.[14]

RENAL COMPLICATIONS

Angiotensin-converting enzyme inhibitors are effective in preventing and slowing the progression of diabetic nephropathy, regardless of their effect on blood pressure. In addition, they can reduce major cardiovascular disease outcomes in patients with diabetes.

NEUROLOGIC COMPLICATIONS

A number of pharmacologic agents are effective for the symptomatic treatment of painful polyneuropathies: cyclics (e.g., amitriptyline, nortriptyline, and imipramine), anticonvulsants (gabapentin, carbamazepine, pregabalin), topical capsaicin (a substance P inhibitor), and duloxetine. Among these drugs, pregabalin and duloxetine have Food and Drug Administration indication for treatment of painful diabetic neuropathy (**Table 224-14**).

Several interventions can improve the quality of life but do not affect the underlying pathology or natural history of the disease process. Dietary modifications and prokinetic agents (e.g., metoclopramide, erythromycin), which decrease gastric emptying time, may improve symptoms of gastroparesis. Treatments for erectile dysfunction include phosphodiesterase type 5 inhibitors, such as sildenafil, and intracorporal or intraurethral prostaglandins[5] (**Table 224-15**).

VACCINATION

For patients with diabetes, vaccinations are recommended, according to the Centers for Disease Control and Prevention Advisory Committee on Immunization Practices (http://www.cdc.gov/vaccines/recs), against influenza annually in the fall and at least once with the pneumococcal polyvalent vaccine. Repeat pneumococcal vaccination is indicated for patients 65 years of age or older provided that their initial vaccination was administered >5 years ago and also in the setting of nephrotic syndrome, chronic renal disease, and other immunocompromised states, such as after transplantation.[17]

LOWER EXTREMITY AND FOOT COMPLICATIONS

From a clinical standpoint, foot ulcers can be classified as non–limb-threatening, limb-threatening, or life-threatening infections. Non–limb-threatening infection is defined as one that is small (<2 cm of surrounding cellulitis or inflammation), does not involve deep structures or bone, and is the result of recent injury to a well-perfused limb. The patient has no signs of systemic toxicity or leukocytosis. Limb-threatening infections are characterized by the presence of >2 cm of

TABLE 224-13 American Diabetes Association Recommendations for Prevention and Management of Diabetes Complications

Risk Factor/Complication	Screening	Treatment
Blood pressure control	Blood pressure should be measured at every routine diabetes visit.*	If 120 ≤ SBP ≤ 139 and DBP ≤80, start lifestyle therapy. If SBP ≥140 or DBP ≥80 (confirmed on 2 separate days), begin pharmacologic (ACEI or ARB) plus lifestyle therapy.
Lipid management	Fasting lipid profile should be measured at least annually.	Lifestyle modifications recommended for all patients. For diabetics: With overt CVD† Age >40 y old and one or more other CVD risk factors† With low-density lipoprotein >100 milligrams/dL Start statin therapy.
Smoking	—	Smoking cessation recommended for all patients.
CVD	—	Treat risk factors (as above). Antiplatelet therapy in diabetic patients with: History of CVD 40 y of age or more Additional risk factors‡
Nephropathy	Annual assessment of urine albumin excretion and serum creatinine	Optimize glucose and blood pressure control. ACEI or ARB in case of microalbuminuria Reduction of protein intake in case of chronic kidney disease
Retinopathy	At diagnosis and annual comprehensive eye examination	Optimize glucose and blood pressure control. Prompt referral of patients with any level of macular edema, severe nonproliferative diabetic retinopathy, or any proliferative diabetic retinopathy; laser photocoagulation therapy in selected patients
Neuropathy	At diagnosis and annual screening for distal symmetric polyneuropathy; at diagnosis screening for diabetic autonomic neuropathy	Improved glycemic control Symptomatic treatment

Abbreviations: ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin II receptor blocker; CVD = cardiovascular disease; DBP = diastolic blood pressure; SBP = systolic blood pressure.

*High readings (≥130/80 mm Hg) should be confirmed on a separate day.

†Regardless of baseline lipid levels.

‡Including family history of CVD, hypertension, smoking, dyslipidemia, and albuminuria.

surrounding cellulitis or inflammation, with associated ascending lymphangitis, deep full-thickness ulceration or abscess, a large area of necrotic tissue, involvement of deep structures or bone, gangrene adjacent to the ulcer, or critical lower extremity ischemia (i.e., absence of palpable pulses). Life-threatening infection has clinical signs of sepsis, including fever, leukocytosis, hypotension, tachycardia, tachypnea, altered mental status, and metabolic abnormalities ranging from hypoglycemia to diabetic ketoacidosis and hyperosmolar hypertonic nonketotic state (**Table 224-16**).

Management of foot ulcers requires a multidisciplinary approach. Principles of management include debridement of necrotic tissues, avoidance of pressure points, management of infection (**Table 224-17**) and/or ischemia, management of medical comorbidities, proper wound handling, and surgery.

Treatment of noninfected chronic wounds mostly relies on avoidance of weight bearing and nonadherent padded dressings. Prophylactic antibiotics are not recommended, as this is costly and may result in adverse drug effects and the emergence of resistant organisms. Clinical signs of

TABLE 224-14 Drugs Used in the Treatment of Symptomatic Diabetic Autonomic Neuropathy

Class	Examples	Typical Dosages*
Tricyclic drugs	Amitriptyline	10–75 milligrams at bedtime
	Nortriptyline	25–75 milligrams at bedtime
	Imipramine	25–75 milligrams at bedtime
Anticonvulsants	Gabapentin	300–1200 milligrams twice a day
	Carbamazepine	200–400 milligrams twice a day
	Pregabalin†	100 milligrams twice a day
5-Hydroxytryptamine and norepinephrine uptake inhibitor	Duloxetine†	60–120 milligrams daily
Substance P inhibitor	Capsaicin cream	0.025–0.075% applied twice a day or four times a day

*Dose response may vary; initial doses need to be low and titrated up.

†Has U.S. Food and Drug Administration indication for treatment of painful diabetic neuropathy.

TABLE 224-15 Symptomatic Treatment of Selected Autonomic Neuropathies in Diabetic Patients

Manifestation of Autonomic Neuropathy	Treatment
Gastroparesis	Frequent small meals, prokinetic agents (e.g., erythromycin, metoclopramide)
Diarrhea	Soluble fiber, anticholinergic agents, cholestyramine
Constipation	Dietary fiber supplementation, bulking agents, stool softener
Neurogenic bladder	Bethanechol, intermittent catheterization
Erectile dysfunction	Psychological counseling, phosphodiesterase inhibitors (e.g., sildenafil)
Postural hypotension	Increasing salt intake (in the absence of hypertension), elastic stockings, or fludrocortisone
Anhydrosis	Scopolamine, emollients, skin lubricants

TABLE 224-16 Clinical Practice Pathways for Diabetic Foot Ulcer and Infection

Extent of Infection	Characteristics	Diagnostic Procedures	Treatment
Non–limb-threatening infection	<2 cm cellulitis	Cultures from base of ulcer (with tissue specimen if possible)	Outpatient management with follow-up in 24–72 h
	Superficial ulcer	Diagnostic imaging (radiography, MRI, nuclear scans as indicated)	Debridement of all necrotic tissue and callus
	Mild infection	Serologic testing	Wound care/dressing
	No systemic toxicity	CBC with differential	Empiric antibiotic coverage, modified by culture findings
	No ischemic changes	ESR	Appropriate off-loading of weight bearing
	No bone or joint involvement	Comprehensive metabolic panel	Wound care continued with packs, dressings, and debridement as needed
	Does not probe to bone		Hospital admission if infection progresses or systemic signs or symptoms develop
			Refer to podiatrist for follow-up care, special shoes, and prostheses as needed
Life- or limb-threatening infection	>2 cm cellulitis	Deep culture from base of ulcer/wound with tissue specimen if possible	Hospital admission
	Deep ulcer		Surgical debridement with resection of all necrotic bone and soft tissue
	Odor or purulent drainage from wound	Diagnostic imaging (radiography, MRI, nuclear scan, bone scan, leukocyte scan, arteriography)	Exploration and drainage of deep abscess
	Fever	Serologic testing	Empiric antibiotic coverage, modified by culture findings
	Ischemic changes	CBC with differential	Surgical resection of osteomyelitis
	Lymphangitis, edema	ESR	Wound care continued with packs, dressings, debridement as needed
	Sepsis or septic shock	Comprehensive metabolic panel	
		Blood cultures	Foot-sparing reconstructive procedures
			Refer to podiatrist for follow-up care, special shoes, and prostheses as needed

Abbreviation: ESR = erythrocyte sedimentation rate.

infection include prominent discharge, local erythema, and cellulites. The patient should be referred to a specialist in diabetes-related foot care within a few days to consider the need for debridement, total contact casting, further evaluation of any bony deformity or neuropathy, and evaluation for peripheral vascular disease.

Non–limb-threatening infections can usually be managed in the outpatient setting with appropriate minor debridement and administration of oral antibiotic therapy (Table 224-17). Application of well-padded dressing and avoidance of pressure to the affected area are necessary for adequate wound healing.

Treatment of limb-threatening infections requires hospitalization, IV antibiotics (Table 224-17), and surgical debridement. Empiric antibiotic therapy should be directed against the predominant pathogens, *Staphylococcus* and *Streptococcus* species. Include coverage for aerobic gram-negative and anaerobic bacteria when gangrenous, ischemic, or malodorous wounds are present. The use of topical antibiotics is generally not recommended. In the absence of palpable pedal pulses, vascular ultrasonography is needed. Further studies can include the ankle-brachial index, toe pressures, or measurement of transcutaneous oxygen tension. Immediate surgical consultation is indicated for incision and debridement, possible revascularization, or amputation.

HYPOGLYCEMIA

PATHOPHYSIOLOGY

Although there is no fixed laboratory definition of hypoglycemia, **it is clinically defined as follows: (1) symptoms consistent with the diagnosis; (2) symptoms associated with a low glucose level, usually <50 milligrams/dL (<2.7 mmol/L); and (3) symptoms resolve with glucose administration**.

Although the human brain depends on glucose as its primary source of energy, it is unable to synthesize or store glucose, accounting for the common manifestation of hypoglycemia as altered mental status. Physiologic response to low blood glucose includes suppression of insulin secretion and release of the counterregulatory hormones (e.g., glucagon and epinephrine). These responses are modified with increasing age. Renal clearance of insulin decreases with age, and this may enhance the risk of hypoglycemia in the elderly. On the other hand, in subjects with T2DM, counterregulatory hormones are secreted at higher blood glucose levels (compared with nondiabetics and those with type 1 diabetes mellitus), resulting in some protection against hypoglycemia in patients with T2DM. Improved glycemic control through insulin therapy lowers the blood glucose level threshold for the counterregulatory response and offsets this protective effect of diabetes.

CLINICAL FEATURES

Hypoglycemia is usually a complication of treatment. It occurs most frequently with insulin and sulfonylureas. **Hypoglycemia is not a common side effect of treatment with glitazones, glinides, or α-glucosidase inhibitors.**[25] Among sulfonylureas, the risk of hypoglycemia depends on the pharmacokinetic properties of each agent. Chlorpropamide, glyburide (glibenclamide), and long-acting glipizide are long-acting sulfonylureas and are associated with more episodes of hypoglycemia. Hypoglycemia is rarely, if ever, encountered in patients using only metformin. Risk factors for severe hypoglycemia in patients with T2DM include age, past history of vascular disease, renal failure, decreased food ingestion, alcohol consumption, and drug interactions.

The clinical manifestations of hypoglycemia are divided into two broad categories: *neuroglycopenic* and *autonomic*. Neuroglycopenic manifestations include alterations in consciousness, lethargy, confusion, combativeness, agitation, seizures, focal neurologic deficits, and unresponsiveness. **Autonomic** findings consist of anxiety, nervousness, irritability, nausea, vomiting, palpitations, and tremor. Cholinergic nervous system stimulation also may occur and result in manifestations such as sweating, changes in pupil size, bradycardia, and salivation. **Table 224-18** lists various medical conditions that may be mistaken for hypoglycemia. The rapidity of onset of the hypoglycemic event determines, in part, the presentation. A gradual onset of hypoglycemia results from a relatively slow decrease in the serum glucose and the development of the neuroglycopenic signs and symptoms.

Piperacillin-tazobactam 4.5 grams every 6–8 h
Or
Clindamycin, 900 milligrams every 6 h *plus* (ciprofloxacin, 400 milligrams every 8–12 h *or* ceftriaxone, 1 gram every 12 h)
Life-threatening*
IV regimens:
Imipenem-cilastatin, 500 milligrams every 6 h
Or
Meropenem 1 gram every 8 h
Or
Vancomycin, 15–20 milligram/kg every 12 h, *plus* metronidazole, 500 milligrams every 8 h, *plus* (aztreonam, 2 grams every 6–8 h *or* ciprofloxacin 400 milligrams every 8–12 h) *(if MRSA coverage is warranted)*

Abbreviation: MRSA = methicillin-resistant *Staphylococcus aureus*.

Note: Adjust all dosages for renal/hepatic function and monitor blood levels where appropriate.

*See the section "Lower Extremity and Foot Complications" for definitions.

†This approach is acceptable under special circumstances with close follow-up.

Conversely, a sudden drop in the blood sugar level will produce anxiety, diaphoresis, tremor, and the other hyperepinephrinemic findings. In most cases of hypoglycemia, however, CNS dysfunction predominates, with some degree of alteration in the level of awareness accompanied by diaphoresis and tachycardia.

Depression

DIAGNOSIS

Diagnosis of hypoglycemia is very straightforward. **Hypoglycemia should always be considered early (including the prehospital setting) as a potential cause of altered mental status.** Failure to determine the blood glucose level early in the evaluation can result in a delayed or missed diagnosis with associated morbidity because of CNS injury or unnecessary invasive procedures and therapies. The diagnosis can easily be confirmed using bedside glucose testing. The accuracy of bedside reflectance tests is acceptable although less reliable at extremely low and high glucose levels. Glucose values of whole blood are approximately 15% less than that of serum or plasma. This discrepancy is a result of the relatively low glucose concentration in red blood cells. Whenever possible, a serum sample should be sent to the laboratory for confirmation of the bedside test result immediately before IV dextrose therapy. **In diabetic patients who develop hypoglycemia while taking the usual dose of sulfonylurea, an underlying cause should be suspected.** Drug interactions, decreased metabolism of the drug, and decreased drug excretion are common precipitating causes.[26]

TREATMENT

Regardless of the cause, management of hypoglycemia in the ED includes prompt diagnosis and PO or IV administration of rapidly metabolized carbohydrates (i.e., glucose or dextrose). In patients with altered mental status, 50% dextrose in water is administered IV as a bolus dose of 50 mL, which provides 25 grams of glucose. This dose may be repeated if hypoglycemia persists. When the patient regains consciousness, carbohydrates should be continued to prevent recurrence of hypoglycemia. This can be accomplished through PO administration of long-acting carbohydrates or continuous IV infusion of dextrose (10% dextrose in water at a rate to maintain the serum glucose >100 milligrams/dL [5.55 mmol/L]). Blood glucose should be determined every 30 minutes for the first 2 hours, looking for rebound hypoglycemia. If hyperglycemia is maintained by slow administration of dextrose, the infusion may be reduced and eventually withdrawn.

Failure to respond to parenteral glucose administration should prompt consideration of other causes of hypoglycemia, such as sepsis, toxin, insulinoma, hepatic failure, or adrenal insufficiency. Hypoglycemia resulting from sulfonylureas is much more challenging than insulin-induced hypoglycemia. Hemodialysis and charcoal hemoperfusion, although mentioned in case reports, are not routinely recommended for sulfonylurea overdose.

Octreotide is a somatostatin analog and is able to suppress insulin secretion. It can be used successfully for the treatment of sulfonylurea-induced hypoglycemia. It is superior to glucose and diazoxide in preventing recurrent hypoglycemia. The ideal dosage and interval of octreotide are not well defined. Recommendations vary from a single 50- to 100-microgram SC injection after a single hypoglycemic episode, to serial SC injections (50 to 100 micrograms every 6 to 8 hours) or constant IV infusion (125 micrograms/h) after a second hypoglycemic episode. Some suggest that the addition of octreotide, 50 micrograms SC, to standard therapy may result in a decrease in frequency of hypoglycemic episodes and an increase in mean plasma glucose.[27] **Octreotide is only recommended after initial glucose therapy has been initiated for sulfonylurea-induced hypoglycemia and can be considered when the response to dextrose is inadequate. It is primarily used to reduce the risk of recurrent hypoglycemia.**

Glucagon is a Food and Drug Administration–approved alternative that may be used SC or IM in the absence of IV access. SC injection of this polypeptide hormone can cause an approximate 100 milligrams/dL (5.55 mmol/L) increase in serum glucose of hypoglycemic patients. Response to glucagon therapy is generally slower when compared with IV dextrose, requiring 7 to 10 minutes for normalization of mental status. Additionally, the response to glucagon administration may be short lived. **In adults, glucagon is administered at the dose of 1 milligram as an SC or IM injection.** Intranasal glucagon has also been used safely in some studies for the treatment of hypoglycemia. Glucagon should be used cautiously in patients with sulfonylurea-induced hypoglycemia.

Diazoxide has also been used in the treatment of refractory sulfonylurea-induced hypoglycemia. It acts by directly inhibiting insulin secretion from pancreatic β cells. Diazoxide may cause hypotension

and so should be administered as a slow IV infusion (300 milligrams over 30 minutes every 4 hours).

DISPOSITION AND FOLLOW-UP

Patients who experience hypoglycemia due to sulfonylureas, non–short-acting insulins, or meglitinides should be admitted for serial glucose monitoring and treatment.

CHAPTER 225

Diabetic Ketoacidosis

Andrew L. Nyce
Cary L. Lubkin
Michael E. Chansky

INTRODUCTION AND EPIDEMIOLOGY

Diabetic ketoacidosis (DKA) is an acute, life-threatening complication of diabetes mellitus. DKA occurs predominantly in patients with type 1 (insulin-dependent) diabetes mellitus, but 10% to 30% of cases occur in newly diagnosed type 2 (non–insulin-dependent) diabetes mellitus, especially in African Americans and Hispanics.[1,2] Between 1993 and 2003, the yearly rate of U.S. ED visits for DKA was 64 per 10,000 with a trend toward an increased rate of visits among the African American population compared with the Caucasian population.[3] Europe has a comparable incidence. A better understanding of the pathophysiology of DKA and an aggressive, uniform approach to its diagnosis and management have reduced mortality to <5% of reported episodes in experienced centers.[4] However, mortality is higher in the elderly due to underlying renal disease or coexisting infection and in the presence of coma or hypotension.

PATHOPHYSIOLOGY

Figure 225-1 illustrates the complex relationships between insulin and counterregulatory hormones. DKA is a response to cellular starvation brought on by relative insulin deficiency and counterregulatory or catabolic hormone excess (**Figure 225-1**). Insulin is the only anabolic hormone produced by the endocrine pancreas and is responsible for the metabolism and storage of carbohydrates, fat, and protein. Counterregulatory hormones include glucagon, catecholamines, cortisol, and growth hormone. Complete or relative absence of insulin and the excess counterregulatory hormones result in hyperglycemia (due to excess production and underutilization of glucose), osmotic diuresis, prerenal azotemia, worsening hyperglycemia, ketone formation, and a wide-anion-gap metabolic acidosis.[4]

INSULIN

Ingested glucose is the primary stimulant of insulin release from the β cells of the pancreas. Insulin's main action occurs at the three principal tissues of energy storage and metabolism—the liver, adipose tissue, and skeletal muscle. Insulin acts on the liver to facilitate the uptake of glucose and its conversion to glycogen while inhibiting glycogen breakdown (glycogenolysis) and suppressing gluconeogenesis. The net effect of these actions is to promote the storage of glucose in the form of glycogen. Insulin increases lipogenesis in the liver and adipose cells by producing triglycerides from free fatty acids and glycerol while inhibiting

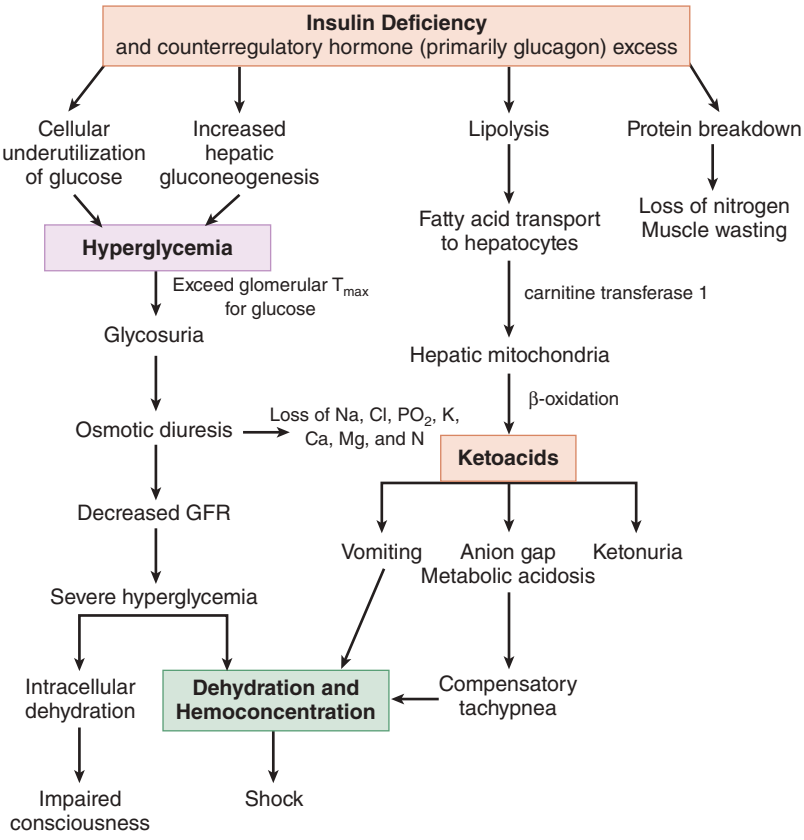

FIGURE 225-1. Insulin deficiency. Pathogenesis of diabetic ketoacidosis secondary to relative insulin deficiency and counterregulatory hormone excess. GFR = glomerular filtration rate.

the breakdown of triglycerides. Insulin stimulates the uptake of amino acids into muscle cells with subsequent incorporation into muscle protein while preventing the release of amino acids from muscle and hepatic protein sources.

Deficiency in insulin secretion due to loss of islet cell mass is the predominant defect in type 1 diabetes mellitus. In the initial stages of diabetes mellitus, the secretory failure of β cells impairs fuel storage and may be evident only during a glucose tolerance test. As levels of insulin decrease, fuel stores are mobilized during fasting, resulting in hyperglycemia. When pancreatic β-cell reserve is present, hyperglycemia may trigger an increase in insulin and a return to normal glucose concentration. With further disease progression, hyperglycemia can no longer trigger an increase in insulin activity. Despite the presence of elevated intravascular glucose, in the absence of insulin, cells are unable to use glucose as a fuel source. The body responds by breaking down protein and adipose stores to try to produce a usable intracellular fuel. Loss of the normal physiologic effects of insulin leads to secretion of catabolic (counterregulatory) hormones and resulting hyperglycemia and ketonemia.

KETOACIDOSIS

The response to cellular starvation seen with insulin insufficiency is increased levels of glucagon, catecholamines, cortisone, and growth hormone. Glucagon is the primary counterregulatory hormone. The catabolic effects of these hormones include increased gluconeogenesis and glycogenolysis, breakdown of fats into free fatty acids and glycerol, and proteolysis with increased levels of amino acids. Increased levels of glucogenic precursors, such as glycerol and amino acids, facilitate gluconeogenesis, worsening hyperglycemia.

Free fatty acids released in the periphery are bound to albumin and transported to the liver, where they undergo conversion to ketone bodies. The primary ketone bodies **β-hydroxybutyrate** (βHB) and **acetoacetic acid** (AcAc) account for the metabolic acidosis seen in DKA. The two are in equilibrium: **AcAc + NADH ⇌ βHB + NAD**. AcAc is metabolized to **acetone**, another major ketone body. Depletion of hepatic glycogen stores favors ketogenesis. Low or absent insulin levels decrease the ability of the brain and cardiac and skeletal muscle to use ketones as an energy source, increasing ketonemia. The persistently elevated serum glucose level eventually causes an osmotic diuresis. The resulting volume depletion worsens hyperglycemia and ketonemia.

The renin-angiotensin-aldosterone system, activated by volume depletion, exacerbates renal potassium losses already occurring from osmotic diuresis. In the kidney, chloride is retained in exchange for the ketoanions being excreted. The loss of ketoanions represents a potential loss of bicarbonate. In the face of marked ketonuria, a superimposed hyperchloremic acidosis is also present. As adipose tissue is broken down, prostaglandins I_2 and E_2 are produced. Both account for paradoxical vasodilation that occurs despite profound levels of volume depletion.

CAUSES OF DKA

Factors known to precipitate DKA are listed in **Table 225-1**.[4] Additional risk factors include poor economic background, lack of insurance or minority status, drug abuse, depression, and the presence of an eating disorder. In many patients, no clear precipitating cause is found.[4]

Heat-related illness
Cerebrovascular accident
GI hemorrhage
Myocardial infarction
Pulmonary embolism
Pancreatitis
Major trauma
Surgery

CLINICAL FEATURES

The clinical manifestations of DKA are related directly to hyperglycemia, volume depletion, and acidosis. The metabolic alterations of DKA tend to evolve within 24 hours.[4] Osmotic diuresis gradually leads to volume loss in addition to renal losses of sodium, chloride, potassium, phosphorous, calcium, and magnesium. Initially, patients may compensate by increasing fluid intake, and polyuria and polydipsia are usually the only symptoms until ketonemia and acidosis develop. As acidosis progresses, ventilation is stimulated physiologically by acidemia to diminish the P_{CO_2} and to counter metabolic acidosis. Acidosis combined with the effects of prostaglandins I_2 and E_2 leads to peripheral vasodilation despite profound levels of volume depletion. Prostaglandin release is also felt to play a role in unexplained nausea, vomiting, and abdominal pain that are seen frequently at presentation, especially in children. Vomiting, which may be a maladaptive physiologic response to diminish the acid load, unfortunately exacerbates potassium losses. As volume depletion progresses, poor absorption of SC insulin renders its administration ineffective. Impaired mental status may develop and is most likely multifactorial, related to metabolic acidosis, hyperosmolarity, low extracellular fluid volume, and poor hemodynamics. **Alteration of consciousness has been reported to correlate better with elevated serum osmolality (>320 mOsm/L or >320 mmol/kg) than with severity of metabolic acidosis.**[5]

Tachycardia, orthostasis or hypotension, poor skin turgor, and dry mucous membranes result from volume depletion. **Kussmaul respirations**, increased rate and depth of breathing, may be observed. Acetone produces the characteristic fruity odor on the breath found in some patients. The absence of fever does not exclude infection. Hypothermia is present occasionally because of peripheral vasodilation.

Abdominal pain and tenderness associated with DKA generally correlates with the level of acidosis. Pain can be due to gastric dilatation, ileus, or pancreatitis, but any other acute abdominal disorder can also develop. Due to the frequency of abdominal pain and the presence of an elevated serum amylase or lipase level in both DKA and pancreatitis, distinguishing these two conditions may be difficult. An elevated serum lipase level is more specific to pancreatitis, but it may also be elevated in DKA.

DIAGNOSIS

A blood glucose level >250 milligrams/dL (13.8 mmol/L), an anion gap >10 mEq/L (>10 mmol/L), a bicarbonate level <15 mEq/L (<15 mmol/L), and pH <7.3 with moderate ketonuria or ketonemia constitute the diagnosis of DKA.[4,6] Patients may sometime present with **"euglycemic ketoacidosis"** (glucose <300 milligrams/dL or <16.6 mmol/L), such as those who present just after receiving insulin, type 1 diabetics who are young and vomiting, patients with impaired gluconeogenesis (alcohol abuse or liver failure), patients with low caloric intake/starvation, patients with depression, or pregnant patients. Euglycemic DKA has recently been described as an adverse effect of sodium-glucose cotransporter 2 (SGLT-2) inhibitors (canaglifozin and others). Check blood ketones, venous pH, bicarbonate levels and anion gap) to avoid missing euglycemic DKA, because the degree of hyperglycemia may not be significant (**Table 225-2**).[7]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of DKA (**Table 225-3**) includes any cause of a high anion gap metabolic acidosis. Patients with hyperosmolar, nonketotic coma tend to be older, have a more prolonged course, and have prominent mental status changes. Serum glucose levels generally are much higher (>600 milligrams/dL or >33.3 mOsm/L), and there is little

TABLE 225-2 Risk Factors for Diabetic Ketoacidosis Patients with Initial Glucose < 300 milligrams/dL (16.6 mmol/L) (Euglycemic Ketoacidosis)

Low caloric intake/starvation
Depression
Pregnancy

to no anion gap metabolic acidosis.[4] The ketosis in alcoholic ketoacidosis and starvation ketosis tend to be milder, and the serum glucose level is usually low or normal. βHB predominates in alcoholic ketoacidosis, so the urinary ketone test may be negative or trace positive.

If an ingestion cannot be excluded, serum osmolarity or drug-level testing is required. Renal failure, anion gap acidosis, and liver function abnormalities may be due to acetaminophen toxicity. Depending on the hemodynamic status, lactic acidosis (poor perfusion) may occur simultaneously with DKA; in these cases, determination of the serum lactate level is indicated. **Patients on metformin with new-onset renal insufficiency are at risk for developing type B (aerobic) lactic acidosis.**

LABORATORY TESTING

Obtain a rapid bedside glucose determination, a urine test strip, and an electrocardiogram to check for hyperkalemia, and obtain a CBC, serum electrolytes, BUN and creatinine, urinalysis, venous blood gas, and phosphate/magnesium/calcium levels. Calculate the anion gap. Blood cultures and other laboratory tests should be done as clinically indicated. Arterial blood gas determinations are optional but may be required for the diagnosis and monitoring of critically ill patients.

Ketone Bodies In DKA, elevated serum levels of βHB and AcAc cause acidosis and ketonuria (ketonemia). The **nitroprusside** reagent normally used to detect urine and serum ketones **only detects AcAc**; acetone is only weakly reactive and βHB not at all. Gas chromatography can be used to detect serum acetone but is expensive and time-consuming.

NADH accumulation in mitochondria, as may occur with lactic acidosis or alcohol metabolism, favors the βHB side of equilibrium noted earlier (**AcAc + NADH ⇌ βHB + NAD**). Paradoxically, as the patient is being treated and clinically improves, ketone levels will increase as the body converts the more acidic βHB to AcAc. Therefore, the blood ketone test (Acetest®) that uses the nitroprusside reaction is not a reliable measure for diagnosis or monitoring of DKA. Although not widely available, a new point-of-care capillary blood ketone test for βHB levels may be more sensitive and specific than traditional testing for urine ketones.[6,8] As point-of-care capillary blood ketone testing for βHB becomes more widespread, this test may offer an alternative approach for the diagnosis and monitoring of DKA management compared to traditional measurements of serum HCO_3, anion gap, and pH.[9]

Acid-Base Abnormalities **DKA leads to a wide-anion-gap metabolic acidosis.** Hyperchloremic acidosis also occurs on the basis of ketoanion exchange for chloride in the urine and is especially common in patients who maintain good hydration status and glomerular filtration rate despite ketoacidosis. Metabolic alkalosis may occur secondary to vomiting, osmotic diuresis, and concomitant diuretic use. Rarely, some patients with DKA may present with normal-appearing [HCO_3^-] or even an elevated [HCO_3^-], if coexisting metabolic alkalosis is severe enough to mask the acidosis. In such situations, an elevated anion gap may be the only clue to the presence of an underlying metabolic acidosis otherwise masked by the concomitant volume contraction–related metabolic alkalosis.

Venous pH has essentially replaced arterial blood gases in the assessment of the acid-base status of the DKA patient. A strong correlation exists between venous and arterial pH in patients with DKA, and the arterial blood gas value does not impact therapy.[10] **Venous pH is about 0.03 lower than arterial pH.** Venous pH obtained during routine phlebotomy should be used to avoid arterial puncture, which is painful and may cause arterial vascular complications.

A low P_{CO_2} determination usually reflects respiratory compensation for metabolic acidosis. If it is lower than explained by the degree of acidosis, a primary respiratory alkalosis exists, which may be an early indication of pulmonary disease (e.g., pneumonia, pulmonary embolus) or sepsis as a possible trigger of DKA. Chapter 15, Acid-Base Disorders, details how compensatory changes in P_{CO_2} can be distinguished from a primary respiratory alkalosis.

Potassium Total-body potassium is depleted by renal losses. **However, the measured serum potassium level is normal or elevated in most patients[4] because of two important factors**: extracellular shift of potassium secondary to acidemia and increased intravascular osmolarity caused by hyperglycemia. Although the actual incidence of initial hypokalemia in DKA is not known, a few studies report an occurrence of 4% to 6%.[5,11,12] **The decrease in serum potassium during therapy is reported to be about 1.5 mEq/L (1.5 mmol/L) and parallels the drop in glucose and the dose of insulin.**[5,11]

Electrocardiogram changes of hyperkalemia or hypokalemia may be seen. The electrocardiogram also should be evaluated for ischemia because myocardial infarction may precipitate DKA.

Sodium and Other Electrolytes Osmotic diuresis leads to excessive renal losses of sodium chloride in the urine. However, the presence of hyperglycemia tends to artificially lower the serum sodium levels. **Standard teaching is that 1.6 mEq (1.6 mmol) should be added to the reported sodium value for every 100 milligrams (5.55 mmol) of glucose >100 milligrams/dL (>5.5 mmol/L). However, the correction factor is probably 2.4, especially for blood glucose levels >400 milligrams/dL (>22.2 mOsm/L).**[13] Osmotic diuresis also causes urinary losses and total-body depletion of phosphorous, calcium, and magnesium. Hemoconcentration frequently leads to initially elevated levels of these electrolytes in serum. As therapy progresses, lower serum levels of each will be evident.

Other Laboratory Values **Serum creatinine frequently may be elevated factitiously if the laboratory assay for creatinine is interfered with by the nitroprusside assay.** Some elevation in creatinine is expected due to prerenal azotemia. Liver function studies may be elevated because of fatty infiltration of the liver, which gradually corrects as the acidosis is treated. Leukocytosis is often present because of hemoconcentration and stress. However, a WBC count >25,000 mm^3 and/or an absolute band count of 10,000 mm^3 or more is suggestive of infection. Elevation of C-reactive protein may reflect the proinflammatory state found in DKA; elevated levels of cytokines may also be present.

TREATMENT

The diagnosis of DKA should be suspected at triage, and aggressive fluid therapy should be initiated before receiving the laboratory results[4] (**Figure 225-2**). Place patients on a cardiac monitor and begin at least one large-bore (16- to 18-gauge) IV infusion of normal saline. A second IV line with 0.45% normal saline at minimal rate to keep the IV line open can be considered. The goals of therapy are (1) volume repletion, (2) reversal of the metabolic consequences of insulin insufficiency, (3) correction of electrolyte and acid-base imbalances, (4) recognition and

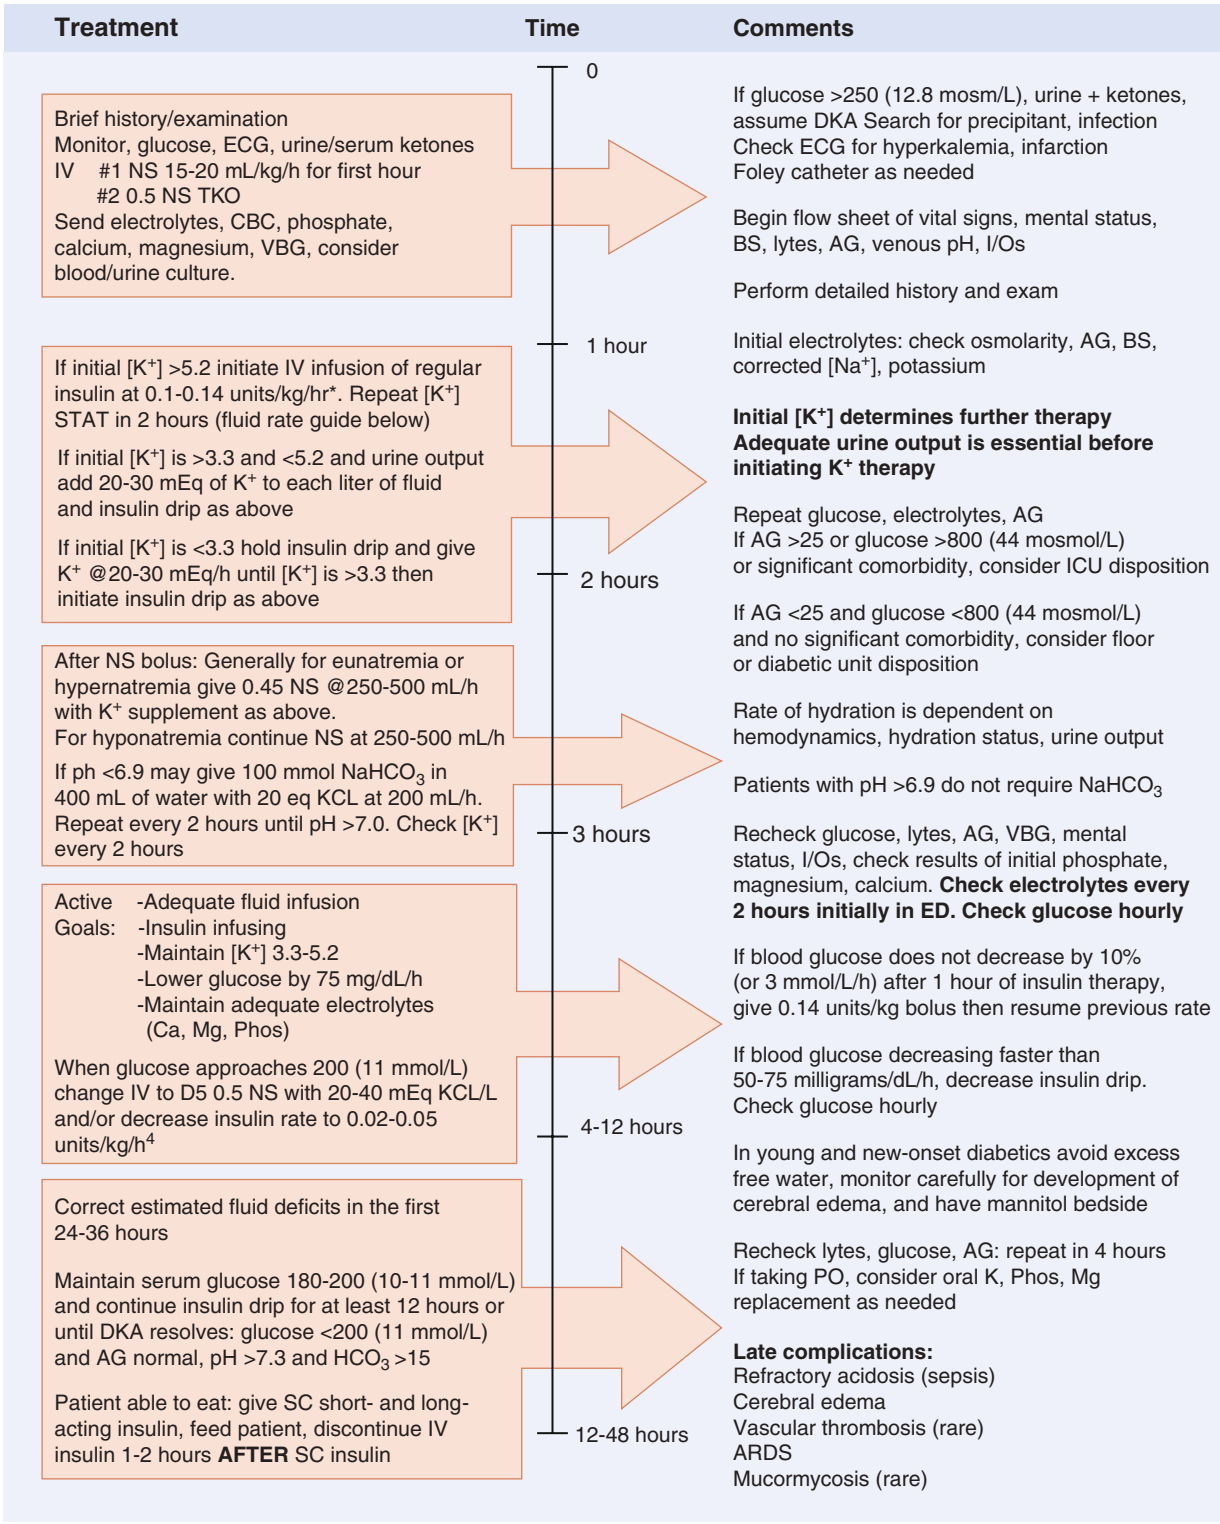

FIGURE 225-2. Timeline for the typical adult patient with suspected diabetic ketoacidosis (DKA). *IV insulin infusion <1.0 units/kg/hr may require a bolus dose of regular insulin (0.1 unit/kg)[4]. AG = anion gap; ARDS = acute respiratory distress syndrome; BS = blood sugar; ECG = electrocardiogram; ICU = intensive care unit; I/Os = inputs/outputs; NS = normal saline; TKO = to keep vein open; VBG = venous blood gas.

treatment of precipitating causes; and (5) avoidance of complications. **The order of therapeutic priorities is volume first and foremost, correction of potassium deficits, and then insulin administration.** Metabolic disturbances should be corrected at the approximate rate of occurrence or over 24 to 36 hours.

Meeting the goals of safely replacing deficits and supplying missing insulin requires monitoring every 2 hours of electrolytes (glucose, potassium, and anion gap), vital signs, level of consciousness, and volume input/output until recovery is well established. **The goal of treatment is glucose <200 milligrams/dL (<11.1 mmol/L), bicarbonate ≥18 mEq/L (≥18 mmol/L), and venous pH >7.3.**

VOLUME REPLETION

Fluid helps restore intravascular volume and normal tonicity, perfuse vital organs, improve glomerular filtration rate, and lower serum

glucose and ketone levels.[4] Rehydration improves the response to low-dose insulin therapy.[4] The average adult patient has a water deficit of 100 mL/kg (5 to 10 L) and a sodium deficit of 7 to 10 mEq/kg (7 to 10 mmol/L/kg).[4] Normal saline is the most frequently recommended fluid for initial volume repletion even though the extracellular fluid of the patient is initially hypertonic.[14] Normal saline does not provide "free water" to correct intracellular fluid loss, but it does prevent an excessively rapid fall in extracellular osmolarity and the potential devastating transfer of excessive water into the CNS. After initial resuscitation with normal saline, change fluids to 0.45% normal saline once the corrected serum sodium is normal or elevated.[6,7]

Based on clinical suspicion alone and before initial electrolyte results, **administer the initial fluid bolus of isotonic saline at a rate of 15 to 20 mL/kg/h during the first hour** unless there are mitigating circumstances.[6] The rate of hydration should depend on hemodynamic stability, hydration status, urine output, and serum electrolytes. After the initial bolus, administer normal saline at 250 to 500 cc/h in hyponatremic patients, or give 0.45% normal saline at 250 to 500 cc/h for eunatremic and hypernatremic patients.[7] **In general, the first 2 L are administered rapidly over 0 to 2 hours, the next 2 L over 2 to 6 hours, and then an additional 2 L over 6 to 12 hours.** This replaces approximately 50% of the total water deficit over the first 12 hours, with the remaining 50% water deficit to be replaced over the subsequent 12 hours. When the blood glucose level is 250 milligrams/dL (13.8 mmol/L), change to 5% dextrose in 0.45% normal saline. Patients without extreme volume depletion can be managed safely with a more modest fluid replacement regimen such as 250 to 500 mL/h for 4 hours. Consider central venous pressure or pulmonary artery wedge pressure monitoring in the elderly or in those with heart or renal disease. Excess fluid may contribute to the development of adult respiratory distress syndrome and cerebral edema.

POTASSIUM REPLACEMENT

Patients in DKA usually present with profound total-body potassium deficits in the range of 3 to 5 mEq/kg (3 to 5 mmol/kg).[4] This deficit is created by insulin deficiency, metabolic acidosis, osmotic diuresis, and frequent vomiting. Only 2% of total-body potassium is intravascular. The initial serum concentration is usually normal or high because of the intracellular exchange of potassium for hydrogen ions during acidosis, the total-body fluid deficit, and diminished renal function. **Initial hypokalemia indicates severe total-body potassium deficits, and large amounts of replacement potassium are usually necessary in the first 24 to 36 hours.**

Correction of the acidosis predicts the change in serum potassium concentration. **For each 0.1 decrease in pH, serum potassium concentration rises approximately 0.5 mEq/L (0.5 mmol/L)**, and the same relationship holds as the pH increases. This can be used as a guide for estimating the serum potassium concentration when pH balance is restored.

Hypokalemia During initial therapy for DKA, the serum potassium concentration may fall rapidly, primarily due to the action of insulin promoting reentry of potassium into cells and, to a lesser degree, the dilution of extracellular fluid, correction of acidosis, and increased urinary loss of potassium. If these changes occur too rapidly, precipitous hypokalemia may result in fatal cardiac arrhythmias, respiratory paralysis, paralytic ileus, and rhabdomyolysis. **The rapid development of severe hypokalemia is potentially the most life-threatening electrolyte derangement during the treatment of DKA.**[4]

As a general guideline, an initial serum potassium level >3.3 mEq/L (>3.3 mmol/L) but <5.2 mEq/L (<5.2 mmol/L) (before fluid resuscitation and insulin, coupled with urine output) calls for 20 to 30 mEq/L (20 to 30 mmol/L) for at least 4 hours to keep K^+ between 4 and 5 mEq/L (4 and 5 mmol/L).[6] Because the most rapid changes occur during the first few hours of therapy, measure the plasma potassium level initially every 2 hours. If oliguria or renal insufficiency is present, withhold or decrease potassium replacement.

Initial hypokalemia (<3.3 mEq/L or <3.3 mmol/L) is uncommon but necessitates a more aggressive replacement before insulin therapy.[4] In this setting, give potassium IV at 20 to 30 mEq/h (20 to 30 mmol/h) and hold insulin until $[K^+]$ is ≥3.5 mEq/L (≥3.5 mmol/L).[6,7] There is no advantage to using potassium phosphate (K_2PO_4) compared to potassium chloride because K_2PO_4 may result in hypocalcemia and metastatic precipitation of calcium phosphate in tissues. Oral potassium replacement is safe and effective and is the preferred route of replacement as soon as the patient can tolerate oral fluids. In DKA, initial potassium replacement is usually by an intravenous line. Each institution may have specific guidelines for potassium replacement, but a general approach is a rate no faster than 10 mEq/h (10 mmol/h) via peripheral IV or 20 mEq/h (20 mmol/h) via central line access. Continuous electrocardiogram monitoring is generally recommended while replacing potassium in the severely hypokalemic patient. During the first 24 hours, 100 to 200 mEq or mmol of KCl is usually required.

Hyperkalemia **Obtain an electrocardiogram immediately and check for signs of hyperkalemia once DKA is suspected.**

Giving potassium to a patient in a hyperkalemic potentiating state (i.e., acidemia, insulin deficiency, volume contraction, renal insufficiency) may dangerously increase the extracellular potassium level and precipitate fatal dysrhythmias. The initial measurement of serum electrolytes, electrocardiogram review for signs of hyperkalemia, and the presence of urine output determine initial potassium therapy. An initial serum potassium level >5.2 mEq/L usually reflects a more profound acidemia and volume depletion, or renal insufficiency. Fluid and insulin therapy alone usually will lower the serum potassium level rapidly. Albuterol nebulization can provide an additional quick potassium-lowering effect. See chapter 17, Fluids and Electrolytes, for further treatment of hyperkalemia.

INSULIN

Low-dose regular insulin administration by an infusion pump is simple and safe, ensures a steady blood concentration of insulin, allows flexibility in adjusting the insulin dose, and promotes a gradual fall in serum glucose and ketone body levels.[4] The half-life of IV insulin is 4 to 5 minutes, with an effective biologic half-life at the tissue level of approximately 20 to 30 minutes.

IV Insulin After the initial fluid bolus, or simultaneously in a second IV line, **administer insulin at a rate of 0.1 to 0.14 unit/kg/h with no insulin bolus once hypokalemia ($[K+]$ <3.3 mEq/L [<3.3 mmol/L]) is excluded**. An alternative insulin regimen is 0.1 unit/kg bolus IM, if it is difficult to establish another IV line,[9] followed by a drip rate at 0.1 unit/kg/h.[7] An IV loading dose of insulin is not recommended in children and new-onset young adult diabetics and is optional in adults.[9,15] Plasma glucose concentration typically decreases by 50 to 75 milligrams/dL/h (2.8 to 4.2 mmol/L/h), but if the blood glucose fails to drop by 10% 1 hour after initial therapy, or 3 mmol/L/h, (assuming adequate hydration), give a 0.14 unit/kg bolus and resume insulin drip rate.[6,7] **Another option is to increase the insulin infusion rate by 1 unit/h.**[9] The incidence of nonresponse to low-dose continuous IV insulin administration is 1% to 2%, with infection being the primary reason for failure to respond.

Resolution of hyperglycemia usually occurs earlier than resolution of the anion gap, so **once the serum glucose is 200 milligrams/dL (11 mmol/L), add dextrose to the IV fluids and reduce the insulin drip rate to 0.02 to 0.05 unit/kg/h**. Maintain the serum glucose between 150 and 200 milligrams/dL (8.3 and 11 mmol/L) until the resolution of DKA.[7] Occasionally a 10% dextrose solution may be needed to maintain glucose levels.[9] **Continue the insulin infusion until the resolution of DKA—glucose <200 milligrams/dL (<11 mmol/L) and two of the following: a serum bicarbonate level >15 mEq/L, a venous pH >7.3, and/or a normal calculated anion gap.**[7] Monitor laboratory values every 1 to 2 hours to ensure that insulin is being administered in the desired amount.

Transition from IV Insulin After DKA Correction **A transition from the IV insulin infusion to SC insulin is necessary to avoid relapse to hyperglycemia or DKA when the insulin infusion is stopped.** Relapse can occur quickly, within an hour after IV insulin is stopped, due to the short duration of action of IV insulin. The method of insulin transition varies, and there is no set protocol. Once the patient eats, the glucose infusion can be stopped. In patients who can eat, the transition should include a short-acting and long-acting insulin given when DKA has resolved. It is best to collaborate with the inpatient team or

endocrinologist to develop a protocol for the transition to SC insulin. One method consists of giving 10 units of SC regular insulin 30 to 60 minutes before the insulin infusion is stopped and 80% of the usual long-acting insulin dose 1 to 2 hours before discontinuing the IV insulin infusion. Another method is to give 50% of the usual long-acting insulin dose 2 hours before the IV insulin infusion is stopped (see Figure 223-1, for onset and duration of action of long-acting insulins). If the patient is a newly diagnosed diabetic, one can estimate a starting dose of long-acting insulin at 0.1 to 0.2 unit/kg. Additional glucose coverage can be provided with short-acting insulin as needed. Continue glucose checks every hour for 2 hours. Further intervals for glucose checks and the need for additional SC regular insulin dosing depend on the patient's response and institutional protocols.

SC Insulin In uncomplicated mild to moderate DKA, the use of rapid-acting SC insulin may be another treatment option, although the standard treatment remains continuous IV insulin.[4,7,16] The dose of SC rapid-acting insulin is an initial injection of 0.2 unit/kg followed by 0.1 unit/kg every hour, or an initial dose of 0.3 unit/kg followed by 0.2 unit/kg every 2 hours until blood glucose is <250 milligrams/dL (<13.8 mmol/L). Then, the insulin dose is decreased by half and administered every 1 or 2 hours until resolution of DKA.[4,7] This can avoid intensive care admissions and lower hospital costs, but still requires close nursing monitoring that is difficult to accomplish in the ED or in a regular hospital bed.

HYPOPHOSPHATEMIA

Serum phosphate levels often are normal or increased on presentation of DKA and do not reflect the total-body phosphate deficits secondary to enhanced urinary losses.[11] Phosphate (similar to glucose and potassium) reenters the intracellular space during insulin therapy, resulting in low phosphate concentrations. Hypophosphatemia is usually most severe 24 to 48 hours after the start of insulin therapy. Acute phosphate deficiency (<1.0 milligram/dL) can result in hypoxia, skeletal muscle weakness, rhabdomyolysis, hemolysis, respiratory failure, and cardiac dysfunction.

There is no established role for initiating IV K_2PO_4 for DKA in the ED.[4,7,11] In general, do not give IV phosphate unless the serum phosphate concentration is <1.0 milligram/dL (0.323 millimol/L). Significant hypophosphatemia tends to develop many hours into therapy, after the patient is already admitted. Undesirable side effects from IV phosphate administration include hyperphosphatemia, hypocalcemia, hypomagnesemia, metastatic soft tissue calcifications, hypernatremia, and volume loss from osmotic diuresis. If *absolutely* necessary (a phosphate level <1.0 milligram/dL early in therapy), IV phosphate replacement should be administered as IV K_2PO_4, 2.5 to 5 milligrams/kg (0.08 to 0.16 millimol/kg).[17] Monitor serum calcium level if giving supplemental phosphate.

HYPOMAGNESEMIA

Osmotic diuresis may cause hypomagnesemia and deplete magnesium stores from bone. Hypomagnesemia may inhibit parathyroid hormone secretion, causing hypocalcemia and hyperphosphatemia. If the serum magnesium concentration is <2.0 mEq/L (<1.0 mmol/L) or symptoms are suggestive of hypomagnesemia, give magnesium sulfate 2 grams IV over 1 hour. Obtain serum magnesium and calcium levels on presentation and 24 hours into therapy. Monitor levels every 2 hours if there is initial hypomagnesemia or hypocalcemia or if symptoms suggestive of hypomagnesemia or hypocalcemia occur.

BICARBONATE

Acidotic patients routinely recover from DKA without alkali therapy, as fluid and insulin therapy inhibit lipolysis and resolve ketoacidosis without added bicarbonate.[4] **Give bicarbonate if the initial pH is ≤6.9, but do not give bicarbonate if the pH is ≥7.0.**[7,16,18,19]

Severe metabolic acidosis is associated with numerous cardiovascular (impaired contractility, vasodilation, and hypotension) and neurologic (cerebral vasodilation and coma) complications. Theoretical advantages of bicarbonate include improved myocardial contractility, elevated ventricular fibrillation threshold, improved catecholamine tissue response, and decreased work of breathing. The disadvantages of bicarbonate include worsening hypokalemia, paradoxical CNS acidosis, worsening intracellular acidosis, impaired (shift to left) oxyhemoglobin dissociation, hypertonicity and sodium overload, delayed recovery from ketosis, elevation of lactate levels, and possible precipitation of cerebral edema. During DKA treatment, hydrogen ion production ceases when ketogenesis stops; excessive hydrogen ions are eliminated through the urine and respiratory tract. Ketone body metabolism results in the endogenous production of alkali.

The decision to use bicarbonate in DKA patients should be based on the clinical condition and pH of the patient. Potential benefits of bicarbonate in the elderly with cardiovascular instability must be balanced against the potential disadvantages.[4] There may be selected patients who benefit from cautious alkali therapy, including those with decreased cardiac contractility and peripheral vasodilatation, and patients with life-threatening hyperkalemia and coma. Patients with severe acidosis may be at higher risk for clinical deterioration, so **adults with a pH <6.9 can be given 100 mEq (100 mmol) of sodium bicarbonate in 400 mL of water with 20 mEq (20 mmol) KCl at 200 mL/h for 2 hours until the venous pH >7.0**. If the pH remains <7.0 despite the infusion, repeat the infusion until pH >7.0.[6,7] Remember to check [K^+] every 2 hours. Severe acidosis (pH <7.0) and worsening pH despite aggressive therapy for DKA should prompt investigation for other causes of metabolic acidosis (see chapter 15).

DISEASE COMPLICATIONS

COMPLICATIONS RELATED TO ACUTE DISEASE

In general, the greater the initial serum osmolality, BUN, and blood glucose concentrations, and the lower the serum bicarbonate level (<10 mEq/L), the greater the mortality.

Infection and myocardial infarction are the main contributors to mortality. Additional factors that increase morbidity include old age, severe hypotension, coma, and underlying renal and cardiovascular disease. Severe volume depletion leaves the elderly at risk for deep venous thrombosis.

COMPLICATIONS RELATED TO THERAPY

Major complications related to therapy of DKA are listed in **Table 225-4**. These include hypoglycemia, hypokalemia, hypophosphatemia, acute respiratory distress syndrome, and cerebral edema. A gradual return to normal metabolic balance will diminish the likelihood of such outcomes.

Acute respiratory distress syndrome is a rare complication of therapy but can develop, particularly in the elderly and those with impaired myocardial contractility. Overly aggressive fluid therapy decreases plasma oncotic pressure and raises left atrial end-diastolic pressure, favoring a shift of fluid across the pulmonary capillary membrane.

In very young children, new-onset diabetics, and adolescents with DKA, **cerebral edema** remains the most common and feared cause of mortality[20-24] (see chapter 145, Diabetes in Children). Young age and new-onset diabetes (particularly in young adolescents) are the only identified potential risk factors. There are no evidence-based recommendations for adults.[4] Cerebral edema is often seen when the patient appears to be improving clinically and biochemically, and carries a high mortality.[22-24] One hypothesis is that the osmotic diuresis promotes loss of water and sodium from both intra- and extracellular spaces. Hyperglycemia leads to a hyperosmolar extracellular state. Brain cells enzymatically produce osmotically active particles that protect cells from further loss of water and shrinkage. During therapy with IV fluid and insulin, water moves into brain cells faster than osmotically active particles can dissipate, promoting cellular swelling.

There are no specific presentation or treatment variables that predict or contribute to the development of cerebral edema.[21,22] Gradual replacement of water and sodium deficits and slow correction of hyperglycemia may lessen the risk.

TABLE 225-4 Potential Pitfalls During Treatment of DKA

Pitfall	Guideline (See Text for Details)
Delay in diagnosis	Blood glucose may be 250–300 milligrams/dL (13.8–16.6 mmol/L); urine ketones may initially be negative
Unrecognized precipitating illness	Check electrocardiogram for infarction; examine patient for site of infection
Inadequate fluids	Majority of adult patients tolerate 15–20 cc/kg/h normal saline for first hour (1–2 L normal saline), additional fluids by clinical condition/serum Na^+
Unrecognized low K^+	Check K^+ prior to insulin; K^+ supplement before insulin for $[K^+]$ <3.3
Overemphasis on insulin	Follow insulin guidelines
Hypoglycemia	Goal for glucose decrease 50–75 milligrams/dL/h (2.8–4.2 mmol/L); add dextrose when glucose <250 milligrams/dL (<13.8 mmol/L)
Unrecognized electrolyte derangements	During first 6 hours of treatment, check glucose hourly and electrolytes every 2 hours
Overzealous use of bicarbonate and phosphate	$NaHCO_3$ not indicated for pH >6.9; no routine indication for phosphate supplementation
Recurrent DKA	Avoid stopping insulin drip until anion gap resolves. Give subcutaneous insulin, feed patient, stop insulin drip 1–2 h before stopping insulin drip.
Cerebral edema **NOT** recognized early	See **Table 225-5**. Very young and new-onset patients at risk; perform frequent neurologic checks for mental status change

Premonitory symptoms are severe headache, incontinence, change in arousal or behavior, pupillary changes, blood pressure changes, seizures, bradycardia, or disturbed temperature regulation. Any change in neurologic function early in therapy is an indication for IV mannitol (1 to 2 grams/kg).[24] Mannitol should be given before respiratory failure or obtaining confirmatory CT scans because serious morbidity and mortality may be prevented. Hypertonic saline (3%), 5 to 10 mL/kg over 30 minutes, may be an alternative to mannitol.[20,22] Intubation and fluid restriction are generally necessary. There are no data supporting glucocorticoid use in DKA-related cerebral edema.

LATER COMPLICATIONS

Metabolic acidosis refractory to routine therapy may be secondary to unrecognized infection (lactic acidosis), rarely insulin antibodies, or improper preparation or administration of the insulin drip. Shock that is unresponsive to aggressive fluid therapy suggests gram-negative bacteremia or silent myocardial infarction. Hyperchloremic non–anion gap metabolic acidosis can develop during therapy due to rapid volume expansion in the face of reduced bicarbonate. In addition, bicarbonate equivalents are excreted in the urine as ketones and are replaced with chloride provided by the normal saline. This emphasizes the importance of monitoring the anion gap during therapy. The non–anion gap metabolic acidosis resolves during recovery as bicarbonate is regenerated and excess chloride is excreted in the urine.

Late vascular thrombosis may occur in any muscular artery, although the cerebral vessels appear to be most susceptible. Volume depletion, low cardiac output, increased blood viscosity, and underlying atherosclerosis may predispose the elderly to this complication. Thrombosis may occur several hours or days after institution of therapy and after resolution of ketoacidosis. Despite this increased risk, no studies support prophylactic anticoagulant use, although some experts suggest the use of heparin may be beneficial in DKA if there is no associated bleeding disorder.[7,14]

Mortality in DKA results mainly from sepsis or pulmonary and cardiovascular complications in the elderly and fatal cerebral edema in children and young adults (**Table 225-6**).

TABLE 225-5 Best Practice to Prevent Cerebral Edema

Slow reduction of osmolality during treatment
Avoid large volumes of hypotonic fluid
Drop blood glucose slowly during treatment
Do not allow plasma Na^+ to fall during treatment
Avoid unnecessary bicarbonate during treatment
Avoid hypoxia, hypo-K^+, PO_4, Mg

DISPOSITION AND FOLLOW-UP

The great majority of patients require hospitalization in a monitored setting where there is nursing experience with IV insulin infusions. In many institutions, patients are cared for initially in an intensive or intermediate care unit. A select group of patients with an anion gap of <25, a glucose level of <600 milligrams/dL (<33.3 mmol/L), and no comorbidity at the time of disposition decision may be managed safely on an inpatient unit with nursing expertise using insulin infusions and managing diabetic patients. Some institutions may have protocols for the use of SC rapid-acting insulin on a medical floor. Patients presenting early in the course of their illness who can tolerate oral liquids may be managed safely in the ED or observation unit and discharged after 6 to 12 hours of therapy.

SPECIAL POPULATIONS

RECURRENT DKA PATIENTS

Patients who present to the ED with recurrent episodes of DKA should have barriers to care access addressed while in the ED or during their hospital stay. In urban settings, insulin noncompliance is a major trigger for recurrent DKA. Cocaine is an independent risk factor for DKA, and patients who use illicit drugs may benefit from drug rehabilitation.[6,7] Using social workers to assist patients with drug access and affordability, drug rehabilitation when indicated, and education provided by the diabetic care team can promote improved glycemic control.[26]

PATIENTS WITH INSULIN PUMPS

See chapter 223, for a detailed discussion of insulin pumps. **Patients with insulin pumps who are suspected to have DKA should have their pumps disconnected and turned off and should be treated just like any other patient. Reinstitution of pump therapy should start in the same time frame as switching over to SC insulin in the non–pump user.**

TABLE 225-6 Complications of Diabetic Ketoacidosis

Related to Acute Disease	Related to Therapy	Later Complications
Loss of airway	Hypokalemia	Recurrent anion gap metabolic acidosis
Sepsis	Hypophosphatemia	Non–anion gap metabolic acidosis
Myocardial infarction	Acute respiratory distress syndrome	Vascular thrombosis
Hypovolemic shock	Cerebral edema	Mucormycosis
	Hypoglycemia	

DKA IN PREGNANCY

DKA in pregnancy is a leading cause of fetal loss, with a fetal mortality rate of approximately 30%.[25,26] Several physiologic changes make diabetic pregnant women prone to DKA. Maternal fasting serum glucose levels are normally lower, which leads to relative insulin deficiency and an increase in baseline free fatty acid levels in the blood. DKA is triggered at lower sugar levels in pregnancy.[24] Pregnant women normally have increased levels of counterregulatory hormones. In addition, the chronic respiratory alkalosis seen in pregnancy leads to decreased bicarbonate levels due to a compensatory renal response, resulting in a decrease in buffering capacity. Pregnancy is associated with vomiting and urinary tract infections, which can precipitate DKA. Maternal hyperglycemia causes fetal hyperglycemia and osmotic diuresis. Maternal acidosis causes fetal acidosis, decreases uterine blood flow and fetal oxygenation, and shifts the oxygen-hemoglobin dissociation curve to the right. Maternal hypokalemia also can lead to fetal dysrhythmias and death. **Correction of maternal hyperglycemia, acidosis, and electrolyte balance are the first priorities.**

CHAPTER 226

Alcoholic Ketoacidosis

William A. Woods
Debra G. Perina

INTRODUCTION

Alcoholic ketoacidosis is a wide anion gap metabolic acidosis, most often associated with acute cessation of alcohol consumption after chronic alcohol abuse, and is typically associated with nausea, vomiting, and vague GI complaints.[1] Metabolism of alcohol combined with little or no glycogen reserves results in elevated ketoacid levels. Although alcoholic ketoacidosis is usually seen in chronic alcoholics, it has been described in first-time binge drinkers. Repeated episodes can occur.[2] Although with proper treatment this illness is self-limited, death has been reported from presumed excessive ketonemia.[2-4]

PATHOPHYSIOLOGY

Ethanol metabolism requires nicotinamide adenine dinucleotide (NAD) and the enzymes alcohol dehydrogenase and aldehyde dehydrogenase to convert ethanol to acetyl coenzyme A. Acetyl coenzyme A may be metabolized directly, resulting in ketoacid production; used as substrate for the Krebs cycle; or used for free fatty acid synthesis (**Figure 226-1**).

Alcoholic ketoacidosis occurs when NAD is depleted by ethanol metabolism, resulting in inhibition of the aerobic metabolism in the Krebs cycle, depletion of glycogen stores, ketone formation, and lipolysis stimulation. Ethanol metabolism results in NAD depletion manifesting as a higher ratio of the reduced form of nicotinamide adenine dinucleotide (NADH) to NAD. When glycogen stores are depleted in a patient stressed by concurrent illness or volume depletion, insulin secretion is also suppressed. Under these same conditions, glucagon, catecholamine, and growth hormone secretion are all stimulated. This hormonal milieu inhibits aerobic metabolism in favor of anaerobic metabolism and stimulates lipolysis. Acetyl coenzyme A is metabolized to the ketoacids, β-hydroxybutyrate (βHB) and acetoacetate.

NAD is used in the conversion of βHB to acetoacetate (AcAc + NADH ⇌ βHB + NAD). Due to the depletion of NAD, βHB is the predominant ketone product formed. Normally, the ratio of acetoacetate to βHB is 1:1; however, in alcoholic ketoacidosis, the ratio can be 1:7 or higher.[5] Once the NADH:NAD returns to normal, lactate levels decrease and acetoacetate increases.[1] The ratio of βHB to acetoacetate is also much higher in alcoholic ketoacidosis than in diabetic ketoacidosis.[1] The high NADH:NAD ratio also results in increased lactate production, so lactate levels are higher than normal in alcoholic ketoacidosis but not as high as in shock or sepsis. Acetoacetate is metabolized to acetone so that acetone and its metabolites are elevated and may cause an osmolal gap.

Ketone production can be further stimulated in malnourished, vomiting patients or in those who are hypophosphatemic.[6] Both conditions are seen commonly in alcoholic patients with alcoholic ketoacidosis.

CLINICAL FEATURES

The typical history is an episode of heavy drinking followed by vomiting and an acute decrease in alcohol consumption. The most common symptoms are nausea, vomiting, and nonspecific abdominal pain.[2] Associated gastritis or pancreatitis may occur. Mental status changes are typically secondary to other causes, such as toxic ingestion, hypoglycemia, alcohol-withdrawal seizures, postictal state, or unrecognized head injury.

DIAGNOSIS

Diagnosis is made in the appropriate clinical setting and is based on laboratory evaluation. Laboratory evaluation should include CBC; electrolyte panel with calcium, phosphate, and magnesium; ethanol, methanol, and isopropyl alcohol levels; hepatic enzymes; lipase; and serum ketones. Determination of serum lactic acid level and serum osmolality also may be helpful. Diagnosis is made by the criteria listed in **Table 226-1**, with metabolic acidosis, positive serum ketones, elevated anion gap, and a low or mildly elevated serum glucose level. Patients frequently have hypophosphatemia, hyponatremia, and/or hypokalemia. Most patients also will have elevated bilirubin and liver enzyme levels due to liver disease from a long history of chronic ethanol use. BUN levels frequently are elevated due to relative volume depletion. The nitroprusside reagent used to measure urine and serum ketones measures acetoacetate. Acetone is

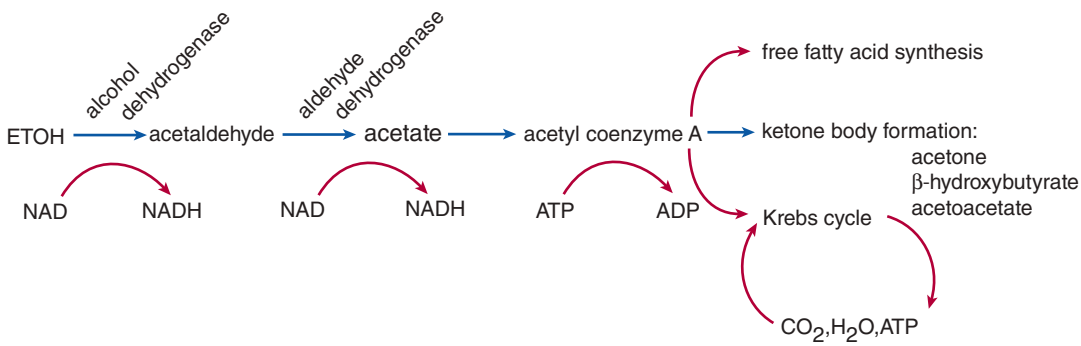

FIGURE 226-1. Ethanol metabolism. ADP = adenosine diphosphate; ATP = adenosine triphosphate; ETOH = ethanol; NAD = nicotinamide adenine dinucleotide; NADH = the reduced form of nicotinamide adenine dinucleotide.

TABLE 226-1 Diagnostic Criteria for Alcoholic Ketoacidosis*

Positive serum ketones*
Wide anion gap metabolic acidosis without alternate explanation

*The absence of ketones in the serum based on the nitroprusside test does not exclude the diagnosis.

weakly reactive, and βHB is not detected at all. So, the initial ketone levels may be low or negative in alcoholic ketoacidosis. With recovery, acetoacetate increases and assays become positive.[1] A small to moderate anion gap is invariable in alcoholic ketoacidosis. **Without routine evaluation of the anion gap in every patient at risk for alcoholic ketoacidosis, the diagnosis can be easily missed.** The anion gap is usually 16 to 33, with a mean of 21,[2] and is due to ketonemia, primarily from βHB. The osmolal gap may be slightly elevated because acetone and its metabolites cause an osmolal gap (<20 mmol/kg).[1] Consider co-ingestions or other causes of anion gap acidosis if the anion gap fails to close with ongoing treatment. Mild lactic acidosis may be present due to a shift to pyruvate metabolism toward lactate[1].

DIFFERENTIAL DIAGNOSIS

Table 226-2 and chapter 15, Acid-Base Disorders, list the most important causes of metabolic acidosis that should be excluded to diagnose alcoholic ketoacidosis.

Alcoholic ketoacidosis should be differentiated from other alcohol ingestions. Methanol and ethylene glycol ingestions do not produce ketosis, and acidosis tends to be severe. Isopropyl alcohol ingestion results in production of ketones. The presence of a large osmolal gap suggests acute isopropyl, ethanol, methanol, or ethylene glycol ingestion. If the blood alcohol level is known, then its contribution to any osmolal gap can be calculated. **Each 100 milligrams/dL (21.7 mmol/L) of ethanol raises the osmolal gap by 22**. Details of osmolal gap are discussed in chapter 17, Fluids and Electrolytes.

The presence of a mixed acid-base disturbance suggests a comorbid disorder. Common concurrent illnesses are dehydration and electrolyte disturbances from vomiting and reduced intake, pancreatitis, gastritis or upper GI bleeding, seizures, alcohol withdrawal, pneumonia, sepsis, and hepatitis.

Starvation ketosis occurs in patients with diminished carbohydrate intake, resulting in lipolysis and ketonuria. Ketone bodies appear after about 3 days of fasting but can appear earlier in the presence of stress and dehydration. Metabolic acidosis and ketonemia are rare in starvation ketosis, but ketonuria is common.[7]

TABLE 226-2 Differential Diagnosis for Alcoholic Ketoacidosis

Alternative diagnosis	Alternative or concomitant diagnosis
Lactic acidosis	Methanol ingestion
Uremia	Ethylene glycol ingestion
Secondary lactic acidosis	Isopropanol ingestion
Sepsis	Pancreatitis
Hypotension	Gastritis
Salicylic acid ingestion	Upper GI bleeding
Toxic alcohol ingestion	Seizures
Diabetic ketoacidosis	Ethanol withdrawal
Starvation ketosis	Pneumonia
	Sepsis
	Hepatitis

TABLE 226-3 Treatment of Alcoholic Ketoacidosis

Administer 5% dextrose in normal saline for rehydration. Then change to 5% dextrose in half normal saline as maintenance until oral intake resumes.
Replace potassium and magnesium.
Optional: 50–100 mg thiamine and 1 mg folate IV concurrent with, or after, glucose administration (see text below).
Avoid bicarbonate therapy unless pH <7.1 and unresponsive to fluid and glucose administration.
Consider other causes of anion gap acidosis if the anion gap is <20 mEq/L or fails to close with ongoing treatment.

TREATMENT

Therapy consists of both glucose administration and volume repletion (**Table 226-3**). Fluids alone do not correct the ketoacidosis as fast as fluids and glucose administered together. Glucose stimulates insulin production, which stops lipolysis and halts further ketone formation. Glucose also increases oxidation of NADH to NAD, thereby further stopping ketone production. The fluid of choice is 5% dextrose in normal saline. Once fluid and electrolyte losses are replaced, change fluids to 5% dextrose in half normal saline until oral intake is assured.[1] Patients with alcoholic ketoacidosis are not hyperosmolar. Unlike treatment of diabetic ketoacidosis, cerebral edema is of little concern with large volumes of fluid administration. Even with vigorous fluid resuscitation, in our review of the literature, cerebral edema has not been reported among those being treated for alcoholic ketoacidosis.

Insulin is of no proven benefit and can even be dangerous, as patients often have depleted glycogen stores and normal or low glucose levels. **Sodium bicarbonate is not indicated unless patients are severely acidemic, with a pH <7.0.** Severe acidemia is unlikely to be explained by alcoholic ketoacidosis alone. Mildly elevated osmolal gaps can exist, but it is important to consider co-ingestions, or other causes of anion gap acidosis, if the gap fails to close with ongoing fluid and carbohydrate treatment. Hypophosphatemia is common in alcoholics and can retard the resolution of acidosis because phosphorus is necessary for mitochondrial utilization of glucose for oxidation of NADH. However, phosphate replacement generally is unwarranted in alcoholic ketoacidosis unless levels are very low (<1.0 milligram/dL or <0.323 mmol/L).[6] Serum ketone levels correlated with clinical status may be used to help guide therapy because an increasingly positive reaction signifies improvement.

The prevalence of key vitamin deficiencies in alcohol-dependent patients is unknown but is probably low.[8] Some feel that the practice of routine administration of **IV thiamine** or **multivitamins** in the ED is necessary to prevent the theoretical precipitation of Wernicke's disease,[9] whereas others feel that vitamin supplementation in the ED should be reserved for those with confirmed deficiencies or who are truly at high risk for such deficiencies.[10] If vitamins are given, they can be provided concurrently with, or after, the administration of glucose.[11] Oral vitamin supplementation has also been described, with IM thiamine added to the oral regimen.[8] Administration of magnesium sulfate should be guided by laboratory results. Acidosis should clear within 12 to 24 hours.

DISPOSITION AND FOLLOW-UP

Patients with an uncomplicated ED course may be safely discharged home if there is resolution of acidosis and the patient is able to tolerate oral fluids. Patients should receive counseling on alcohol dependence, be encouraged to use multivitamins, and be offered treatment in an alcohol detoxification program. Patients with a complicated course, underlying illnesses, or persistent acidosis should be admitted for further evaluation and treatment (**Table 226-3**).

CHAPTER 227

Hyperosmolar Hyperglycemic State

Charles S. Graffeo

INTRODUCTION AND EPIDEMIOLOGY

The **hyperosmolar hyperglycemic state (HHS)** is characterized by progressive hyperglycemia and hyperosmolarity typically found in a debilitated patient with poorly controlled or undiagnosed type 2 diabetes mellitus, limited access to water, and commonly, a precipitating illness. A number of terms, including ***hyperosmolar hyperglycemic nonketotic state/coma/syndrome*** and ***nonketotic hyperglycemic coma***, are used to describe HHS. The syndrome does not necessarily include ketosis or coma, and we will use the terminology adopted by the American Diabetes Association.[1] Most cases of HHS occur in the elderly with comorbid organ or metabolic diseases, and about 70% of patients have been previously diagnosed as diabetics. However, the incidence in children is increasing, with the common risk factors being obesity and African American race.[2]

PATHOPHYSIOLOGY

The basic pathophysiology of diabetes is discussed in chapter 223, Type 1 Diabetes Mellitus, and chapter 224, Type 2 Diabetes Mellitus. The development of HHS is attributed to three main factors: (1) insulin resistance and/or deficiency; (2) an inflammatory state with marked elevation in proinflammatory cytokines (C-reactive protein, interleukins, tumor necrosis factors) and counterregulatory hormones (growth hormone, cortisol) that cause increased hepatic gluconeogenesis and glycogenolysis; and (3) osmotic diuresis followed by impaired renal excretion of glucose.[3]

In a patient with type 2 diabetes, physiologic stresses combined with inadequate water intake in an environment of insulin resistance or deficiency lead to HHS. As serum glucose concentration increases, an osmotic gradient develops, attracting water from the intracellular space into the intravascular compartment, causing cellular dehydration. The initial increase in intravascular volume is accompanied by a temporary increase in the glomerular filtration rate. As serum glucose concentration increases, the capacity of the kidneys to reabsorb glucose is exceeded, and glucosuria and osmotic diuresis occur. During osmotic diuresis, significant urinary loss of sodium and potassium, as well as more modest losses of calcium, phosphate, and magnesium may occur. As volume depletion progresses, renal perfusion decreases, and the glomerular filtration rate is reduced. Renal tubular excretion of glucose is impaired, which further worsens hyperglycemia. A sustained osmotic diuresis may result in total body water losses that often exceed 20% to 25% of total body weight, or approximately 8 to 12 L in a 70-kg patient.

The relative lack of severe ketoacidosis in HHS is poorly understood and has been attributed to three possible mechanisms: (1) higher levels of endogenous insulin than are seen in diabetic ketoacidosis, which inhibits lipolysis; (2) lower levels of counterregulatory "stress" hormones; and (3) inhibition of lipolysis by the hyperosmolar state itself. Evidence of significant ketoacidosis in a patient thought to have type 2 diabetes should bring into question the possibility of variants of type 1 diabetes, such as latent autoimmune diabetes in adults.[4] Additionally, a greater proportion of ketosis-prone type 2 diabetes has been described in black, Hispanic, and other populations.[5,6] This growing body of evidence identifying ketosis-prone type 2 diabetes has prompted a call by some for the reclassification of diabetes mellitus.[7]

CLINICAL FEATURES

HISTORY AND COMORBIDITIES

The typical patient with HHS is usually elderly with comorbid medical conditions who is often referred by a caretaker for fever, other abnormalities in vital signs, and/or mental status changes that have evolved over days or weeks. Complaints are often nonspecific and may include weakness, anorexia, fatigue, dyspnea, or chest or abdominal pain. Many patients have previously undiagnosed or poorly controlled type 2 diabetes precipitated by pneumonia or urinary tract infection. Underlying cardiovascular, respiratory, renal, or neurologic disease is common. Psychiatric patients taking antipsychotics or lithium may present a particular risk, and HHS should be considered as part of the medical screening process for ED psychiatric patients.[8]

HHS is associated with a host of conditions (**Table 227-1**) and drugs (**Table 227-2**) that may predispose to hyperglycemia and volume depletion.

TABLE 227-1 Conditions That May Precipitate Hyperosmolar Hyperglycemic State

Diabetes
Infection, especially pneumonia or urinary tract infection
Myocardial infarction
Renal insufficiency
Cerebrovascular events
Mesenteric ischemia
GI hemorrhage
Pulmonary embolism
Pancreatitis
Severe burns
Parenteral or enteral alimentation
Peritoneal or hemodialysis
Heat-related illness
Rhabdomyolysis

PHYSICAL EXAMINATION

The physical manifestations associated with HHS are nonspecific. Generally, clinical signs of volume depletion such as poor skin turgor, dry mucous membranes, sunken eyes, and hypotension will correlate with the degree of hyperglycemia and hyperosmolality.

Normothermia or hypothermia is common due to vasodilation, and hypothermia is a poor prognostic sign. HHS may develop in those who have sustained a physiologic stress, such as a cerebrovascular accident, severe burns, a myocardial infarction, infection, or other acute illness. Up to 15% of patients may present with seizures, which are typically focal, although generalized seizures may occur. The degree of lethargy and coma has a linear relationship to serum osmolality. Patients with coma tend to be older and have higher osmolality, more severe hyperglycemia, acidosis, and greater volume contraction.[9]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

HHS is "defined" by severe hyperglycemia with serum glucose usually >600 milligrams/dL (>33.3 mmol/L), an elevated calculated plasma osmolality of >315 mOsm/kg (>315 mmol/kg), serum bicarbonate

TABLE 227-2 Some Drugs That May Predispose Individuals to the Development of HHS

#Anion gap calculation: $[Na^+] - [Cl^-] + [HCO_3^-]$.

>15 mEq/L (>15 mmol/L), an arterial pH >7.3, and serum ketones that are negative to mildly positive in a 1:2 dilution (by nitroprusside method). These values, however, are fairly arbitrary. Metabolic acidosis or ketonemia associated with HHS is likely to be due to tissue hypoperfusion (lactic acidosis), starvation ketosis, and azotemia in various combinations, although there is growing evidence for ketosis-prone type 2 diabetic subgroups. **It is important to recognize the potential for a variety of mixed acid-base patterns in patients with HHS.**

A comparison of the laboratory features of diabetic ketoacidosis and HHS is shown in **Table 227-3**.

LABORATORY TESTING AND IMAGING

Tailor laboratory tests to the patient and the clinical findings. A comprehensive metabolic profile, calculated and measured serum osmolality, urine osmolality, lactic acid, serum ketones, magnesium, CBC with differential, and blood and urine cultures should all be considered. In addition, cardiac markers, total creatine phosphokinase, arterial or venous blood gas, thyroid function studies, procalcitonin, and coagulation profiles might be needed. Chest radiographs and electrocardiograms are generally recommended. Diagnostic studies, such as CT, lumbar puncture, and toxicologic studies, should be patient specific.

In general, electrolyte abnormalities vary. Initially, contraction alkalosis due to a profound water deficit may occur. An anion gap metabolic acidosis is often attributable to sepsis, poor tissue perfusion, starvation ketosis, or renal impairment.

Sodium Serum sodium level varies and is not a reliable indicator of the degree of volume contraction. Hyperglycemia has a dilutional effect on measured serum sodium: **Serum Na^+ decreases by approximately 1.6 mEq/L (1.6 mmol/L) for every 100 milligrams/dL (5.6 mmol/L) increase in serum glucose >100 milligrams/dL (5.6 mmol/L) (Formula 222-1).**

Formula for glucose in mg/dL

$$\text{Corrected}\,[Na^+] = \text{Measured}\,[Na^+] + \frac{1.6 \times (\text{glucose in mg/dL} - 100)}{100}$$

Formula for glucose in mmol/L

$$\text{Corrected}\,[Na^+] = \text{Measured}\,[Na^+] + \frac{1.6 \times (\text{glucose in mmol/L} - 5.6)}{5.6}$$

FORMULA 227-1. Formula for correction of sodium in presence of severe hyperglycemia.

For glucose levels >400 milligrams/dL (22.2 mmol/L), a correction factor of 2.4 may be more accurate.

Osmolality Serum osmolality correlates positively with severity of disease as well as mental status changes and coma. A calculated effective serum osmolality excludes osmotically inactive urea, which is usually included in laboratory measures of osmolality (**Formula 227-2**).

$$2[Na^+] + \frac{\text{glucose}}{18}$$

FORMULA 227-2. Formula for calculation of serum osmolality in presence of severe hyperglycemia.

The normal serum osmolality range is approximately 275 to 295 mOsm/kg. Values >300 mOsm/kg are usually indicative of significant hyperosmolality, and those >320 mOsm are commonly associated with alterations in cognitive function.

Potassium On average, potassium losses range from 4 to 6 mEq/kg, although deficits can be as high as 10 mEq/kg body weight. Despite these total body deficits, initial serum laboratory measurements may be normal or even high in the presence of acidemia. Initial values may be reported as normal with volume contraction and with metabolic acidosis when intravascular $[H^+]$ ions are exchanged for intracellular $[K^+]$ ions. As intravascular volume is replaced and acidemia is reversed, $[K^+]$ deficiency becomes more apparent.

Other Laboratory Testing Hypomagnesemia is common, and serum magnesium levels should be monitored and replaced as appropriate.[10] Consequences of hypophosphatemia, such as CNS abnormalities, cardiac dysfunction, and rhabdomyolysis, are uncommon and usually associated with serum phosphate levels below 1.0 milligram/dL. Routine replacement of phosphate, unless severe, is usually unnecessary, and replacement may lower ionized calcium levels.[11] Prerenal azotemia is common, with plasma blood urea nitrogen:creatinine ratios often exceeding 30:1. Leukocytosis is variable but is usually due to infection or hemoconcentration.

TREATMENT

Improvement of tissue perfusion is the key to effective recovery in HHS. **Treatment includes correction of hypovolemia, identifying and treating precipitating causes, correcting electrolyte abnormalities, gradual correction of hyperglycemia and hyperosmolarity, and frequent monitoring.** The therapeutic plan must be carefully considered and adjusted for concurrent medical illnesses such as left ventricular dysfunction and renal insufficiency. Data flow sheets that document chronological clinical and laboratory parameters are important adjuncts to successful patient management.

Due to the potential for complications associated with patient comorbidities, rapid therapy should be reserved for potentially life-threatening electrolyte abnormalities only. A protocol for treating severely ill patients likely requiring intensive care unit–level care is shown in **Figure 227-1.**

FLUID RESUSCITATION

Fluid resuscitation replenishes intravascular volume, improves tissue perfusion, and decreases serum glucose about 35 to 70 milligrams/dL/h. **Begin normal saline infusion before insulin therapy is started.**

The average fluid deficit in HHS is in the range of 20% to 25% of total body water, or 8 to 12 L. In the elderly, approximately 50% of body weight is due to total body water. By using the patient's usual current weight in kilograms, normal total body water and water deficit can be calculated. **One half of the fluid deficits should be replaced over the initial 12 hours and the balance over the next 24 hours when possible.** The actual rate of fluid administration should be individualized for each patient, based on the presence of renal and cardiac impairment. **Begin fluid resuscitation with 0.9% normal saline at a rate of 15 to 20 mL/kg/h during the first hour, followed by rates from 4 to 14 mL/kg/h.** Limit the rate of volume repletion during the first 4 hours to <50 mL/kg of normal saline. Patients

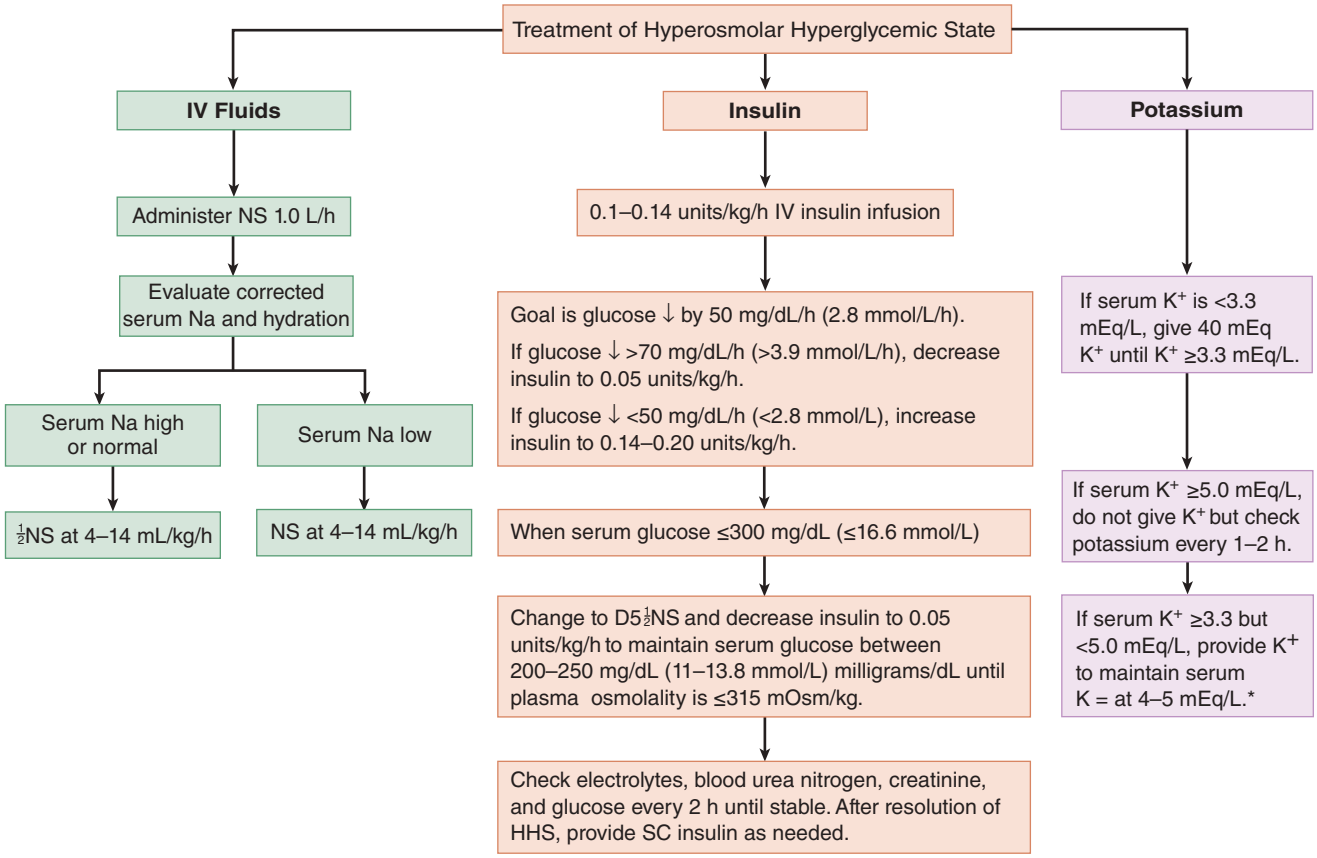

FIGURE 227-1. Protocol for the management of severely ill adult patients with hyperosmolar hyperglycemic state (HHS). *Concentrations of K^+ ≥20 mEq/L should be administered via central line. D5½NS = 5% dextrose in half normal saline; HHS = hyperosmolar hyperglycemic state; NS = normal saline.

with cardiac disease may require a more conservative rate of volume repletion. Once hypotension, tachycardia, and urinary output improve, 0.45% NaCl can be used to replace the remaining free water deficit. Urinary bladder catheterization and intravascular arterial and central venous access should be considered for monitoring progress in the critically ill.

ELECTROLYTES

Hypokalemia is a risk for dysrhythmia and should be anticipated, and potassium should be replaced during volume repletion and insulin administration. If the initial serum potassium measurement is <3.3 mEq/L, begin potassium supplementation and withhold insulin therapy until potassium is replenished.

In general, replace potassium at a rate of 10 to 20 mEq/h. For life-threatening hypokalemia, infusion rates of up to 40 mEq/h may be needed. If properly diluted, infusions of potassium through peripheral IV lines are well tolerated; however, the central venous line route is preferred when available and decreases the risk of extravasation. Monitor serum potassium levels every hour until a steady state has been achieved.

Sodium deficits are replenished fairly rapidly, considering the amount of normal saline given during IV fluid replacement. Replace **magnesium deficits** with 1 to 2 grams of magnesium given over 1 hour. Phosphate should only be replaced if the phosphate level is <1.0 milligram/dL (<1.0 mmol/L). The dose of IV potassium phosphate is 2.5 to 5 milligrams/kg (0.08 to 0.16 mmol/kg) over 6 hours. **Sodium bicarbonate** is recommended only if serum pH is <7.0.[1] Adverse effects of bicarbonate include hypokalemia, hypocalcemia, and abrupt changes in CNS pH levels.

INSULIN

Begin insulin after fluid resuscitation has begun. Intravascular volume may be further depleted as insulin causes a shift of osmotically active glucose into the intracellular space, bringing free water with it.

The absorption of insulin by the IM or SC route is unreliable in patients with HHS, and a continuous infusion of regular insulin is recommended. Although initiation of insulin therapy with a bolus of 0.1 unit/kg followed by a continuous infusion of 0.1 unit/kg/h is included as a treatment option in the current American Diabetes Association recommendations, there is no proven benefit over a simple continuous infusion beginning at >0.1 unit/kg/h.[1] The addition of bolus dosing of insulin is included as a recommendation when initial glucose levels have not dropped by 10% in the first hour of treatment. With adequate hydration and insulin therapy, the goal of therapy is to maintain a steady rate of decline in the glucose concentration of 50 to 75 milligrams/dL/h (2.8–4.1 mmol/L/h). With adequate hydration, the insulin infusion may be doubled every hour until a steady glucose decline as described above is achieved. If glucose falls too rapidly, decrease the infusion rate by half, to 0.05 or 0.07 unit/kg/h. Once serum glucose decreases to <300 milligrams/dL (<16.6 mmol/L), change the IV solution to 5% dextrose in half normal saline, and reduce the insulin infusion to 0.02 to 0.05 unit/kg/h until serum osmolality is <315 mOsm/kg and glucose is maintained between 200 and 300 milligrams/dL (11.1–16.6 mmol/L). Once the patient is mentally alert and able to eat, considerations for SC insulin dosing can be made.

DISEASE COMPLICATIONS

Despite cerebral edema representing >50% of fatalities in children with diabetic ketoacidosis, **cerebral edema is an uncommon complication in adults with HHS**. There are little data on the incidence of or clinical indicators that may predispose to cerebral edema in adults. The current recommendation is to limit the rate of volume repletion during the first 4 hours to <50 mL/kg of normal saline. Monitor the patient's mental

status during treatment, and obtain a stat head CT if mental deterioration develops during treatment. While there are no evidence-based treatments for cerebral edema, mannitol as an osmotic agent remains the most practical option.

More common complications, such as hypoglycemia, hypokalemia, and pulmonary edema, are generally associated with overzealous resuscitation and inadequate monitoring.

DISPOSITION AND FOLLOW-UP

When considering the patient population predisposed to developing HHS (debilitated patients with multiple comorbidities), intensive care unit monitoring for the initial 24 hours of care is usually the most appropriate ED disposition. Patients without significant comorbid conditions and who demonstrate a good response to initial therapy as evidenced by documented improvement in vital signs, urine output, electrolyte balance, and mentation may be considered for step-down admission.

CHAPTER 228

Hypothyroidism

Alzamani Mohammad Idrose

INTRODUCTION AND EPIDEMIOLOGY

Hypothyroidism is a clinical syndrome caused by insufficient thyroid hormone production, which slows cell metabolism. Hypothyroidism is common in areas where iodine deficiency is common, particularly inland areas where there is no access to marine foods. In iodine-sufficient areas, chronic autoimmune destruction of thyroid gland (e.g., Hashimoto's thyroiditis) and iatrogenic causes from treatment of Graves' disease are the leading causes of hypothyroidism (after thyroidectomy or radioactive iodine ablation). The prevalence of hypothyroidism increases with age, and the disorder is nearly 10 times more common in females than in males.[1] Subclinical hypothyroidism is more prevalent than overt hypothyroidism in all age groups and can be seen in 4% to 15% of women, especially the elderly.[2,3]

Hypothyroidism occurs in 1% to 32% of patients taking amiodarone.[1]

PATHOPHYSIOLOGY

Primary hypothyroidism is caused by the intrinsic dysfunction of the thyroid gland, and this is the most common type. **Secondary hypothyroidism** is caused by a deficiency of thyroid-stimulating hormone from the pituitary gland or deficiency of thyrotropin-releasing hormone from the hypothalamus. **Table 228-1** lists common causes of hypothyroidism. **Euthyroid sick syndrome or low thyroxine syndrome**, also called nonthyroidal illness, is the term used for patients with low triiodothyronine and thyroxine levels and a normal or low thyroid-stimulating hormone level, but who are clinically euthyroid. This condition is found in critically ill patients or those with severe systemic illness.

Triiodothyronine is the major form of thyroid hormone. The ratio of triiodothyronine to thyroxine released in the blood is about 10:1. Peripherally, triiodothyronine is converted to the active **thyroxine**, which is three to four times more potent than triiodothyronine. The half-life of triiodothyronine is 7 days, and the half-life of thyroxine is about 1 day.

TABLE 228-1 Common Causes of Hypothyroidism

Primary Hypothyroidism (disorders of thyroid gland)	Secondary Hypothyroidism (disorders at hypothalamic-pituitary axis)
Autoimmune etiologies (Hashimoto's)	Panhypopituitarism
Thyroiditis (subacute, silent, postpartum)*	Pituitary adenoma
Iodine deficiency	Infiltrative causes (e.g., hemochromatosis, sarcoidosis)
After ablation (surgical, radioiodine)	
After external radiation	Tumors impinging on the hypothalamus
Infiltrative disease (lymphoma, sarcoid, amyloidosis, tuberculosis)	History of brain irradiation Infection (e.g., tuberculosis of the brain)
Other Causes	
Congenital	
Drugs affecting thyroid gland function	
Amiodarone	
Lithium	
Potassium perchlorate	
Iodine (in patients with preexisting autoimmune disease)	
α-Interferon	
Interleukin-2	
Idiopathic	

*Self-limiting etiologies, often preceded by hyperthyroid phase before getting into hypothyroid phase.

CLINICAL FEATURES OF HYPOTHYROIDISM

Symptoms can manifest in all organ systems and range in severity based on the degree of hormone deficiency (**Table 228-2**).

The common clinical features of hypothyroidism are listed in **Table 228-2**. Additional cardiopulmonary findings include angina, bradycardia, distant heart sounds from pericardial effusion, low voltage on the electrocardiogram, pleural effusions, cardiomyopathy, or hypoventilation.

Figures 228-1 and **228-2** show some characteristic findings of myxedema.

Table 228-3 describes the differences between primary and secondary hypothyroidism.

TABLE 228-2 Symptoms and Signs of Hypothyroidism

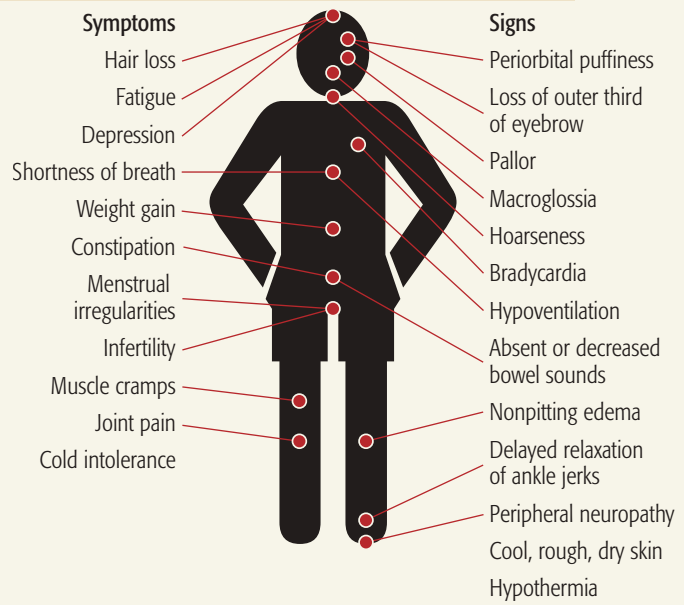

FIGURE 228-1. Myxedema (non-pitting edema) in a patient with hypothyroidism. [Image used with permission of Dr. Zanariah Hussein.]

CLINICAL FEATURES OF MYXEDEMA CRISIS

Myxedema crisis is a state of metabolic and multiorgan decompensation characterized by uncorrected hypothyroidism, mental status changes or coma, and hypothermia (usually <35.5°C [95.9°F]).[1] In hypothyroid patients, myxedema coma can be precipitated by a number of conditions, including infection, anesthetic agents, cold exposure, trauma, myocardial infarction or congestive heart failure, cerebrovascular accident, GI hemorrhage, metabolic conditions, hypoxia, hypercapnia, hyponatremia, hypoglycemia, surgery, burns, medications (e.g., β-blockers, sedatives, narcotics, phenothiazine, amiodarone), or thyroid medication noncompliance.

FIGURE 228-2. Hypothyroidism patient with facial swelling. [Image used with permission of Dr. Zanariah Hussein.]

TABLE 228-3 Differentiation of Primary and Secondary Hypothyroidism

Point of Difference	Primary Hypothyroidism	Secondary Hypothyroidism
Previous thyroid operation	Yes	None
Obese	More obese	Less obese
Hypothermia	More common	Less common
Voice	Coarse	Less coarse
Pubic hair	Present	Absent
Skin	Dry and coarse	Fine and soft
Heart size	Increased	Normal
Menses and lactation	Normal	No lactation, amenorrhea
Sella turcica size	Normal	May be increased
Serum TSH	Increased	Decreased
Plasma cortisol	Normal	Decreased
Response to TSH	None	Good
Response to levothyroxine without steroids	Good	Poor response

Abbreviation: TSH = thyroid-stimulating hormone.

The characteristic hypothyroid habitus is evident, as well as bradycardia, hypotension, hypothermia, hypoventilation, and altered mental status or coma. Blood pressure is quite variable, but of patients in full myxedema coma, half initially exhibit clinical shock with systolic pressure <100 mm Hg.[4,5] The capillaries are "leaky," and this may contribute to hypotension. Infection may be present even though fever, tachycardia, sweating, and leukocytosis may not be evident, because bradycardia and hypothermia mask these signs. Respiratory insufficiency and altered mental status can result from carbon dioxide narcosis. Pleural effusions are frequently demonstrable. Other potential respiratory problems include upper airway obstruction from glottic edema, vocal cord edema, and macroglossia. Metabolism of tranquilizers, sedatives, and anesthetics is reduced in hypothyroidism, and the exaggerated effects of such medications can also contribute to altered mental status. **Hypothermia is so common in myxedema that a normal temperature should suggest an underlying infection.** Hypothyroid habitus, absence of shivering, and pseudomyotonic reflexes (prolonged relaxation phase of deep tendon reflex—at least twice as long as the contraction phase) may help distinguish myxedematous from accidental hypothermia.

DIAGNOSIS

The diagnosis of hypothyroidism is based on laboratory testing. The diagnosis of myxedema crisis is clinical. The differential diagnoses include sepsis, depression, adrenal crisis, congestive heart failure, hypoglycemia, cerebrovascular accidents, hypothermia, drug overdose, and meningitis.

LABORATORY EVALUATION AND IMAGING

The baseline levels of thyroid-stimulating hormone, thyroxine, triiodothyronine, and cortisol levels should be drawn before initiating treatment. This facilitates eventual diagnosis as well as response to treatment.

High thyroid-stimulating hormone, with low total or free thyroxine and triiodothyronine, confirms primary hypothyroidism (thyroid gland etiology). Low thyroid-stimulating hormone with low total or free thyroxine and triiodothyronine points toward secondary hypothyroidism (hypothalamic–pituitary etiology). The assay of free thyroxine and triiodothyronine is preferable, as the result is more accurate and is not affected by protein binding.

Thyroid hormone levels may also be altered as a result of interactions with drugs such as amiodarone, lithium, ethionamide, α-interferon, and interleukin-2. Nevertheless, thyroid function usually normalizes after discontinuation of these drugs. Ideally, thyroid function tests should be obtained before initiating therapy with these agents and periodically thereafter.

Hypothyroidism may be associated with pernicious anemia, and thus macrocytic anemia may be evident. However, if menorrhagia after hypothyroidism is severe, anemia may be microcytic from iron deficiency. **Hyponatremia** due to increased antidiuretic hormone and impaired free water clearance is common. **Hypoglycemia** is common because of decreased gluconeogenesis, decreased insulin clearance, and concomitant adrenal insufficiency or growth hormone deficiency. Arterial blood gases typically show hypoxemia, hypercapnia, metabolic acidosis from tissue hypoxia, and respiratory acidosis from hypoventilation due to muscle weakness.

Further laboratory assessment depends on the differential diagnosis, comorbidities, and search for precipitating factors. Electrocardiogram is necessary to identify myocardial infarction or bradyarrhythmias or heart block. Chest radiograph is needed to identify pneumonia, pleural effusion, or cardiomegaly.

TREATMENT OF SYMPTOMATIC HYPOTHYROIDISM

If a patient has symptoms of hypothyroidism or has been noncompliant with thyroid medication, and hypothyroidism can be confirmed by thyroid function tests done in the ED, oral levothyroxine may be started. Full replacement dose for patients without cardiac disease is 1.6 micrograms/kg.[6] The average starting dose for healthy adults younger than 50 is 50 micrograms of oral levothyroxine once a day. For those older than 50 years or with cardiac disease, the initial dose is lower, 12.5 to 25 micrograms once a day. For all adults, the dose is adjusted by 12.5- to 25-microgram increments at 4- to 6-week intervals. Instruct the patient to follow up with the primary care physician for monitoring and further dose adjustments in a month.

TREATMENT OF MYXEDEMA CRISIS

Management of myxedema crisis is shown in **Table 228-4**. **The treatment includes supportive care, thyroid hormone replacement (supplementing with thyroxine, triiodothyronine, or combination of both), and identification and treatment of precipitating factors.**

THYROID HORMONE REPLACEMENT FOR MYXEDEMA CRISIS

Administer thyroid hormone upon clinical suspicion of myxedema crisis, as confirmatory laboratory thyroid hormone levels will not be available initially. Thyroxine is the usual replacement. Triiodothyronine alone can be given if it is available, but should be avoided in the elderly or those with cardiac disease. Triiodothyronine and thyroxine together can be given if the patient has persistent hemodynamic instability or poor respiratory effort. Because myxedema crisis is such a rare condition, there are no clear recommendations for the use of thyroxine alone, combined thyroxine and triiodothyronine, or triiodothyronine alone.

Thyroid hormone replacement should initially be given IV because severe or even mild hypothyroidism results in decreased intestinal motility and GI absorption. Once the patient has received IV replacement, intestinal motility should recover, and oral medication can be given.

Thyroxin (Levothyroxine) The dose is 4 micrograms/kg IV, with the usual dose from 200 micrograms to a maximum of 500 micrograms IV. The onset of action for IV thyroxine is between 6 and 8 hours. The advantages of thyroxine are a smooth, slow, and steady onset of action and its widespread availability. Disadvantages include the fact that extrathyroidal conversion of thyroxine to triiodothyronine may be reduced in myxedema coma. The onset of action of thyroxine is longer than that of triiodothyronine.

Triiodothyronine (Liothyronine) For triiodothyronine (liothyronine), start at 20 micrograms IV followed by 10 micrograms IV every 8 hours until oral medication can be given. The advantage of triiodothyronine over thyroxine is the fact that deiodinase conversion of thyroxine to the active hormone triiodothyronine is reduced in myxedema crisis. IV triiodothyronine also has a rapid onset of action, between 2 and 4 hours. In a primate study, triiodothyronine crossed the blood–brain barrier more readily than thyroxine.[7] However, the disadvantages of triiodothyronine are a more potent effect, fluctuating serum levels, and the fact that triiodothyronine is more likely to cause cardiac arrhythmias or myocardial infarction than thyroxine. Avoid replacement with triiodothyronine in patients with cardiac disease. If triiodothyronine is given, provide continuous cardiac monitoring and obtain interval electrocardiograms to identify myocardial ischemia.

TABLE 228-4 ED Treatment for Myxedema Crisis

Supportive care

Airway, breathing, and circulation support: ensure airway control, oxygen, IV access, and cardiac monitor

IV therapy: dextrose for hypoglycemia; water restriction for hyponatremia

Vasopressors: if indicated (ineffective without thyroid hormone replacement)

Hypothermia: treated with passive rewarming

Steroids: hydrocortisone (due to increased metabolic stress; 100–200 milligrams IV)

↓

Thyroid replacement therapy (see discussion of Thyroid Hormone Replacement in text)

IV thyroxine (levothyroxine) at 4 micrograms/kg (typically between 200 and 500 micrograms as initial dose), followed in 24 h by 100 micrograms IV, then 50 micrograms IV until oral medication is tolerated. **Thyroxine is readily available. Thyroxine is preferred in the elderly and those with cardiac disease. Starting dose in the elderly is 100 micrograms IV.**

OR

IV triiodothyronine (liothyronine) at a dose of 20 micrograms IV followed by 10 micrograms IV every 8 h until the patient is conscious. **Start with no more than 10 micrograms IV for the elderly or those with coronary artery disease**. *Triiodothyronine is less preferred in patients with cardiac disease, as its potency could precipitate cardiac arrhythmias or infarction.*

Note: *Either thyroxine or triiodothyronine alone can be used, but in patients with persistent hemodynamic instability or poor respiratory effort, both can be given simultaneously. When used together, the dose of thyroxine is 200 micrograms IV and triiodothyronine is 20 micrograms IV.*

↓

Identify and treat precipitating and comorbid factors

- Infections
- Sedatives
- Cold exposure
- Trauma
- Myocardial infarction or congestive heart failure
- Cerebrovascular accident
- Gastrointestinal hemorrhage
- Hypoxia
- Hypercapnia
- Hyponatremia
- Hypoglycemia

DISPOSITION AND FOLLOW-UP

Myxedema crisis carries a high mortality rate, ranging from 30% to 60% depending on comorbid diseases. Factors such as advanced age, bradycardia, and persistent hypotension suggest a poor prognosis. All patients with myxedema coma require intensive care unit admission. Milder hypothyroidism patients may only be discharged with a clear plan of management and followed up by either an endocrinologist or primary care physician.

SPECIAL POPULATIONS

PREGNANT WOMEN

Overt hypothyroidism is seen in about 1% to 2% of pregnant women.[8] Subclinical hypothyroidism is seen in another 2.5%.[9]

Most cases of hypothyroidism during pregnancy have the same cause as in hypothyroidism in general. Pregnancy increases the requirement of thyroid hormone because of the increased rate of metabolism in the mother and the transplacental transport of thyroid hormone, which is essential for the development and maturation of the different organs of the fetus. For women who are being treated for hypothyroidism, the dose of thyroxine should be increased approximately by 30% as soon as the pregnancy is confirmed.[10]

Thyroid function test results during pregnancy may be difficult to interpret. This is because pregnant patients may have a higher production of thyroid hormone from stimulation of the gland by human chorionic gonadotropin, which has a similar structure to that of thyroid-stimulating hormone. On top of that, increased estrogen during pregnancy results in higher levels of thyroid-binding globulin, which transports thyroid hormone in the blood. Therefore, a normal thyroid hormone level in a pregnant woman may not mean the patient is euthyroid, especially if the patient has symptoms of hypothyroidism. Thyroid hormone replacement may still be required in this case.

Hypothyroidism is diagnosed in pregnancy if patients have symptoms and, in general, have high levels of thyroid-stimulating hormone and low free thyroxine. Subclinical hypothyroidism in pregnancy can be identified if the test results show high levels of thyroid-stimulating hormone and normal free thyroxine. Subclinical hypothyroidism should be treated to ensure healthy pregnancy.

Synthetic thyroxine, which is identical to the thyroxine made by the thyroid gland, is used for pregnant women. It is safe for the fetus. Pregnant women with existing hypothyroidism require an increased dose of thyroxine during pregnancy, and the thyroid function is usually checked every 8 weeks.

ELDERLY PATIENTS

Age, the presence of cardiac comorbidities, and a high dose of thyroxine are associated with a poor outcome in myxedema crisis.[10] Standard doses of thyroxine, and especially of triiodothyronine, can precipitate cardiac arrhythmias. Start with no more than half the recommended dose of thyroxine or triiodothyronine for elderly patients.

PATIENTS WITH CARDIAC DISEASE

Thyroxine has fewer cardiac effects than triiodothyronine. Thyroxine is the preferred choice for thyroid hormone replacement in patients with heart disease.

THE ASYMPTOMATIC PATIENT WITH A PALPABLE NODULE IDENTIFIED IN THE ED

Solitary thyroid nodules are a common physical finding in the general population. Although most are benign colloid nodules that will disappear over time, a small percentage of solitary nodules are thyroid carcinomas. Biopsy results identify 70% of nodules to be benign, 5% to be malignant, and the remainder to be cytologically indeterminate.[11] Therefore, referral for fine-needle aspiration biopsy is indicated for all patients with palpable nodules.

LEVOTHYROXINE OVERDOSE

Synthetic levothyroxine is the most widely used agent for thyroid replacement. Deaths from overdose have not been reported. When taken in overdose, symptoms do not occur until 24 hours later as a result of metabolic conversion of thyroxine to triiodothyronine. Treatment is not standardized. For acute ingestion, activated charcoal can be given. Cholestyramine can decrease fecal elimination, and propranolol can control tachycardia and anxiety. Contact your local poison control center for specific treatment recommendations.

CHAPTER 229

Hyperthyroidism

Alzamani Mohammad Idrose

INTRODUCTION AND EPIDEMIOLOGY

Thyroid hormone affects all organ systems and is responsible for increasing metabolic rate, heart rate, and ventricle contractility, as well as muscle and central nervous system excitability. Two major types of thyroid hormones are thyroxine and triiodothyronine. Thyroxine is the major form of thyroid hormone. The ratio of thyroxine to triiodothyronine released in the blood is 20:1. Peripherally, thyroxine is converted to the active triiodothyronine, which is three to four times more potent than thyroxine.

Hyperthyroidism refers to excess circulating hormone resulting only from thyroid gland hyperfunction, whereas thyrotoxicosis refers to excess circulating thyroid hormone originating from any cause (including thyroid hormone overdose).

Thyroid storm is the extreme manifestation of thyrotoxicosis. This is an acute, severe, life-threatening hypermetabolic state of thyrotoxicosis caused either by excessive release of thyroid hormones causing adrenergic hyperactivity or altered peripheral response to thyroid hormone following the presence of one or more precipitants.

The mortality of thyroid storm without treatment is between 80% and 100%, and with treatment, it is between 15% and 50%.

Primary hyperthyroidism is caused by the excess production of thyroid hormones from the thyroid glands. Secondary hyperthyroidism is caused by the excess production of thyroid-releasing hormones or thyroid-stimulating hormones in the hypothalamus and pituitary, respectively (**Tables 229-1** and **229-2**).

In the case of thyroid storm, the most common underlying cause of hyperthyroidism is Graves' disease (85% of all hyperthyroidism cases in the United States). It is caused by the thyrotropin receptor antibodies that stimulate excess and uncontrolled thyroidal synthesis and secretion of thyroid hormones. It occurs most frequently in young women (10 times more common in women compared with men) at any age group.[1]

PATHOPHYSIOLOGY

The pathophysiologic mechanisms underlying the shift from uncomplicated thyrotoxicosis to thyroid storm are not entirely clear. However, they involve adrenergic hyperactivity either by increased release of thyroid hormones (with or without increased synthesis) or increased receptor sensitivity. Many of the signs and symptoms are related to adrenergic hyperactivity. Patients with thyroid storm reportedly have relatively higher levels of free thyroid hormones as opposed to those with uncomplicated thyrotoxicosis. The total thyroid hormone level may or may not be increased in these patients.

When there is excess of thyroid hormones, circulating thyroxin and triiodothyronine are taken into the cytoplasm of cells. Thyroxin is converted to its active form, triiodothyronine. Within the cytoplasm, the triiodothyronine then exerts its effect by passing into the nucleus and binding to thyroid hormone receptors or thyroid hormone–responsive elements to induce gene activation and transcription.[2] The receptors receiving the hormone will stimulate changes specific to the tissue.

TABLE 229-1 Causes of Hyperthyroidism: Primary and Secondary Hyperthyroidism

Primary Hyperthyroidism	
Graves' disease (toxic diffuse goiter) (**Figure 229-1**)	Most common of all hyperthyroidism (85% of all cases) Associated with diffuse goiter, ophthalmopathy, and local dermopathy
Toxic multinodular goiter	Second most common cause of hyperthyroidism
Toxic nodular (adenoma) goiter (**Figure 229-2**)	An enlarged thyroid gland that contains a small rounded mass or masses called nodules with overproduction of thyroid hormone
Thyroiditis	Inflammation of the thyroid gland
Hashimoto's thyroiditis	Initially gland is overactive (hyperthyroidism state), but this is usually followed by a state of hypothyroidism
Subacute painful thyroiditis (de Quervain's thyroiditis)	
Subacute painless thyroiditis	
Radiation thyroiditis	
Secondary Hyperthyroidism	
Thyrotropin-secreting pituitary adenoma	Thyroid gland stimulated to produce hormones

In the pituitary gland, thyroid hormones exert negative regulation on the transcription of the genes for the subunit and the common subunit of thyroid-stimulating hormone, resulting in thyroid-stimulating hormone suppression.

During thyroid storm, precipitants such as infection, stress, myocardial infarction, or trauma will multiply the effect of thyroid hormones by freeing thyroid hormones from their binding sites or increasing receptor sensitivity.

THYROID STORM PRECIPITATION

The precipitants of thyroid storm are as shown in **Table 229-3.** In some patients undergoing radioactive iodine therapy for hyperthyroidism, thyroid storm may ironically occur following treatment due to withdrawal of antithyroid drugs, release of thyroid hormones from damaged thyroid follicles, or the effect of radioactive iodine itself.

FIGURE 229-2. Pathology specimen of multinodular goiter: second most common cause of hyperthyroidism. Multinodular appearance can be seen. [Image used with permission of the University of Malaya Pathology Museum.]

CLINICAL FEATURES

HISTORY AND COMORBIDITIES

The patient may only complain of constitutional symptoms such as generalized weakness and fatigue. Heat intolerance, diaphoresis, fever, voracious appetite but poor weight gain, anxiety, emotional lability, palpitations, diarrhea, and hair loss are common historical features. If there is a history of hyperthyroidism, ask about treatment and compliance with medication.

PHYSICAL EXAMINATION

In general, patients often appear toxic and agitated. The signs and symptoms of hyperthyroidism patients are as shown in **Table 229-4**.

TABLE 229-2 Other Causes of Hyperthyroidism

Nonthyroidal Disease	
Ectopic thyroid tissue (struma ovarii)/teratoma	A rare form of mature teratoma that contains mostly thyroid tissue
Metastatic thyroid cancer	Stimulates production of thyroid hormones
Human chorionic gonadotropin	Secreting hydatidiform mole
Drug Induced	
Iodine	Iodine-induced thyrotoxicosis (called *Jod-Basedow disease*) After treatment of endemic goiter patients with iodine or stimulation of thyroid hormones from use of iodine-containing agents such as radiographic contrast agents
Amiodarone	Contains iodine; may cause either thyrotoxicosis or hypothyroidism
α-Interferon Interleukin-2	During treatment for other diseases, such as viral hepatitis and human immunodeficiency virus infection
Thyrotoxicosis factitia	Munchausen-like; thyroid hormone is taken by patient to fake illness
Ingestion of meat containing beef thyroid tissue	Cow thyroid tissue contains thyroid hormones
Excessive thyroid hormone ingestion	

TABLE 229-3 Precipitants of Thyroid Storm

Systemic insult	**Cardiovascular insult**
Infection	Myocardial infarction
Trauma	Cerebrovascular accidents
General surgery	Pulmonary embolism
Endocrinal insult	**Obstetrics related**
Diabetic ketoacidosis	Parturition
Hyperosmolar coma	Eclampsia
Drug or hormone related	**Radioactive iodine therapy**
Withdrawal of anti-thyroid medication	
Iodine administration	
Thyroid gland palpation	
Ingestion of thyroid hormone	
Unknown cause in up to 25% of cases	

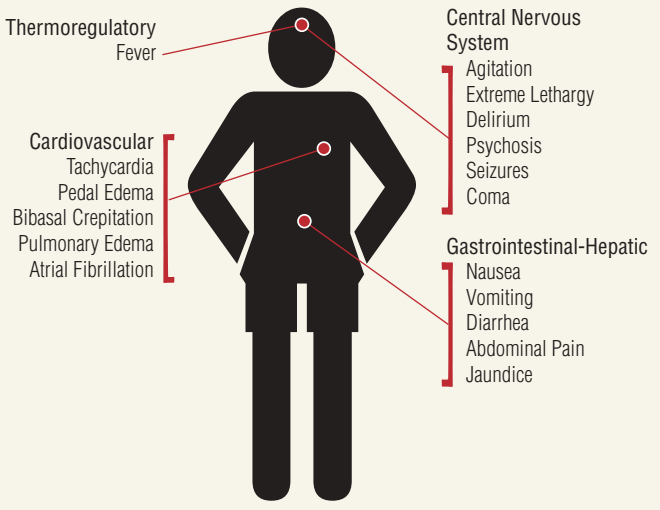
TABLE 229-4 Symptoms and Signs of Thyrotoxicosis

Affected System	Symptoms	Signs
Constitutional	Lethargy Weakness Heat intolerance	Diaphoresis Fever Weight loss
Neuropsychiatric	Emotional lability Anxiety Confusion Coma Psychosis	Fine tremor Muscle wasting Hyperreflexia Periodic paralysis
Ophthalmologic	Diplopia Eye irritation	Lid lag Dry eyes Exophthalmos Ophthalmoplegia Conjunctival infection
Endocrine: thyroid gland (**Figure 229-3**)	Neck fullness Tenderness	Thyroid enlargement Bruit
Cardiorespiratory	Dyspnea Palpitations Chest pain	Widened pulse pressure Systolic hypertension Sinus tachycardia Atrial fibrillation or flutter High output heart failure
Gastrointestinal	Diarrhea Yellowish sclera	Hyperactive bowel sound Jaundice
Reproductive	Oligomenorrhea Decreased libido	Gynecomastia Telangiectasia
Gynecologic	Menorrhagia Irregularity	Sparse pubic hair
Hematologic	Pale skin	Anemia Leukocytosis
Dermatologic	Hair loss	Pretibial myxedema* Warm, moist skin Palmar erythema Onycholysis

*Pretibial myxedema may be present in 5% of patients with Graves' disease.

FIGURE 229-3. Goiter with hyperthyroidism symptoms: patient has large solitary toxic adenoma on the left lobe.

As for thyroid storm, the additional signs and symptoms apart from those evident in thyrotoxicosis are as shown in **Table 229-5**.



Fever is often present in thyroid storm and may be quite high. It may herald the onset of thyrotoxic crisis in previously uncomplicated disease. Palpitations, tachycardia, and dyspnea are common. A pleuropericardial rub may be heard. The direct inotropic and chronotropic effects of thyroid hormone on the heart cause increased blood volume, increased contractility, and increased cardiac output. Enhanced contractility produces elevations in systolic blood pressure and pulse pressure, leading to a dicrotic or water-hammer pulse. Atrial fibrillation occurs in 10% to 35% of thyrotoxicosis cases.[3,4]

The severity of exophthalmos does not necessarily parallel the magnitude of thyroid dysfunction but reflects the responsible autoimmune process. Not all hyperthyroidism patients present with goiter. A goiter is not present with exogenous administration of thyroid hormone and apathetic thyrotoxicosis. Likewise, the presence of a goiter does not necessarily confirm the diagnosis of thyrotoxicosis. Thyroid gland tenderness can be found in inflammatory conditions such as subacute thyroiditis.[5]

DIAGNOSING THYROID STORM

Thyroid storm is a clinical diagnosis for patients with preexisting hyperthyroidism. In determining whether or not a patient has thyroid storm, the main systems to concentrate on are the **thermoregulatory system**

TABLE 229-5 Presenting Signs and Symptoms of Thyroid Storm

(rise in temperature), **CV system** (ranging from tachycardia to atrial fibrillation and congestive cardiac failure), **CNS** (ranging from being agitated to seizure), and the **GI-hepatic system** (ranging from nausea to vomiting and jaundice) (**Table 229-5**). **Table 229-6** provides a scoring system for thyroid storm as compared with severe thyrotoxicosis. A score ≥45 is highly suggestive of thyroid storm. The system is sensitive in picking up thyroid storm but is not very specific.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of thyroid storm is shown in **Table 229-7**.

TABLE 229-7 Differential Diagnosis for Thyroid Storm

Infection and sepsis
Sympathomimetic ingestion (e.g., cocaine, amphetamine, ketamine drug use)
Heat exhaustion
Heat stroke
Delirium tremens
Malignant hyperthermia
Malignant neuroleptic syndrome
Hypothalamic stroke
Pheochromocytoma
Medication withdrawal (e.g., cocaine, opioids)
Psychosis
Organophosphate poisoning

LABORATORY TESTING

Serum Thyroid-Stimulating Hormone Level In **primary hyperthyroidism**, the thyroid-stimulating hormone level is low as a result of the negative feedback mechanism toward a high thyroid hormone level. Nevertheless, a low thyroid-stimulating hormone level by itself is not diagnostic, as serum thyroid-stimulating hormone may be reduced as a result of chronic liver or renal disease or the effect of certain drugs such as glucocorticoids, which reduce thyroid-stimulating hormone secretion.

In **secondary hyperthyroidism**, thyroid-stimulating hormone is increased because of increased production in the pituitary.

TABLE 229-6 Burch and Wartofsky's Diagnostic Parameters and Scoring Points for Thyroid Storm

Diagnostic Parameters	Scoring Points
1. Thermoregulatory dysfunction	
Temperature °C (°F)	
37.2–37.7 (99–99.9)	5
37.7–38.3 (100–100.9)	10
38.3–38.8 (101–101.9)	15
38.9–39.4 (102–102.9)	20
39.4–39.9 (103–103.9)	25
≥40 (≥104.0)	30
2. CNS effects	
Absent	0
Mild (agitation)	10
Moderate (delirium, psychosis, extreme lethargy)	20
Severe (seizures, coma)	30
3. GI-hepatic dysfunction	
Absent	0
Moderate (diarrhea, nausea/vomiting, abdominal pain)	10
Severe (unexplained jaundice)	20
4. CV dysfunction	
Tachycardia (beats/min)	
90–109	5
110–119	10
120–129	15
≥140	25
5. Congestive heart failure	
Absent	0
Mild (pedal edema)	5
Moderate (bibasilar rales)	10
Severe (pulmonary edema)	15
6. Atrial fibrillation	
Absent	0
Present	10

Scoring system:
Score of ≥45: Highly suggestive of thyroid storm.
Score of 25–44: Suggestive of impending storm.
Score of <25: Unlikely to represent thyroid storm.
(Reproduced with permission from Burch HB, Wartofsky L. Life-threatening thyrotoxicosis. Thyroid storm. *Endocrinol Metab Clin North Am* 22: 263, 1993.)

Free Thyroid Hormone Levels: Free Thyroxine and Free Triiodothyronine A low thyroid-stimulating hormone with an elevated free thyroxine confirms primary hyperthyroidism. A high thyroid-stimulating hormone with high free thyroxine denotes secondary causes of hyperthyroidism. On the other hand, a low thyroid-stimulating hormone with a normal free thyroxine but elevated free triiodothyronine is also diagnostic of triiodothyronine thyrotoxicosis. Triiodothyronine thyrotoxicosis occurs in <5% of patients who have thyrotoxicosis in North America.[5] Total thyroid hormone levels are not necessarily acutely elevated when the transition from uncomplicated thyrotoxicosis to thyroid storm occurs.

Triiodothyronine Resin Uptake Triiodothyronine resin uptake estimates free thyroxine levels by measuring unoccupied thyroxine-binding globulin sites and is also used to account for changes in binding protein concentration. A higher triiodothyronine resin uptake value means less thyroxine-binding globulin is available, implying the presence of hyperthyroidism.

Total Thyroid Hormone Level of Thyroxine and Triiodothyronine Total serum thyroxine and triiodothyronine (bound and unbound) are increased in thyrotoxicosis. Eighty percent of circulating triiodothyronine is derived from mono-deiodination of thyroxine in peripheral tissues, whereas 20% emanates from direct thyroidal secretion. Both thyroxine and triiodothyronine are then bound to proteins in the form of thyroxine-binding globulin, transthyretin, and albumin. Only a small fraction of the hormones are free and unbound. Laboratory measurement of total triiodothyronine and total thyroxine measures mainly protein-bound hormone concentrations. In thyroid storm, total thyroid hormone level may or may not be increased. Results also may be affected by conditions that affect protein binding. With the improved assays for free thyroxine and free triiodothyronine, there is now little indication to measure total triiodothyronine and total thyroxine.

Thyroid Antibody Titers Thyroid-stimulating antibodies are detected in Graves' disease. Thyroid antibody titers (to thyroid peroxidase or thyroglobulin) will help determine diagnosis.

Ancillary Tests Obtain a CBC, electrolytes, glucose, and renal and liver function tests to identify comorbidities, but start treatment upon suspicion of the diagnosis. In thyroid storm, CBC typically shows leukocytosis with shift to the left. Hyperglycemia tends to occur because of a catecholamine-induced inhibition of insulin release and increased glycogenolysis and rapid intestinal absorption of glucose. Mild hypercalcemia and elevated alkaline phosphatase can occur because of hemoconcentration and enhanced thyroid hormone–stimulated bone resorption.[6]

Thyrotoxicosis also induces liver enzyme metabolism, causing raised liver enzymes. A high serum cortisol value is an expected finding in thyrotoxic individuals. This should be the normal reaction of an adrenal

gland to a body under stress. The finding of an abnormally low cortisol level in a patient with Graves' disease should raise suspicion of coincidental adrenal insufficiency.

Imaging Chest radiograph can be done to rule out infection as a precipitant for thyroid storm. A thyroid sonogram with Doppler flow can be done to assess thyroid gland size, vascularity, and the presence of nodules. Typically, a thyroid gland secreting excessive hormones would be enlarged. On the other hand, in the setting of subacute, postpartum thyroiditis, silent thyroiditis, or exogenous causes of hyperthyroidism, the thyroid gland is not expected to be enlarged. Nuclear medicine imaging with iodine-131 would reveal a greatly increased uptake of radioiodine as early as 1 or 2 hours after administration of the agent. CT of the brain may be necessary to exclude neurologic conditions if diagnosis is uncertain, as CNS abnormalities causing altered mental status may precipitate thyroid storm.

Electrocardiogram in Thyrotoxicosis Electrocardiogram findings in thyrotoxicosis most commonly include sinus tachycardia and atrial fibrillation. Sinus tachycardia occurs in approximately 40% of cases.[4] Atrial fibrillation occurs in 10% to 35% of thyrotoxicosis patients—more commonly in patients >60 years old with underlying structural heart disease.[4] Premature ventricular contractions and heart blocks may be present. Atrial premature contractions and atrial flutter may also occur.

TREATMENT

The order of therapy in treating thyroid storm is very important with regard to the use of thionamide and iodine therapy. **Inhibition of thyroid gland synthesis of new thyroid hormone with a thionamide should be initiated before iodine therapy to prevent the stimulation of new thyroid hormone synthesis that can occur if iodine is given too soon.**

Treatment aims are as follows:

1. Supportive care
2. Inhibition of new hormone synthesis
3. Inhibition of thyroid hormone release
4. Peripheral β-adrenergic receptor blockade
5. Preventing peripheral conversion of thyroxine to triiodothyronine

The treatment recommendations are shown in **Table 229-8**, with specific comments in the following sections.

TREATMENT AIM 1: SUPPORTIVE CARE

Fluid losses could result from the combination of fever, diaphoresis, vomiting, and diarrhea. Check blood glucose and if blood sugar is relatively low, IV fluids with dextrose (isotonic saline with 5% or 10% dextrose) may be given to replenish glycogen stores.

Cholestyramine Cholestyramine is used to inhibit thyroid hormone reabsorption. Thyroid hormone is metabolized mainly in the liver, where it is conjugated to glucuronides and sulfates. These conjugation products are then excreted in the bile. Free hormones are released in the intestine and finally reabsorbed, completing the enterohepatic circulation of thyroid hormone. In states of thyrotoxicosis, there is increased enterohepatic circulation of thyroid hormone. Cholestyramine is an anion exchange resin that decreases reabsorption of thyroid hormone from the enterohepatic circulation. Cholestyramine in combination with methimazole or propylthiouracil, causes a more rapid decline in thyroid hormone levels than standard therapy with thionamides alone.[1]

TREATMENT AIM 2: INHIBITION OF NEW THYROID HORMONE SYNTHESIS

Thionamides Thionamides used for the treatment of thyrotoxicosis are either methimazole or propylthiouracil. Thionamide therapy decreases the synthesis of new hormone production but also has immunosuppressive effects.[7] Thionamides inhibit synthesis of thyroid hormones by preventing organification and trapping of iodide to iodine and by inhibiting coupling of iodotyrosines.

Methimazole has a longer half-life than propylthiouracil, permitting less frequent dosing. It presents in free form in the serum, whereas 80% to 90% of propylthiouracil is bound to albumin.[7]

The dose for methimazole is 40 to 100 milligrams given PO as loading dose followed by 20 milligrams every 4 hours. The total daily dose that should be given is 120 milligrams/d. If given PR, 40 milligrams should be crushed in aqueous solution. Although there are no commercially available parenteral formulations of the thionamides, there are case reports of methimazole being administered IV in circumstances in which the PO and PR routes of administration could not be used.[8] Methimazole was shown to have similar pharmacokinetics for both PO and IV use in normal subjects and in subjects with hyperthyroidism. In some centers, only carbimazole (which is the prodrug of methimazole) is available. If methimazole is not available, carbimazole can be used with the same potency.[9] The initial dose is 40 to 60 milligrams, followed by a maintenance dose of between 5 and 20 milligrams daily.

As for propylthiouracil, the dose for thyroid storm is 600 to 1000 milligrams given PO as a loading dose followed by 200 to 250 milligrams every 4 hours. The total daily dose that should be given is between 1200 and 1500 milligrams/d. The drug can be given by nasogastric tube or PR. Outside the thyroid gland, only propylthiouracil, not methimazole, can inhibit conversion of thyroxine to triiodothyronine.

Warning on Use of Propylthiouracil The U.S. Food and Drug Administration (FDA) in 2009 notified healthcare professionals of the risk of serious liver injury, including liver failure and death, with the use of propylthiouracil in adults and children. There is an increased risk of hepatotoxicity with propylthiouracil when compared with methimazole.10 Since 2010, the FDA has added a boxed warning to the prescribing information of propylthiouracil to include information about reports of severe liver injury and acute liver failure, some of which have been fatal. The FDA recommends that propylthiouracil be reserved for patients who cannot tolerate methimazole.

Propylthiouracil is preferred only in the case of pregnant patients during the first trimester, as methimazole use during this period had been associated with teratogenicity.[11] Nevertheless, methimazole is again suggested for use during the second and third trimesters of pregnancy. If propylthiouracil is used, signs and symptoms of liver injury should be closely monitored, especially in the first 6 months of therapy initiation. Its use must be discontinued immediately in cases of suspected liver injury. Propylthiouracil should not be used in children unless the patient is allergic to or intolerant of methimazole and no other treatment options are available.

TREATMENT AIM 3: INHIBITION OF HORMONE RELEASE

Iodine Lugol solution, potassium iodide, ipodate (Oragrafin®), or lithium carbonate can be given to stop thyroid hormone release. **Thionamide therapy must be instituted first and these drugs only given at least 1 hour later.** Iodine therapy blocks the release of prestored hormone and decreases iodide transport and oxidation in follicular cells. Lugol solution can be given 30 to 40 drops/d divided three to four times a day. One may start with 8 to 10 drops initially. Lugol solution provides 8 milligrams of iodide per drop.

Iodinated radiographic contrast dyes that contain ipodate (Oragrafin®) 0.5 to 3 grams/d orally or IV iopanoic acid (Telepaque®) 1 gram every 8 hours for the first 24 hours followed by 500 milligrams twice a day have also been used to inhibit hormone release, and they also have the added property to effectively prevent conversion of thyroxine to triiodothyronine.

Nevertheless, iodine-containing solution should not be given to patients with iodine overload or iodine-induced hyperthyroidism or those with amiodarone-induced thyrotoxicosis. Lithium or potassium perchlorate may be used instead.

TREATMENT AIM 4: PREVENTING PERIPHERAL CONVERSION OF THYROXINE TO TRIIODOTHYRONINE

The peripheral conversion of thyroxine to triiodothyronine, which is responsible for 85% of triiodothyronine present in the circulation, is blocked by propylthiouracil, propranolol, and glucocorticoid. Nevertheless, for propylthiouracil and propranolol, this effect is not quantitatively significant. Therefore, glucocorticoids such as hydrocortisone or dexamethasone are essential in treatment. Glucocorticoid use in thyroid storm also improves survival rates.[2,12] In patients who have severe thyrotoxicosis, especially in conjunction with hypotension, treatment with glucocorticoids is a standard practice because of the possibility of relative adrenal insufficiency.

TABLE 229-8 Treatment for Thyroid Storm

1. **Supportive care**

   General: oxygen, cardiac monitoring

   Fever: external cooling; acetaminophen 325–650 milligrams PO/PR every 4–6 h (aspirin is contraindicated because it may increase free thyroid hormone)

   Dehydration: IV fluids, IV isotonic saline with 5% dextrose may be used to replace glycogen depletion if blood sugar is low

   Nutrition: glucose, multivitamins, thiamine, including folate can be considered (deficient secondary to hypermetabolism)

   Cardiac decompensation (atrial fibrillation, congestive heart failure): rate control and inotropic agent, diuretics, sympatholytics as required

2. **Inhibition of new thyroid hormone synthesis with thionamides**

   Methimazole 40 milligrams given PO as loading dose and followed by 25 milligrams every 4 h. Total daily dose should be given: 120 milligrams/d. If given PR, 40 milligrams should be crushed in aqueous solution.

   (Avoid methimazole for pregnant women in first trimester as it can cause teratogenic effect. It can only be used in second and third trimester of pregnancy.)

   or

   PTU, a loading dose of 600–1000 milligrams given PO and followed by 200–250 milligrams every 4 h. Total daily dose should be given: 1200–1500 milligrams/d. Drug can be given via nasogastric tube or PR. (PTU also blocks peripheral conversion of thyroxin to triiodothyronine.)

   (PTU is used for pregnant women in first trimester. PTU also has a boxed warning issued by the U.S. Food and Drug Administration in 2010 regarding its rare but severe side effect toward liver function. Methimazole is preferred as first-line treatment unless contraindicated.)

3. **Inhibition of thyroid hormone release (at least 1 h after step 2)**

   Lugol solution 8–10 drops PO every 6–8 h

   or

   Potassium iodide (SSKI) five drops PO every 6 h

   or

   IV iopanoic acid (Telepaque®), 1 gram every 8 h for first 24 h, then 500 milligrams twice a day

   or

   Ipodate (Oragrafin®), 0.5–3 grams/d PO (especially useful with thyroiditis or thyroid hormone overdose)

   or

   Lithium carbonate (if allergic to iodine or agranulocytosis occurs with thionamides), 300 milligrams PO every 6 h (1200 milligrams/d) and subsequently to maintain serum lithium at 1 mEq/L

4. **β-Adrenergic receptor blockade**

   Propranolol IV in slow 1- to 2-milligram boluses, which may be repeated every 10 to 15 min until the desired effect is achieved. For less toxic patient, PO dose of 20 to 120 milligrams per dose or 160 to 320 milligrams/d in divided doses (contraindicated in bronchospastic disease and congestive heart failure)

   or

   Esmolol 500 micrograms/kg IV bolus, then 50–200 micrograms/kg/min maintenance

   or

   Reserpine 2.5–5.0 milligrams IM every 4–6 h, preceded by 1-milligram test dose while monitoring blood pressure (use if β-blocker contraindicated but avoid in congestive heart failure or hypotension and cardiac shock)

   or

   Guanethidine 30–40 milligrams PO every 6 h (use if β-blocker contraindicated but avoid in congestive heart failure, hypotension, and cardiac shock)

5. **Preventing peripheral conversion of thyroxine to triiodothyronine**

   Hydrocortisone 100 milligrams IV initially, then 100 milligrams three times/d until stable (also for adrenal replacement due to hypermetabolism)

   or

   Dexamethasone 2 milligrams IV every 6 h

6. **Treat precipitating event**

   All triggers of thyroid storm should be searched and treated accordingly (infection, myocardial infarct, diabetic ketoacidosis, etc.).

7. **Definitive therapy**

   Radioactive iodine ablation therapy or surgery may be necessary.

Note: Replacement therapy: dialysis and plasmapheresis are last resorts for patients who do not respond to treatments 1–5.

Abbreviation: PTU = propylthiouracil.

TREATMENT AIM 5: β-ADRENERGIC RECEPTOR BLOCKADE

Propranolol can be given IV in slow 1- to 2-milligram boluses, which may be repeated every 10 to 15 minutes until the desired effect is achieved. Orally, propranolol therapy usually begins at 20 to 120 milligrams per dose or 160 to 320 milligrams/d in divided doses.

The contraindications to peripheral blockade are the same as those for other medical conditions. Exercise caution in patients with congestive cardiac failure and thyrotoxic cardiomyopathy. Complicated patients with both a tachydysrhythmia and congestive heart failure can be managed first with rate control and an inotropic agent.

ALTERNATIVE TREATMENTS

Several alternative therapeutic agents are considered when the first-line therapies of thionamides, iodide, β-blockers, and glucocorticoids fail or cannot be used owing to toxicity or contraindicated conditions.

Alternative Drugs for Inhibition of New Hormone Synthesis or Release • *Potassium Perchlorate* Potassium perchlorate blocks thyroid uptake of iodine and thus interferes with the production of new hormones The perchlorate anion, ClO4–, is a competitive inhibitor of iodide transport. The recommended dose is 0.5 gram of potassium perchlorate per day.13 It is used in amiodarone-induced thyrotoxicosis for which iodine replacement is contraindicated. However, it has side effects of aplastic anemia and nephrotic syndrome.

Lithium In situations in which there is a contraindication to giving iodine (e.g., hypersensitivity to iodine), an alternative such as lithium can be used. In severe thyroid storm conditions, lithium can also be used in combination with propylthiouracil or methimazole. Lithium inhibits thyroid hormone release from thyroid gland. Lithium also has effects on the thyroid gland that decrease thyroid hormone synthesis, thereby increasing intrathyroidal iodine content and inhibiting coupling of iodotyrosine residues that form thyroxine and triiodothyronine. In thyroid storm, the dosing for lithium is 300 milligrams every 8 hours. To avoid lithium toxicity, lithium level should be monitored regularly every day to maintain a concentration of approximately 0.6 to 1.0 mEq/L (0.6-1.0 mmol/L). Very frequent monitoring of serum lithium levels is mandatory, especially because the serum lithium concentrations may change as the patient is rendered more euthyroid.

Alternative Drugs for Peripheral Blockade of β-Receptor: Reserpine and Guanethidine Reserpine or guanethidine can be used, usually in severe asthmatic patients needing treatment for thyroid storm, as they do not block β-receptors. These agents would be indicated only in rare situations in which β-adrenergic receptor antagonists are contraindicated and when there is no hypotension or evidence of central nervous system–associated mental status changes.[2] Side effects of both medications include hypotension and diarrhea.

Reserpine is an alkaloid agent that depletes catecholamine stores in sympathetic nerve terminals and the central nervous system. It can have central nervous system depressant effects. In severe asthmatics, IM reserpine, 2.5 milligrams every 4 hours, may be considered in lieu of peripheral blockade.[13] Guanethidine inhibits the release of catecholamines. Dosing for guanethidine in thyroid storm is 30 to 40 milligrams PO every 6 hours.

Thyroid Hormone Removal In patients who have contraindications to propylthiouracil and methimazole, such as a prior severe reaction, direct removal of thyroid hormone has been described. Plasmapheresis, charcoal hemoperfusion, resin hemoperfusion, and plasma exchange have been found to be effective in rapidly reducing thyroid hormone levels in thyroid storm.[13,14]

IDENTIFY PRECIPITATING FACTORS

Search for infection in febrile thyrotoxic patients. Obtain an electrocardiogram to identify myocardial infarction, ischemia, or arrhythmia.

In cases of thyroid storm precipitated by diabetic ketoacidosis, myocardial infarction, pulmonary embolism, or other acute processes, appropriate management of the specific underlying problem should proceed along with the treatment of the thyrotoxicosis.[2]

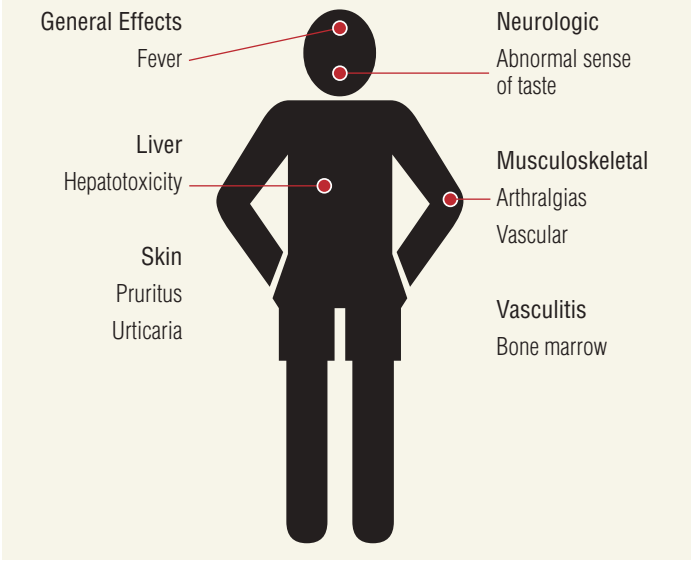
DEFINITIVE THERAPY

Definitive therapy with radioactive iodine ablation may not be able to be done for several weeks or months after treatment with iodine for thyroid storm. Close follow-up and monitoring should continue, with plans for definitive therapy to prevent a future recurrence of life-threatening thyrotoxicosis.[2]

GUIDE FOR PREPARATION OF THYROTOXIC PATIENTS FOR EMERGENCY SURGERY

In the event that a patient has thyrotoxicosis background and requires emergent surgery, the recommendation of drug supplementation is as shown in **Table 229-9**. The supplementation is important, as surgery in a patient with hyperthyroidism may precipitate thyroid storm.

ADVERSE SIDE EFFECTS FROM ANTITHYROID DRUGS



Common adverse side effects of the antithyroid drugs are shown in **Table 229-10**.

TABLE 229-9 Rapid Preparation of Thyrotoxic Patients for Emergent Surgery

Drug Class	Recommended Drug	Dosage	Mechanism of Action	Continue Postoperatively?
β-Adrenergic blockade	Propranolol	40–80 milligrams PO 3 to 4 times a day	β-Adrenergic blockade; decreased thyroxine-to-triiodothyronine conversion (high dose)	Yes
	or			
	Esmolol	50–100 micrograms/kg/min	β-Adrenergic blockade	Change to PO propranolol
Thionamide	Propylthiouracil	200 milligrams PO every 4 h	Inhibition of new thyroid hormone synthesis; decreased thyroxine-to-triiodothyronine conversion	Stop immediately after near-total thyroidectomy; continue after nonthyroidal surgery
	or			
	Methimazole	20 milligrams PO every 4 h	Inhibition of new thyroid hormone synthesis	Stop immediately after near-total thyroidectomy; continue after nonthyroidal surgery
Oral cholecystographic agent	Iopanoic acid	500 milligrams PO twice a day	Decreased release of thyroid hormone; decreased thyroxine-to-triiodothyronine conversion	Stop immediately after surgery
Corticosteroid	Hydrocortisone	100 milligrams PO or IV every 8 h	Vasomotor stability; decreased thyroxine-to-triiodothyronine conversion	Taper over first 72 h
	or			
	Dexamethasone	2 milligrams PO or IV every 6 h	Vasomotor stability; decreased thyroxine-to-triiodothyronine conversion	Taper over first 72 h
	or			
	Betamethasone	0.5 milligram PO every 6 h, IM or IV	Vasomotor stability; decreased thyroxine-to-triiodothyronine conversion	Taper over first 72 h

(Reproduced with permission from Langley RW, Burch HB: Perioperative management of the thyrotoxic patient. *Endocrinol Metab Clin of North Am* 32: 519, 2003. Copyright Elsevier.)

TABLE 229-10 Common Adverse Side Effects from Antithyroid Drugs

After surgery, the precipitating event should be determined, and definitive therapy of thyrotoxicosis should be planned.

DISPOSITION AND FOLLOW-UP

Thyroid storm patients typically require admission to the intensive care unit. Patients with thyroid storm often have concomitant diseases precipitating the attack and require close monitoring. Complete recovery may take 1 week until circulating levels of thyroid hormones are depleted. Stable hyperthyroid patients with minimal symptoms can only be discharged for follow-up either by an endocrinologist or primary care physician, if the patient is already on medication with a clear plan of follow-up.

SPECIAL POPULATIONS

ELDERLY PATIENTS

Older patients may present with "apathetic" thyrotoxicosis (i.e., with some atypical symptoms, including weight loss, palpitations, weakness, dizziness, syncope, memory loss, and physical findings of sinus tachycardia or atrial fibrillation).[5] Signs and symptoms of this condition are few and subtle, and the initial appearance of disease may be single-organ failure (e.g., congestive heart failure), producing diagnostic confusion by pointing to diagnoses other than thyrotoxicosis.

DRUG INTERACTIONS IN THYROTOXIC PATIENTS

Many drugs interfere with protein binding, including heparin, furosemide, phenytoin, carbamazepine, diazepam, salicylates, opiates, estrogens, and nonsteroidal anti-inflammatory drugs. Because of this interference with total thyroid hormone levels, free hormone concentrations are preferable in the diagnosis of thyrotoxicosis.[6]

THYROTOXIC PATIENTS AND AMIODARONE

Amiodarone is an essential anti-arrhythmic drug used in the ED. Amiodarone is also a precipitant of thyroid storm. It is 37% organic iodine by weight, and as such, can have many effects on thyroid function. Normal maintenance doses result in iodine loads of 10 to 20 times the normal dietary requirement of iodine. Chronic use of amiodarone causes either a hypothyroid or a thyrotoxic state in 20% to 30% of patients.[15]

THYROTOXIC PATIENTS WITH ATRIAL FIBRILLATION

The issue of anticoagulation in atrial fibrillation in the setting of thyrotoxicosis is controversial. Studies assessing the incidence of embolic events in thyrotoxic patients who have atrial fibrillation have yielded conflicting information regarding the incidence of embolism. Thyrotoxic patients who have atrial fibrillation may not be at greater risk for embolic events, compared with age-matched patients who have atrial fibrillation due to other causes.[16] Therefore, standard therapy with warfarin or aspirin would be indicated. Thyrotoxic patients may require a lower maintenance dose of warfarin than euthyroid patients because of increased clearance of vitamin K–dependent clotting factors.[17]

CHAPTER 230

Adrenal Insufficiency

Alzamani Mohammad Idrose

INTRODUCTION

The adrenal gland synthesizes steroid hormones in the cortex and catecholamines in the medulla. **Adrenal insufficiency** is deficiency of adrenal gland hormone production in the cortex. **Primary adrenal insufficiency,** or Addison's disease, is due to intrinsic adrenal gland dysfunction and results in decreased cortisol, aldosterone, and sex hormone production. The condition is rare, with prevalence ranging from 39 to 144 cases per million population.[1]

Secondary adrenal insufficiency is due to hypothalamic-pituitary dysfunction with failure to secrete corticotropin-releasing hormone and/or adrenocorticotropic hormone. This disorder results in cortisol deficiency only.

Adrenal crisis is a life-threatening exacerbation of adrenal insufficiency when an increased demand fails to increase hormone production.

ADRENAL GLAND PHYSIOLOGY

The adrenal gland is made up of the cortex and medulla producing steroid hormones and catecholamines, respectively. The adrenal cortex produces three categories of steroids: the glucocorticoids (**cortisol**), mineralocorticoids (**aldosterone**), and gonadocorticoids (**sex hormones**). Glucocorticoids are produced in the zona fasciculata, and mineralocorticoids and gonadocorticoids are produced in the zona glomerulosa and zona reticularis of the adrenal cortex. The adrenal medulla produces adrenaline, noradrenaline, and a small amount of dopamine in response to stimulation by sympathetic preganglionic neurons.

Cortisol is secreted in response to direct stimulation by adrenocorticotropic hormone. Adrenocorticotropic hormone secretion is stimulated by corticotropin-releasing factor released from the hypothalamus. Secretion occurs in a diurnal rhythm, with higher levels secreted in the morning and lower levels in the evening. In normal circumstances, the daily cortisol equivalent is about 20 milligrams/d of hydrocortisone. Plasma cortisol suppresses the release of adrenocorticotropic hormone through negative feedback inhibition. Cortisol facilitates the stress response by affecting the heart, vascular bed, water excretion, electrolyte balance, potentiation of catecholamine action, and control of water distribution. It affects fat, protein, and carbohydrate metabolism by stimulating glycogenolysis and neoglycogenesis. It is involved in immunologic and inflammatory responses and affects calcium metabolism. It promotes growth and development but, in excess, interferes with the GI tract mucosa maintenance, leading to peptic ulcer.

Aldosterone secretion is controlled primarily by the renin-angiotensin system and serum potassium concentration. The renin-angiotensin system controls aldosterone levels in response to changes in

TABLE 230-1 Causes of Primary Adrenal Insufficiency

Primary Adrenal Insufficiency	Examples
Autoimmune	Isolated adrenal insufficiency or associated with polyglandular insufficiencies (polyglandular autoimmune syndrome type I or II)
Adrenal hemorrhage or thrombosis	Necrosis caused by meningococcal sepsis Coagulation disorders Overwhelming sepsis (Waterhouse-Friderichsen syndrome)
Drugs	*Adrenal enzyme inhibitors (affect those with limited pituitary or adrenal reserve)* Etomidate Aminoglutethimide (can be used by body builders) Mitotane (orphan drug used to treat adrenocortical carcinoma) Ketoconazole
Infections	Tuberculosis Fungal, bacterial sepsis Acquired immunodeficiency syndrome involving adrenal glands
Infiltrative disorders	Sarcoidosis Hemochromatosis Amyloidosis Lymphoma Metastatic cancer
Surgery	Bilateral adrenalectomy Bariatric surgery
Hereditary	Adrenal hypoplasia Congenital adrenal hyperplasia Adrenoleukodystrophy Familial glucocorticoid deficiency

TABLE 230-2 Causes of Secondary Adrenal Insufficiency

Secondary Adrenal Insufficiency (hypothalamic-pituitary dysfunction)	Examples
Sudden cessation of prolonged glucocorticoid therapy	Chronic use of steroid inhibits CRH and ACTH production
Pituitary necrosis or bleeding	Postpartum pituitary necrosis (Sheehan's syndrome)
Exogenous glucocorticoid administration	Causes decreased production of CRH at hypothalamus and ACTH at pituitary
Brain tumors	Pituitary tumor Hypothalamic tumor Local invasion (craniopharyngioma)
Pituitary irradiation Pituitary surgery Head trauma involving the pituitary gland	Disrupts corticotropin-releasing hormone and ACTH production capacity in hypothalamic-pituitary axis
Infiltrative disorders of the pituitary or hypothalamus	Sarcoidosis Hemosiderosis Hemochromatosis Histiocytosis X Metastatic cancer Lymphoma
CNS infections involving hypothalamus or pituitary	Tuberculosis Meningitis Fungus Human immunodeficiency virus

Abbreviations: ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone.

volume, posture, and sodium intake. Serum potassium (hyperkalemia) influences the adrenal cortex directly to increase aldosterone secretion. Aldosterone maintains sodium and potassium plasma concentrations. It regulates extracellular volume and controls sodium and water balance.

Gonadocorticoids include androgen hormones and estrogen. Androgens produced include testosterone, dehydroepiandrosterone, and dehydroepiandrosterone sulfate, which are present in both men and women. In women, androgens are produced in the adrenal glands as well as the ovaries and promote the development of sex characteristics such as axillary and pubic hair and libido. In men, most androgens (testosterone) are produced in the testes. Androgens made by the adrenal glands are less important for normal sexual function.

PRIMARY ADRENAL INSUFFICIENCY

Causes of primary adrenal insufficiency (Addison's disease) are shown in **Table 230-1**. Approximately 90% of the gland must be destroyed for clinical adrenal insufficiency to develop.[2] In the United States, autoimmune disorders are responsible for most cases of primary adrenal insufficiency.[1,3] Autoimmune disorders may occur as an isolated process or as a component of polyglandular autoimmune syndrome types I and II. **Polyglandular autoimmune syndrome type I** is associated with candidiasis, hypoparathyroidism, and adrenal failure. **Polyglandular autoimmune syndrome type II** consists of Addison's disease plus either an autoimmune thyroid disease or type 1 diabetes mellitus associated with hypogonadism, pernicious anemia, celiac disease, or primary biliary cirrhosis.

In terms of infection, worldwide, tuberculosis is the most common cause of primary adrenal insufficiency. Human immunodeficiency virus may cause adrenal insufficiency through opportunistic infections (principally cytomegalovirus) or use of medications, such as ketoconazole. Secondary adrenal insufficiency can develop through inhibition of the hypothalamus-pituitary-adrenal axis.[4-7]

Infiltrative diseases such as amyloidosis, hemosiderosis, and bilateral metastasis from cancer may also cause primary adrenal insufficiency. Thrombosis and/or hemorrhage of the adrenals may occur as a complication of anticoagulation therapy, sepsis, disseminated intravascular coagulation, meningococcemia (Waterhouse-Friderichsen syndrome), or antiphospholipid syndrome.[8-10]

SECONDARY ADRENAL INSUFFICIENCY

Causes of secondary adrenal insufficiency are shown in **Table 230-2**. Secondary adrenal failure is usually characterized by depressed adrenocorticotropic hormone secretion, which reduces cortisol production, but aldosterone levels remain normal because of preserved stimulation by both the renin-angiotensin axis and potassium. Adrenal sex hormone production is also preserved. Intracranial disorders such as brain tumor, pituitary disease, postpartum pituitary necrosis, or major head trauma may affect the hypothalamic-pituitary function, resulting in secondary adrenal insufficiency.[11]

The most common cause of secondary adrenal insufficiency is long-term therapy with pharmacologic doses of glucocorticoids. Severity of adrenal suppression is variable and depends on the dose and potency of the glucocorticoid and the time of day the drug was taken (suppression is greater when taken in the evening). Recovery of the hypothalamus-pituitary-adrenal axis may take a few months to 1 year after steroid cessation. Although hypothalamus-pituitary-adrenal axis suppression is related to duration of treatment, steroid dose, and total cumulative dose, there is no strict correlation with any of these factors.[12] Some critically ill patients demonstrate reduced cortisol clearance and suppression of adrenocorticotropic hormone release.[13]

ADRENAL CRISIS

Adrenal crisis is shock refractory to volume resuscitation and pressors. It can result from acute destruction of the hypothalamic-pituitary axis or the adrenal glands or from acute stressors in the setting of underlying primary or secondary adrenal insufficiency. Reported stressors include

TABLE 230-3 Difference between Primary and Secondary Adrenal Insufficiency

Presentation	Primary	Secondary
Volume depletion and hypotension	Marked	Not as severe unless crisis is present
Serum potassium	Hyperkalemia	Hypokalemia
Serum sodium	Hyponatremia (due to salt wasting)	Hypernatremia (aldosterone functioning) or hyponatremia (due to water retention)
Cushingoid appearance	Absent	May be present (if due to long-term glucocorticoid use)
Symptoms of other pituitary hormone deficiencies (e.g., hypothyroidism and amenorrhea)	Absent	May be present (depends on the hypothalamic-pituitary site of lesion)
Skin pigmentation	Present (due to high ACTH level)	Absent

Abbreviation: ACTH = adrenocorticotropic hormone.

acute infection, especially gastrointestinal infection; surgery; extreme physical activity; acute severe injury or burns; and cessation of chronic glucocorticoid replacement.[14]

CLINICAL FEATURES

Primary and secondary adrenal insufficiency have dissimilar clinical presentations. These are depicted in **Table 230-3**. **Primary adrenal insufficiency** presents with symptoms of diminished cortisol, aldosterone, and gonadocorticoids, and increased adrenocorticotropic hormone, which causes skin hyperpigmentation. On the other hand, **secondary adrenal insufficiency** presents with symptoms of diminished cortisol only and possibly with related symptoms of intracranial lesions (e.g., headache, visual changes, galactorrhea).

Cortisol deficiency symptoms include weight loss, lethargy, weakness, mental status changes, and GI symptoms (anorexia, nausea, vomiting, abdominal pain, and diarrhea). **Aldosterone deficiency symptoms** include dehydration, syncope, salt craving, and hypotension (usually with orthostatic changes). **Gonadocorticoid deficiency symptoms** are observed more in women, who present with decreased axillary and pubic hair and decreased libido.

ADRENAL CRISIS

Acute adrenal crisis is characterized by severe hypotension refractory to vasopressors. Other symptoms include severe abdominal pain, nausea, and vomiting, mimicking an acute abdomen. CNS symptoms of confusion, disorientation, and lethargy may be present. There may be associated sepsis, even without fever. Consider adrenal crisis in situations of unexplained hypotension, especially in patients with a history of glucocorticoid therapy; those with acquired immunodeficiency syndrome, tuberculosis, autoimmune disease, or severe head trauma; those with a history of chronic fatigue and hyperpigmentation; and those with disorders known to cause acute adrenal crisis (as seen in Tables 230-1 and 230-2).

LABORATORY STUDIES AND IMAGING

Obtain a bedside glucose determination to identify hypoglycemia. Obtain CBC, full chemistries, hepatic function studies, ECG, and urinalysis. Additional studies are determined by the presumptive underlying source such as sepsis, hemorrhage, or CNS abnormality.

Primary adrenal insufficiency is typically characterized by hyponatremia and hyperkalemia due to aldosterone deficiency. **Secondary adrenal insufficiency** is characterized by either hypernatremia from functioning aldosterone causing sodium reabsorption in kidney or hyponatremia following water retention, and hypokalemia. In both primary and secondary adrenal insufficiency, cortisol deficiency is a common sequela, and hypotension or hypoglycemia may present. Mild metabolic acidosis is evident due to tissue hypoxia from hypovolemia and hypotension. ECG changes are generally related to potassium imbalances (e.g., prolonged QT, peaked T waves, and heart block in hyperkalemia in primary adrenal insufficiency, or inverted T waves and presence of U wave in hypokalemia in secondary adrenal insufficiency). An abdominal CT scan can identify adrenal gland hemorrhage or infarction.

Serum cortisol or adrenocorticotropic hormone levels are not usually readily available at ED presentation. If available, a serum cortisol >18 micrograms/dL generally rules out adrenal insufficiency.[15] The adrenocorticotropic hormone stimulation test measures serum cortisol after stimulation by synthetic adrenocorticotropic hormone (cosyntropin). Serum cortisol rises significantly in secondary, but not in primary, insufficiency. Serum corticotropin (adrenocorticotropic hormone) level[14] measurement also helps differentiate between primary and secondary adrenal insufficiency. A high adrenocorticotropic hormone level is seen in primary adrenal insufficiency, but adrenocorticotropic hormone is low in secondary adrenal insufficiency.

TREATMENT

ADRENAL INSUFFICIENCY

For **primary insufficiency**, treatment requires daily dosing of glucocorticoid and mineralocorticoid, usually for life. Androgen replacement may be recommended for women. The goal of treatment is to stabilize hormone levels and relieve symptoms. Mineralocorticoids are replaced with an oral, synthetic mineralocorticoid drug such as fludrocortisone (Florinef®). The dose is tailored to manage blood pressure and fluid balance. For **secondary insufficiency**, only glucocorticoid replacement is required.

ADRENAL CRISIS

The recommended treatment is outlined in **Table 230-4**. Begin therapy immediately in any suspected case of adrenal crisis, because prognosis is related to the rapidity of treatment onset. Give IV fluids early to treat hypotension. If hypoglycemia is present, give dextrose-containing solutions.

TABLE 230-4 Treatment Guide for Adrenal Crisis

Administer IV Fluids for Hypotension

Use dextrose-containing saline if hypoglycemic.

↓

Give Steroids

Hydrocortisone (100-milligram bolus) is the drug of choice for cases of adrenal crisis or insufficiency, especially for underlying primary insufficiency (provides both glucocorticoid and mineralocorticoid effects).

or

Dexamethasone, 4-milligram bolus (preferred if rapid adrenocorticotropic hormone stimulation test is contemplated).

↓

Consider Vasopressors

Administer only after steroid therapy in patients unresponsive to aggressive fluid resuscitation (choice of norepinephrine, dopamine, or phenylephrine [Neo-Synephrine®]).

↓

Consider Steroid Supplementation

Patients may require lifelong glucocorticoids ± mineralocorticoid ± androgen supplementation.

↓

Determine Underlying Cause

Investigate as appropriate—sepsis, adrenal hemorrhage, CNS abnormality.

↓

Optimize Maintenance Dosage of Steroids

During periods of stress, increase maintenance doss of chronic steroids to three times the daily dose, to satisfy increased physiologic need for cortisol.[16]

Hydrocortisone is the steroid drug of choice for cases of adrenal crisis or insufficiency because it provides both glucocorticoid and mineralocorticoid effects. IV hydrocortisone (100-milligram minimum bolus) can be administered. Alternatively, IV dexamethasone (4-milligram bolus) may be given rapidly if adrenocorticotropic hormone stimulation test is contemplated as part of diagnostic strategy. Give vasopressors only after steroid therapy in patients unresponsive to fluid resuscitation.

Determine the underlying cause. For **primary adrenal insufficiency**, abdominal CT scan may be performed to evaluate the adrenal glands. Consider retroviral screening if HIV is under consideration. Consider chest radiography to assess for bronchopneumonia or tuberculosis. For **secondary adrenal insufficiency**, a head CT or MRI, as well as blood tests of pituitary hormones, may be required.

For patients receiving chronic steroids, increase the maintenance dose during periods of stress (e.g., illness, surgery, trauma, GI upset) to satisfy the increased physiologic need for cortisol. Dosage recommendations vary and are based on expert opinion. **A typical stress dose is three times the daily maintenance dose of glucocorticoid.** Mineralocorticoid dosage generally stays the same. Endocrinology consultation can be helpful for further recommendations.

DISPOSITION AND FOLLOW-UP

Admit patients with adrenal crisis to an intensive care unit for careful clinical monitoring, IV steroid administration, and confirmation of diagnosis and identification of etiology. Discharge can only be considered for mild cases of adrenal insufficiency with identified etiologies and after a clear plan of management is established, often with endocrinology consultation.

SPECIAL POPULATIONS

PATIENTS ON CHRONIC CORTICOSTEROIDS

Hypothalamus-pituitary-adrenal axis function is inhibited with chronic use of steroids. Always consider adrenal insufficiency in patients with chronic steroid use presenting with any acute illness. Hypothalamus-pituitary-adrenal axis function should recover within about 1 month after the last dose of steroid intake, but may be longer in some cases. Patients who receive steroids by topical, intranasal, inhalational, or PR routes are not at risk for hypothalamus-pituitary-adrenal axis suppression.

PATIENTS WITH CHRONIC ADRENAL INSUFFICIENCY WITH ACUTE ILLNESS OR INJURY

Patients with chronic adrenal insufficiency who present to the ED with a minor illness or injury require special attention to steroid dosing.[15] In normal circumstances, about 20 milligrams/d of hydrocortisone is equivalent to the daily production of cortisol. For a minor illness or injury, triple the daily glucocorticoid dose for 24 to 48 hours until symptoms improve.[16] Increasing the mineralocorticoid dose, if the patient is receiving one, is usually not necessary. Arrange follow-up care in 24 hours with the primary care physician or endocrinologist. Patients should return to the ED if nausea, vomiting, fever, weakness, or any other untoward symptoms develop, or if they cannot retain their medications.

PREGNANCY WITH ADRENAL INSUFFICIENCY

Most women with primary adrenal insufficiency are able to undergo healthy pregnancy, labor, and delivery. They need to take medications on schedule with close monitoring of mother and fetus. Some may require adjustment of glucocorticoid doses, especially during the third trimester and during labor. Women with hyperemesis gravidarum may need to switch from oral medication to parenteral medication until symptoms subside.

SECTION 18

Hematologic and Oncologic Disorders

CHAPTER 231

Anemia

John C. Ray
Robin R. Hemphill

INTRODUCTION

Anemia is a common medical problem worldwide, affecting approximately one quarter of the world's population, especially children, pregnant and premenopausal women, the elderly, and the chronically ill.[1-7] Anemia is not so much a disease as a sign or symptom. There are three broad causes of anemia: (1) blood loss, (2) decreased red blood cell production, and (3) increased red blood cell destruction.

PATHOPHYSIOLOGY

Anemia is a reduced concentration of red blood cells (RBCs) from the normal ranges based on age, gender, and race.[8] In healthy persons, normal erythropoiesis ensures that the concentration of RBCs present is adequate to meet the body's demand for oxygen and that the destruction of RBCs balances the production. The average life of the circulating erythrocyte is approximately 110 to 120 days. Any process or condition that results in the loss of RBCs, that impairs RBC production, or that increases RBC destruction will result in anemia if the body cannot produce enough new cells to replace those lost (**Table 231-1**). It is not uncommon for more than one mechanism to produce anemia in the same individual.

Quantification of the erythrocyte concentration is reflected in (1) RBC count per microliter, (2) hemoglobin concentration, and (3) hematocrit (percentage of RBC mass to blood volume). Normal RBC values for adults vary between genders, with small variations for ethnicity and age (**Table 231-2**).

The body responds to anemia in several ways in order to blunt the effect of a reduction in the oxygen-carrying capacity. The mechanisms vary, depending on the rapidity of onset, the degree of anemia, and the underlying condition of the patient. In acute forms of anemia that result from intravascular volume loss, the peripheral vasculature compensates by vasoconstriction, while the central vasculature vasodilates to help preserve blood flow to vital organs.[9] As the condition worsens, systemic small-vessel vasodilation will occur, allowing increased blood flow to tissues. These mechanisms result in decreased systemic vascular resistance, increased cardiac output, and often tachycardia. Along with these changes, the RBCs themselves enhance their ability to release oxygen to the tissues. If the anemia is chronic in nature, there is commonly an increase in plasma volume that maintains total blood volume at a constant level.

TABLE 231-1 Classification of Anemia

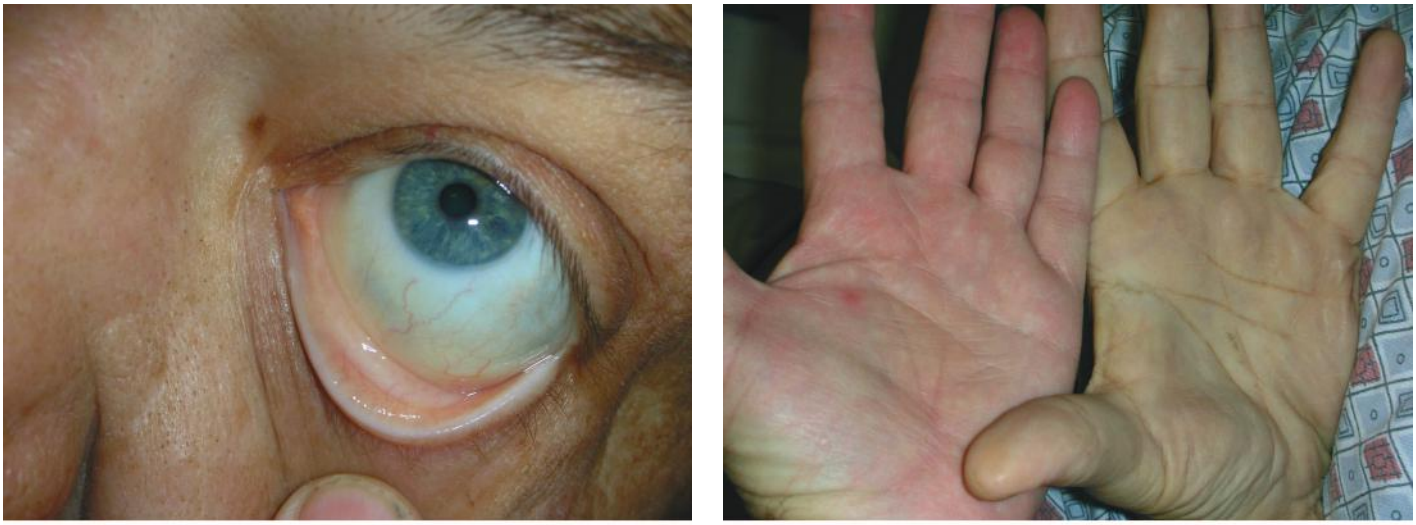
Mechanism	Example
Loss of red blood cells by hemorrhage	Acute GI bleeding
Increased destruction	Sickle cell disease Drug-induced autoimmune hemolytic anemia
Impaired production	Nutritional deficiency anemia (iron, folate) Aplastic or myelodysplastic anemia
Dilutional	Rapid IV crystalloid infusion

TABLE 231-2 Normal Red Blood Cell Values for Adults

	Male	Female
Red blood cell count (million/mm^3)	4.5–6.0	4.0–5.5
Hemoglobin (grams/dL)	14–17	12–15
Hematocrit (%)	42–52	36–48
Mean corpuscular volume (fL)	78–100	78–102
Mean corpuscular hemoglobin (picograms/cell)	25–35	25–35
Mean corpuscular hemoglobin concentration (grams/dL)	32–36	32–36
Red cell distribution width (%)	11.5–14.5	11.5–14.5
Reticulocytes (%)	0.5–2.5	0.5–2.5

Note: Normal values may vary depending on the equipment used, patient's age, and the altitude of the equipment location.

Finally, anemia will result in the stimulation of erythropoietin as a result of tissue hypoxia and breakdown products from RBC destruction. New immature erythrocytes, known as reticulocytes, will appear in the blood within 3 to 7 days.



CLINICAL FEATURES

The severity of signs and symptoms related to anemia depends on several factors: the rate of development of anemia (acute vs chronic), the extent of anemia that is present, the age and general physical condition of the patient, and other existing comorbidities. Children and young adults, for example, may tolerate a significant decline in RBC volume with minimally altered vital signs until they become acutely hypotensive, whereas elderly patients frequently have other comorbidities that make physiologic compensation challenging.[3,4] Patients with chronic and slowly developing anemia may have no complaints even with hemoglobin levels as low as 5 to 6 grams/dL. Typically, most otherwise healthy adults will be symptomatic when hemoglobin levels decrease to about 7 grams/dL.

Patients with chronic anemia may note weakness, fatigue, dizziness, lethargy, dyspnea with minimal exertion, palpitations, and orthostatic symptoms. Specific historical features can be helpful in the identification and diagnosis of anemia; a history of recent trauma, hematochezia, melena, hemoptysis, hematemesis, hematuria, or menorrhagia suggests possible anemia. More subtle historical features include relevant comorbidities such as peptic ulcer disease, chronic liver disease, and chronic renal disease. Specific inquiries about the use of antiplatelet agents, anticoagulants, and nonsteroidal anti-inflammatory agents should be made.

Physical exam findings that may be present in patients with clinically significant anemia include tachycardia; skin, nail bed, and mucosal pallor; systolic ejection murmur; bounding pulse; and widened pulse pressure (**Figure 231-1**). Signs of easy bleeding or bruising suggest a coagulation disorder. Evidence of jaundice and hepatosplenomegaly suggests hemolysis. Unusual skin ulcerations, peripheral neuropathy, or neurologic signs such as ataxia or altered mental status may be evidence of nutritional deficiencies. Additional manifestations may depend on comorbid illnesses. For example, a patient with preexisting angina may find that episodes of chest pain are markedly worsened when anemia is present.

Patients who develop an acute, severe anemia may have all the signs and symptoms noted above and, in addition, may have hypotension, resting and exertional dyspnea, palpitations, diaphoresis, anxiety, or severe weakness that may progress to lethargy and altered mental status.

A B

FIGURE 231-1. Pale conjunctiva (**A**) and palms (**B**) in patient with anemia. In **B**, the physician's hand is on the left for comparison with the patient's hand on the right. [Image used with permission of J. Stephan Stapczynski, MD.]

They may also complain of thirst and will usually have decreased urine output. Loss of >40% of blood volume from trauma or spontaneous hemorrhage can lead to severe symptoms that are due more to intravascular volume depletion than to anemia.[10] In healthy patients, myocardial oxygen delivery usually is not limited until hemoglobin concentration is 50% or less of normal.

DIAGNOSIS

The diagnosis is established by a finding of decreased RBC count, hemoglobin, and hematocrit on the routine CBC. It is rarely essential that a specific cause of anemia be established in the ED. However, appropriate assessment initiated in the ED can help expedite a diagnosis and should therefore be started before the transfusion of packed RBCs.[6,8]

The initial evaluation of a patient newly diagnosed with anemia includes several steps. First, look for a source of bleeding, including the most common internal sites—GI or uterine bleeding. If there is no physical or historical evidence of GI or uterine bleeding, then review RBC indices provided with the CBC, reticulocyte count, and peripheral blood smear (**Table 231-3**). The mean corpuscular volume is the most useful guide to the possible etiology of an anemia and is used to classify the anemic process as microcytic, normocytic, or macrocytic. Other useful diagnostic tests include the red cell distribution width and reticulocyte count. The serum ferritin is the most useful test for the diagnosis of iron deficiency anemia.[11] Following this initial classification, additional tests can lead to a specific diagnosis (**Figures 231-2, 231-3,** and **231-4**).[5,7,8,12-15]

TABLE 231-3 Laboratory Tests in the Evaluation of Anemia

Test	Interpretation	Clinical Correlation
MCV	Measure of the average RBC size.	Decreased MCV (microcytosis) is seen in chronic iron deficiency, thalassemia, anemia of chronic disease, and lead poisoning.
		Increased MCV (macrocytosis) can be due to vitamin B_{12} or folate deficiency, alcohol abuse, liver disease, reticulocytosis, and some medications (see "Diagnosis" section).
MCH	Measure of the amount of hemoglobin in average RBC.	—
RDW	Measures the size variability of the RBC population.	In early deficiency anemia (iron, vitamin B_{12}, or folate), may be increased before the MCV becomes abnormal.
MCHC	Measure of hemoglobin concentration in average RBC.	Low MCHC can be seen in iron deficiency anemia, defects in porphyrin synthesis, and hemolytic anemia.
Ferritin	Ferritin is a protein in the body that binds to iron. Serum levels serve as an indication of the amount of iron stored in the body.	Low serum ferritin is associated with iron deficiency anemia and helps differentiate this anemia from other causes.
Reticulocyte count	These RBCs of intermediate maturity are a marker of production by the bone marrow.	Decreased reticulocyte count reflects impaired RBC production.
		Increased counts are a marker of accelerated RBC production.
Peripheral blood smear	Allows visualization of the RBC morphology.	May guide to new diagnosis of diseases such as sickle cell disease.
	Allows evaluation for abnormal cell shapes.	Aids in the diagnosis of entities such as hemolytic anemia.
	Allows examination of the WBCs and platelets.	May guide the diagnosis of other diseases that cause anemia.
Direct and indirect Coombs test	Direct Coombs test is used to detect antibodies on RBCs.	Direct Coombs test is positive in autoimmune hemolytic anemia, transfusion reactions, and some drug-induced hemolytic anemia.
	Indirect Coombs test is used to detect antibodies in the sera.	Indirect Coombs test is routinely used in compatibility testing before transfusion.

Abbreviations: MCH = mean corpuscular hemoglobin; MCHC = mean corpuscular hemoglobin concentration; MCV = mean corpuscular volume; RBC = red blood cell; RDW = red cell distribution width.

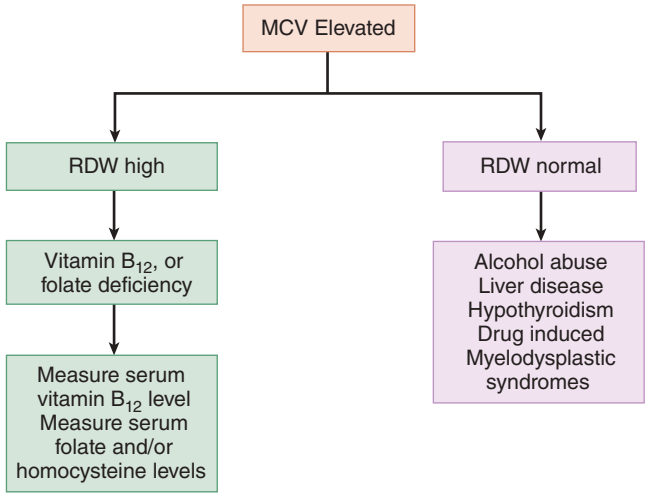


FIGURE 231-2. Evaluation of macrocytic anemia. MCV = mean corpuscular volume; RDW = red cell distribution width.

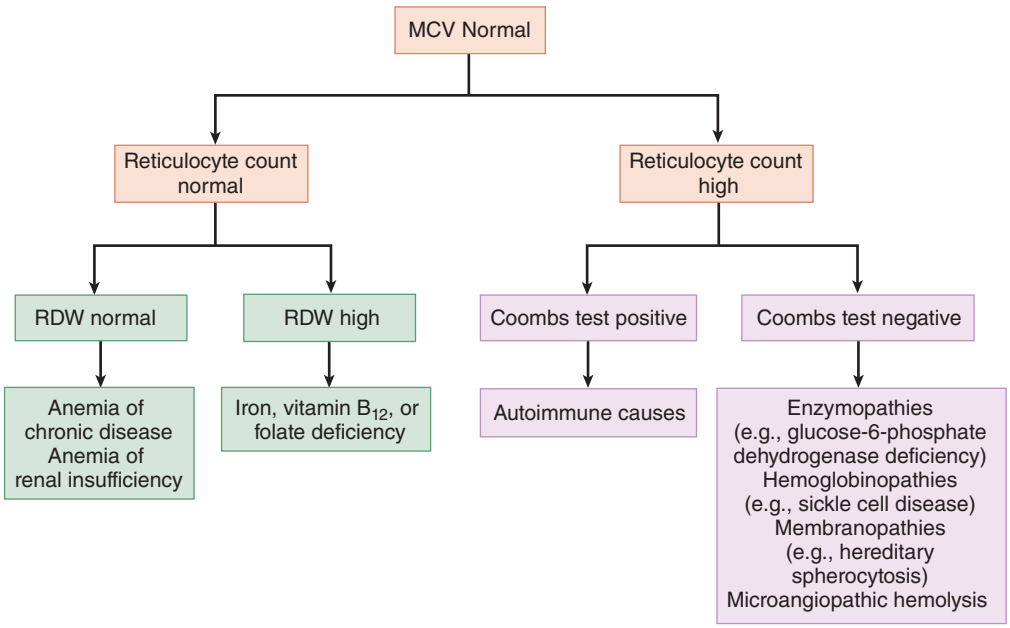

FIGURE 231-3. Evaluation of normocytic anemia. MCV = mean corpuscular volume; RDW = red cell distribution width.

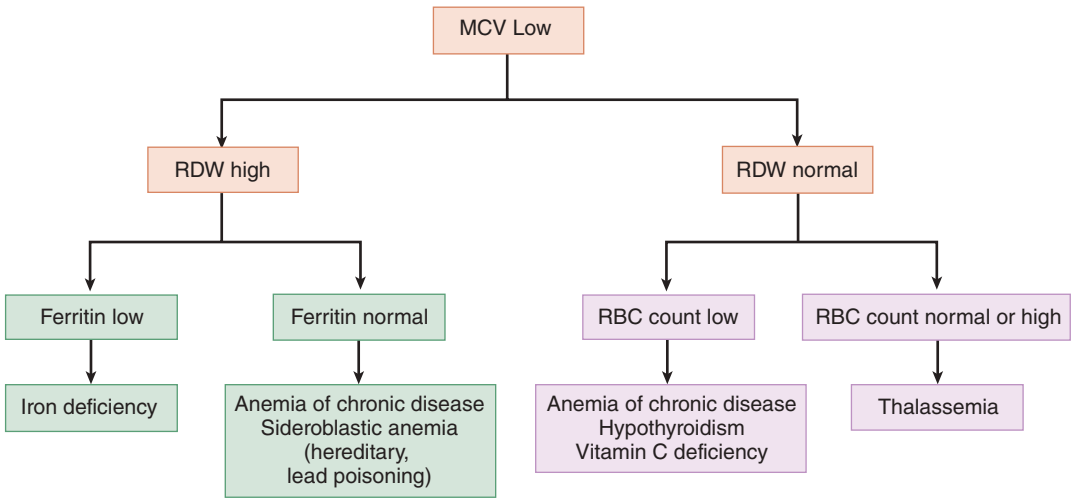

FIGURE 231-4. Evaluation of microcytic anemia. MCV = mean corpuscular volume; RBC = red blood cell; RDW = red cell distribution width.

TABLE 231-4 Treatment for Specific Anemias

Anemia Type	Treatment (Adult Doses)
Iron deficiency anemia	Elemental iron, 200–300 milligrams PO daily (e.g., ferrous sulfate, 325 milligrams PO, 3–4 tablets taken on an empty stomach over the course of day); reticulocyte count should increase within 4–7 d and peak at 10 d; sustained treatment after correction of anemia is usually necessary to replenish iron stores.
Cyanocobalamin (vitamin B_{12}) deficiency anemia	Cyanocobalamin, 1000 micrograms IM per week for 8 wk and every month thereafter; reticulocyte count should increase within 4 d and peak at 7 d. Oral replacement with 2000 micrograms daily is also effective (see "Treatment" section).
Folate deficiency anemia	Folate, 1 milligram PO daily (doses up to 5 milligrams may be needed for patients with malabsorption); reticulocyte count should increase within 4 d with normalization of hemoglobin level in 1–2 mo.
Sideroblastic anemia	Evaluate for reversible causes, including alcohol or other drug toxicity, or toxin exposure. Discontinue any offending agents. Treatment is mainly supportive, consisting primarily of blood transfusions to maintain the hemoglobin level. A trial of pyridoxine at pharmacologic doses (500 milligrams PO daily) may be helpful, with response most commonly seen in cases resulting from ethanol abuse or the use of pyridoxine antagonists. Some patients with hereditary, X-linked sideroblastic anemia also respond to pyridoxine. Improvement with pyridoxine is rare for sideroblastic anemia of other causes.
Aplastic anemia	Supportive care, including transfusion if appropriate. Referral for further workup.
Anemia of chronic disease	Supportive care, including transfusion if appropriate. Referral for further workup and evaluation for underlying disease.

Macrocytosis can result from multiple causes; most common are alcohol abuse, liver disease, vitamin B_{12} and/or folate deficiency, and hypothyroidism.[14,15] A variety of medications can affect folate absorption or metabolism and produce macrocytosis. Drugs include phenytoin, valproate, trimethoprim, sulfamethoxazole, and metformin. The reverse transcriptase inhibitors used to treat human immunodeficiency virus infection can also produce macrocytosis, but they do so without causing anemia. Reticulocytes are larger than mature RBCs, so automated blood cell counters can report a mean corpuscular volume value above the normal range when an increased reticulocyte count is present.

TREATMENT

The treatment of anemia depends on the etiology, symptoms, and clinical status of the patient. In the ED, anemia that requires the most urgent attention results from acute blood loss.[10] All patients who have ongoing blood loss and anemia should have their blood typed and cross-matched, so that information is available for transfusion, if needed (see chapter 238, "Transfusion Therapy"). The decision to transfuse RBCs must be individualized for each patient, taking into account clinical symptoms, age of the patient, presence of comorbid disease, and the likelihood of further blood loss.[16-20] In general, patients who are symptomatic and hemodynamically unstable and show evidence of tissue hypoxia and/or limited cardiopulmonary reserve should have RBCs transfused. In most settings, patients with anemia resulting from acute blood loss benefit when transfused at hemoglobin levels of 6 to 8 grams/dL. Liberal transfusion strategy (defined as a hemoglobin threshold of 9.5 to 10 grams/dL) is not associated with clinical benefit, so a hemoglobin value threshold of 6 to 8 grams/dL for RBC transfusion is recommended in most circumstances.[21]

ED patients with chronic anemia or a newly diagnosed anemia of uncertain etiology not caused by acute blood loss may not require immediate transfusion unless they are hemodynamically unstable, hypoxic, or have acidosis or ongoing cardiac ischemia. In a patient with newly diagnosed anemia of uncertain etiology, obtain laboratory studies for hematologic evaluation before transfusion. Consultation with a hematologist may be beneficial to guide this evaluation. The subsequent evaluation of some patients with chronic anemias or anemias of uncertain etiology can be made more difficult by transfusion, so transfusion should not be undertaken unless specifically indicated.

Treatment for nutritional deficiency anemias usually produces a reticulocyte response in 4 to 7 days (**Table 231-4**). Standard therapy for iron or folate deficiency uses oral replacement. Vitamin B_{12} replacement has traditionally been intramuscular because of concern that malabsorption of the vitamin, a common predisposing condition for vitamin B_{12} deficiency, would limit the effectiveness of oral replacement.[22] However, oral doses of 2000 micrograms of vitamin B_{12} per day are as effective as the intramuscular route in achieving the desired clinical response.[23,24]

DISPOSITION AND FOLLOW-UP

Patients with anemia from ongoing blood loss should be admitted to the hospital for further evaluation and treatment. Patients with isolated anemia that is chronic or newly diagnosed and not related to blood loss do not necessarily require hospital admission if they are asymptomatic and hemodynamically stable, they have minimal comorbid disease, and close follow-up can be arranged. Patients newly diagnosed with anemia who also have abnormalities in the WBC or platelet count should have hematologic consultation and should probably be admitted.

CHAPTER 232

Tests of Hemostasis

Stephen John Cico
Robin R. Hemphill

THE BLEEDING PATIENT

Most bleeding seen in the ED is a result of trauma—local wounds, lacerations, or other structural lesions—and the majority of traumatic bleeding occurs in patients with normal hemostatic mechanisms.[1] In these patients, specific assessment of hemostasis is unnecessary. However, some ED patients have abnormal bleeding due to impaired hemostasis. Identifying these patients requires attention to the history and physical findings.[2-4] Generally speaking, when patients have spontaneous bleeding from multiple sites, bleeding from untraumatized sites, delayed bleeding several hours after trauma, and bleeding into deep tissues or joints, the possibility of a bleeding disorder should be considered.

Important historical data that aid in identifying a congenital bleeding disorder include the presence of unusual or abnormal bleeding in the patient and other family members and any occurrence of excessive bleeding after dental extractions, surgical procedures, or trauma.[5] Many patients with abnormal bleeding have an acquired disorder, such as liver disease, renal disease, or drug use (particularly ethanol, aspirin, nonsteroidal anti-inflammatory drugs, antiplatelet drugs, oral anticoagulants, antibiotics, and other salicylate-containing products).[2-4] Many supplements and herbal preparations, including garlic, ginseng, ginkgo biloba, ginger, and vitamin E, can also increase bleeding tendencies.

The site of bleeding may provide an indication of the hemostatic abnormality. Mucocutaneous bleeding, including petechiae, ecchymoses, epistaxis, GI or GU bleeding, or heavy menstrual bleeding, is characteristic of qualitative or quantitative platelet disorders. Purpura is often associated with thrombocytopenia and commonly indicates a

systemic illness. Bleeding into joints and potential spaces, such as between fascial planes and into the retroperitoneum, and delayed bleeding are most commonly associated with coagulation factor deficiencies. Patients who demonstrate both mucocutaneous bleeding and bleeding in deep spaces may have disorders such as disseminated intravascular coagulation, in which both platelet abnormalities and coagulation factor abnormalities are present (see chapters 233, "Acquired Bleeding Disorders," 234, "Clotting Disorders," and 235, "Hemophilias and von Willebrand's Disease").

Common laboratory tests for hemostasis have their limitations.[6,7] They are generally useful and reliable for identifying disorders of coagulation factor function and quantitative platelet availability. However, tests of qualitative platelet function show a significant biologic variation, so that standardization has been difficult to achieve.[8,9] In addition, liver disease and renal failure—two conditions that increase the potential for abnormal hemorrhage—may not give rise to consistent and measurable abnormal results on routine tests of hemostasis.[10-12]

THE PATIENT WITH A THROMBUS

Presentation of a patient to the ED with a disorder due to an intravascular thrombosis, such as a deep venous thrombosis or pulmonary embolus, suggests the potential for an underlying hypercoagulable state (see chapter 234). Premature coronary artery disease and acute coronary syndrome in individuals as young as teenagers have also been linked to hypercoagulable conditions. However, many, if not most, occurrences of intravascular thrombosis are not due to exaggerated hemostasis, but rather are due to local conditions, with blood vessel wall injuries, local inflammation, or vascular stasis provoking the thromboembolic event.[13,14]

The susceptibility to hypercoagulation may be acquired or genetically transmitted. Common acquired hypercoagulable disorders include essential thrombocythemia, polycythemia vera, paroxysmal nocturnal hemoglobinuria, antiphospholipid syndrome, and cancer (often occult at the time of acute thrombosis). Inherited hypercoagulable disorders include factor V Leiden, prothrombin mutations, hyperhomocysteinemia, and deficiencies of protein C, protein S, and antithrombin. Patients with inherited hypercoagulable conditions tend to have venous thrombosis, whereas those with acquired disorders can have both arterial and venous clots.

Proteins C and S are vitamin K–dependent antihemostatic factors made in the liver, associated with disorders leading to deficiencies of these proteins inherited in an autosomal manner. Protein C is activated by thrombin and functions with protein S to stop fibrin formation and to stimulate the process of fibrinolysis. Antithrombin is also an antihemostatic protein that blocks activated coagulation factors. Elevated homocysteine level is also a known risk factor for thromboembolism.

Laboratory tests for a hypercoagulable diathesis show wide biologic variation, and standardization among laboratories has been difficult to achieve. The clinical utility of testing patients for suspected hypercoagulable conditions is dependent on the specific disorder.[13-15]

NORMAL COAGULATION

The normal hemostatic system consists of a complex process that limits blood loss through the formation of a platelet plug (primary hemostasis) and the production of cross-linked fibrin (secondary hemostasis), which strengthens the platelet plug. These reactions are counterregulated by the fibrinolytic system, which limits the size of the fibrin clot that is formed and thereby prevents excessive clot formation. Congenital and acquired abnormalities occur in all these systems. The affected patient may have excessive hemorrhage, excessive thrombus formation, or both.

PRIMARY HEMOSTASIS

Primary hemostasis is the platelet interaction with the vascular subendothelium that results in the formation of a platelet plug at the site of injury. Required components for this to occur are normal vascular subendothelium (collagen), functional platelets, normal von Willebrand factor (connects the platelet to the endothelium via glycoprotein Ib), and normal fibrinogen (connects the platelets to each other via glycoprotein IIb and IIIa) (**Figure 232-1**). Primary hemostasis begins within 20 seconds of injury, is short-lived, and requires secondary hemostasis for clot stabilization.

SECONDARY HEMOSTASIS

Secondary hemostasis consists of the tightly regulated reactions of the plasma coagulation proteins. The final product is cross-linked fibrin, which is insoluble and strengthens the platelet plug formed in primary hemostasis (**Figure 232-2**).

Secondary hemostasis is also known as the *coagulation cascade*. The inactivated coagulation proteins (factors) are identified by Roman numerals, and after activation, the activated factor is designated by *a*. There are two independent activation pathways. The contact system is known as the *contact activation pathway* or *intrinsic pathway*, and the tissue factor system is known as the *tissue factor pathway* or *extrinsic pathway*. The pathways merge at the point of activation of factor X. Medications such as rivaroxaban (Xarelto®) and apixaban (Eliquis®) inhibit the activity of factor Xa. The combination of factor Xa, factor Va, phospholipid, and calcium ("thrombinase complex") more efficiently catalyzes the conversion of prothrombin to thrombin than free factor Xa. In turn, thrombin catalyzes the conversion of fibrinogen to fibrin monomer. Medications such as bivalirudin (Angiomax®) or dabigatran (Pradaxa®) are direct thrombin inhibitors. The *common pathway* describes the steps from factor X activation to cross-linked fibrin formation.

THE FIBRINOLYTIC SYSTEM

The fibrinolytic system regulates the hemostatic mechanism by limiting the size of the fibrin clots that are formed (**Figure 232-3**). Tissue plasminogen activator (tPA), released from endothelial cells, is the principal physiologic trigger for the fibrinolytic process, converting plasminogen, synthesized in the liver and adsorbed in the fibrin clot, to plasmin. Plasmin degrades fibrinogen and fibrin monomer into low-molecular-weight fragments known as fibrin degradation products and degrades cross-linked fibrin into D-dimers.

Other physiologic inhibitors of hemostasis with clinical relevance include antithrombin and the protein C–protein S system. Antithrombin is a protein that forms complexes with all the serine protease coagulation factors (factors XIIa, XIa, Xa, IXa, and thrombin), thereby inhibiting their function. Heparin potentiates this interaction, and this is the basis for its use as an anticoagulant. Proteins C and S are vitamin K–dependent factors that are produced in the liver. Activated protein C binds to the cell-surface-bound protein S, and this complex is capable of inactivating the two plasma cofactors factors Va and VIIIa and inhibiting their participation in the coagulation cascade. A single amino acid substitution in factor V, a condition named factor V Leiden, prevents activated protein C from binding and inhibiting the activity of factor Va. Thus, patients with this inherited condition have prolonged thrombogenic factor Va activity. Factor V Leiden, deficiency or defects in antithrombin, protein C, and protein S produce a potentially hypercoagulable condition and predispose the patient to venous thromboses.

DIAGNOSIS

Before embarking on a sequence of hemostatic testing, evaluate the patient in three areas: (1) Is the bleeding abnormal? (2) Is there a current medical condition associated with increased hemorrhage? (3) Is there a structural cause that explains the bleeding?[13-17]

The basic laboratory tests obtained for a patient with a suspected abnormal bleeding disorder are a CBC and platelet count, prothrombin time, and activated partial thromboplastin time (**Table 232-1**). The

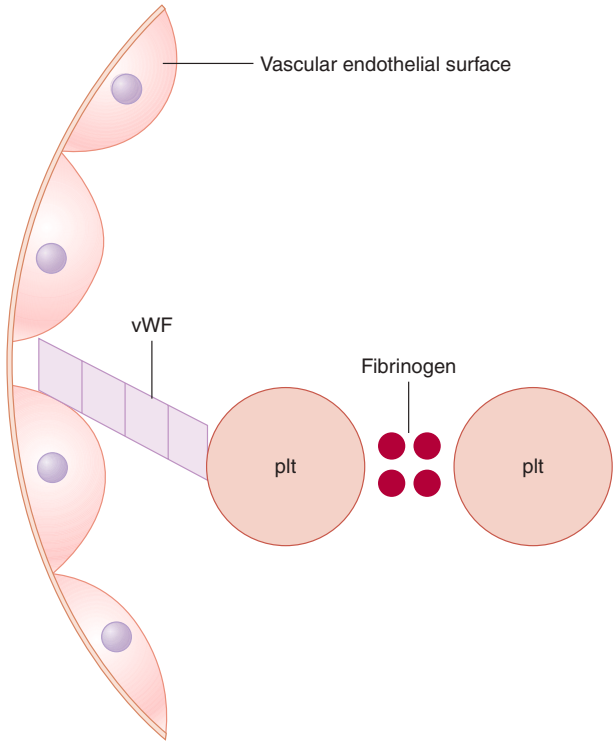

FIGURE 232-1. Primary hemostasis. plt = platelet; vWF = von Willebrand factor.

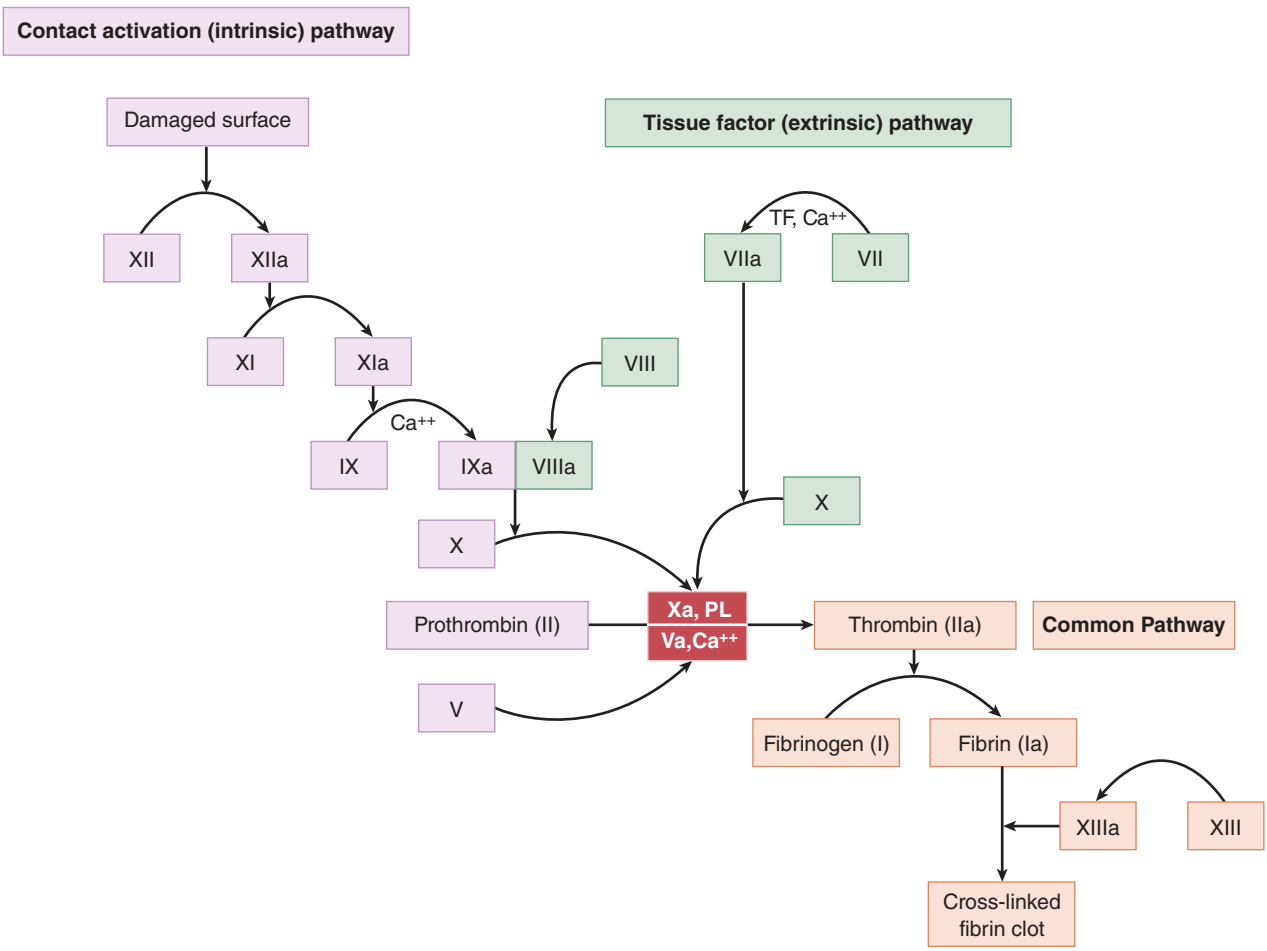

FIGURE 232-2. Secondary hemostasis. Ca^{2+} = calcium; fibrinogen is factor I; PL = phospholipid surface (often platelets); prothrombin is factor II.

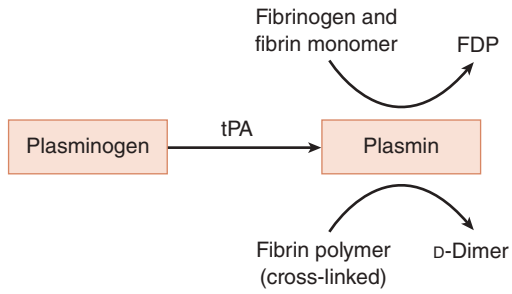

FIGURE 232-3. The fibrinolytic system. FDP = fibrin degradation product; tPA = tissue plasminogen activator.

TABLE 232-1 Initial Tests of Hemostasis

Screening Tests	Reference Value	Component Measured	Clinical Correlations
Primary Hemostasis			
Platelet count	150–400/mm^3 (150–400 × 10^9/L)	Number of platelets per mm^3	*Decreased platelet count (thrombocytopenia)*: bleeding usually not a problem until platelet count is <50,000/mm^3 (50 × 10^9/L); high risk of spontaneous bleeding, including CNS bleeding, seen with count of <10,000/mm^3 (10 × 10^9/L); usually due to decreased production or increased destruction of platelets
			Elevated platelet count (thrombocytosis): commonly a reaction to inflammation or malignancy, and occurs in polycythemia vera; can be associated with hemorrhage or thrombosis
Bleeding time (BT)	Variable	Interaction between platelets and the subendothelium	*Prolonged BT* caused by:
	Typically 2.5–10.0 min using a BT template		Thrombocytopenia (platelet count <50,000/mm^3 or 50 × 10^9/L)
			Abnormal platelet function (von Willebrand's disease, antiplatelet drugs, uremia, liver disease)
Secondary Hemostasis			
Prothrombin time (PT) and international normalized ratio (INR)	PT: 11–13 s; depends on reagent	Extrinsic system and common pathway—factors VII, X, V, prothrombin, and fibrinogen INR = 1.7 corresponds to approximately 30% activity of coagulation factors as a whole	*Prolonged PT* most commonly caused by:
	INR: 1.0		Warfarin (inhibits production of vitamin K–dependent factors II, VII, IX, and X)
			Liver disease with decreased factor synthesis
			Antibiotics that inhibit vitamin K–dependent factors (moxalactam, cefamandole, cefotaxime, cefoperazone)
Activated partial thromboplastin time (aPTT)	22–34 s	Intrinsic system and common pathway—factors XII, XI, IX, VIII, X, V, prothrombin, and fibrinogen	*Prolonged aPTT* most commonly caused by:
	Depends on type of thromboplastin reagent used		Heparin therapy
	"Activated" with kaolin		Factor deficiencies (factor levels have to be <30% of normal to cause prolongation)
Fibrinogen level	Slightly variable according to specific test	Protein made in liver; converted to fibrin as part of normal coagulation cascade	Low levels seen in disseminated intravascular coagulation
	Typically 200–400 milligrams/dL (2–4 g/L)		Elevated in inflammatory processes (acute-phase reactant)
Thrombin clotting time (TCT)	10–12 s	Conversion of fibrinogen to fibrin monomer	*Prolonged TCT* caused by:
			Low fibrinogen level
			Abnormal fibrinogen molecule (liver disease)
			Presence of heparin, fibrin degradation products, or a paraprotein (multiple myeloma); these interfere with the conversion
			Occasionally seen in hyperfibrinogenemia
"Mix" testing	Variable	Performed when results on one or more of the above screening tests is prolonged; the patient's plasma ("abnormal") is mixed with "normal" plasma and the screening test is repeated	*If the mixing corrects* the screening test result: one or more factor deficiencies are present
			If the mixing does not correct the screening test result: a circulating inhibitor is present

TABLE 232-2 Additional Hemostatic Tests

Test	Reference Value	Component Measured	Clinical Correlations/Comments
Fibrin degradation product (FDP) and D-dimer levels	FDP: variable depending on specific test, typically <2.5–10 micrograms/mL (2.5–10 milligrams/L)	FDP test: measures breakdown products from fibrinogen and fibrin monomer	Levels are elevated in diffuse intravascular coagulation, venous thrombosis, pulmonary embolus, and liver disease, and during pregnancy
	D-Dimer: variable depending on specific test, typically <250–500 nanograms/mL (250–500 micrograms/L)	D-Dimer test: measures breakdown products of cross-linked fibrin	
Factor level assays	60%–130% of reference value (0.60–1.30 units/mL)	Measures the percent activity of a specified factor compared to normal	To identify specific deficiencies and direct therapeutic management
Protein C level	Variable	Level of protein C in the blood	Vitamin K dependent
	Typically 60%–150% of reference value		Increases with age
			Values higher in males than females
			Deficiency associated with thromboembolism in people <50 y of age
Protein S level	Variable	Level of protein S in the blood	Vitamin K dependent
	Typically 60%–150% of reference value		Increases with age
			Values higher in males than females
			Deficiency associated with thromboembolism in people <50 y of age
Factor V Leiden (FVL)	Variable	Screening test looks for activated protein C resistance, and confirmatory test analyzes DNA sequence of factor V gene	FVL not inactivated by activated protein C
		Screening assay uses activated partial thromboplastin time with and without added activated protein C	Heterozygotes have 7× and homozygotes have a 20× increased lifetime risk of venous thrombosis
			Mutation associated with thromboembolism in people <50 y of age
Antithrombin level	Variable depending on specific test	Measures level of antithrombin in the blood	Not vitamin K dependent; patients with deficiency require higher dosages of heparin for anticoagulation therapy
	Typically 20–45 milligrams/dL (200–450 milligrams/L)		Deficiency associated with thromboembolism in people <50 y of age
Antiphospholipid antibodies	IgG <23 GPL units/mL and IgM <11 MPL units/mL	Tests for antibodies that bind to phospholipids	*Lupus anticoagulant*: elevated in systemic lupus erythematosus (SLE) and other autoimmune diseases
		Lupus anticoagulant	*Anticardiolipin antibody*: elevated in SLE, other autoimmune diseases, syphilis, and Behçet's syndrome
		Anticardiolipin antibody	Increased risk of spontaneous abortions, fetal loss, and fetal growth retardation
Anti–factor Xa activity	During therapeutic anticoagulant use: 0.7–1.1 units/mL	Inhibition of factor Xa activity	Used to monitor low-molecular-weight heparin therapy, and newer anticoagulants such as apixaban and rivaroxaban
	During prophylactic anticoagulant use: 0.2–0.3 units/mL		May be elevated in renal dysfunction
Platelet function assay	88–183 s	Tests for platelet adhesion and aggregation	Affected by uremia, anemia, thrombocytopenia, antiplatelet medications, and von Willebrand's disease
	Variable		Initial test done with epinephrine. A prolonged test is repeated using ADP, and if normal <122 s, indicates probable aspirin effect
Peripheral blood smear	Qualitative and quantitative based on visualization	Estimates quantity and appearance of platelets, WBCs, and red blood cells	Allows identification of clumped platelets, abnormal cells interfering with coagulation (leukemia)
			Operator dependent
Dilute Russell viper venom time	23–27 s	Venom directly activates factor X and converts prothrombin to thrombin when phospholipid and factor V are present	Prolonged in the presence of antiphospholipid antibodies
Inhibitor screens	Variable	Verifies the presence or absence of antibodies directed against one or more of the coagulation factors	*Specific inhibitors*: directed against one coagulation factor, most commonly against factor VIII
			Nonspecific inhibitors: directed against more than one coagulation factor; example is lupus-type anticoagulant
Des-γ-carboxyprothrombin or PIVKA II (protein induced by vitamin K absence or antagonism) test	Variable	Measures inactive under-carboxylated form of prothrombin	Increased in vitamin K–deficient states, such as hemorrhagic disease of the newborn
			Increased in overdoses of warfarin or cholestatic liver diseases that can respond to vitamin K therapy

Abbreviations: ADP = adenosine diphosphate; GPL = 1 microgram of affinity-purified immunoglobulin G anticardiolipin antibody from an original index serum; IgM, immunoglobulin M; MPL = 1 microgram of affinity-purified immunoglobulin M anticardiolipin antibody from an original index serum.

results of these tests, coupled with clinical evaluation, should enable formulation of a differential diagnosis.[18] Additional studies are ordered as indicated (**Table 232-2**). Obtain hematologic consultation if the differential diagnosis or the laboratory approach is unclear. In patients with postoperative bleeding, the basic laboratory tests for coagulation are of little help in assessment or management.[19]

CHAPTER 233

Acquired Bleeding Disorders

Robert W. Shaffer
Sally A. Santen

INTRODUCTION

Normal regulation of bleeding is a complex process involving platelets and the coagulation system (see chapter 232, "Tests of Hemostasis"). Platelet defects typically manifest with petechiae and mucosal bleeding, whereas coagulation defects usually present as spontaneous or excessive hemorrhage. Management of significant acquired bleeding disorders should be discussed with a hematologist because there are often subtleties in diagnosis and treatment.

ACQUIRED PLATELET DEFECTS

Circulating platelets provide the initial defense against bleeding. Acquired platelet disorders may be quantitative (decreased number of circulating platelets) or qualitative (poorly functioning platelets). Both significant thrombocytopenia and qualitative platelet dysfunction are commonly manifested by the presence of nonpalpable petechiae, often most pronounced in the lower extremities and in areas where blood flow is restricted. Other typical findings may include purpura, mucosal bleeding (gingival, epistaxis), menorrhagia, hemoptysis, hematuria, and hematochezia, whereas deep tissue bleeding and hemarthrosis are less common.

Securing circulatory stability is the primary treatment priority in the bleeding patient. Once this is done, the history, physical examination, and directed laboratory testing are used to define the clinical syndrome. Recent illness, symptoms, and medications are potentially relevant in the patient who appears to have a platelet disorder. Physical examination should assess for additional bleeding sites and the type of bleeding. Assess for lymphadenopathy, splenomegaly, pallor, or jaundice that suggests diagnoses such as leukemia, lymphoma, systemic lupus erythematosus, infectious mononucleosis, or hemolytic anemia.

THROMBOCYTOPENIA

Quantitative defects that result in thrombocytopenia are caused by decreased production, increased destruction, splenic sequestration, platelet loss, or a combination (**Table 233-1**).[1] The etiologies of thrombocytopenia are diverse, and the pathologic mechanism is not always initially clear. Viral infections may impair thrombopoiesis due to direct infection of the megakaryocyte, toxic effects of viral proteins or cytokines, hemophagocytosis, or production of antibodies that bind to platelets and enhance immune destruction.[2] A drug history is important, because many medications have been implicated in causing thrombocytopenia or impairing platelet function (**Table 233-2**).[3,4]

A CBC will establish the presence and degree of thrombocytopenia and determine whether other hematologic cell lines are affected. A peripheral smear should be examined to assess platelet morphology and evaluate other cell lines. Rarely, in vitro platelet agglutination occurs, which leads to spuriously low platelet counts reported by automated cell counters (pseudothrombocytopenia) when collected in ethylenediaminetetraacetic acid–coated blood tubes; this can be detected by the presence of platelet clumping on a peripheral smear. In this case, a correct platelet count may be obtained by using citrated or heparin-anticoagulated blood tubes.

Testing for human immunodeficiency virus and hepatitis C virus is recommended in cases of isolated thrombocytopenia, as low platelets may be the only readily apparent manifestation in early infections.[5] If the etiology of low platelets remains unclear, further laboratory testing to evaluate for disorders such as hemolysis and disseminated intravascular coagulation (DIC) may be needed. Although usually not necessary in instances of isolated thrombocytopenia, bone marrow biopsy may be obtained when malignancy or other bone marrow pathologies are of concern.

When circulating platelet levels decrease to below 10,000 to 20,000/mm^3 (10 to 20 × 10^9/L), the risk of spontaneous bleeding becomes con-

TABLE 233-1 Pathophysiology of Acquired Thrombocytopenia

Mechanism	Associated Clinical Conditions
Decreased platelet production	Marrow infiltration (tumor or infection)
	Viral infections (rubella, HIV, hepatitis C, others)
	Drugs (Table 233-2)
	Radiation
	Vitamin B_{12} and/or folate deficiency
Increased platelet destruction	Immune thrombocytopenia
	Thrombotic thrombocytopenic purpura
	Hemolytic-uremic syndrome
	Disseminated intravascular coagulation
	Viral infections (HIV, mumps, varicella, Epstein-Barr virus)
	Drugs (Table 233-2)
Platelet loss	Excessive hemorrhage
	Hemodialysis, extracorporeal circulation
Splenic sequestration	Sickle cell disease, cirrhosis

Abbreviation: HIV = human immunodeficiency virus.

TABLE 233-2 Drugs That Produce Thrombocytopenia or Impair Platelet Function

Produce Thrombocytopenia	Impair Function
Heparin 4+	Aspirin
Gold salts 4+	Nonsteroidal anti-inflammatory drugs
Sulfa-containing antibiotics 4+	Glycoprotein IIb–IIIa agents: ticlopidine and clopidogrel
Quinine and quinidine 4+	
Ethanol (chronic use) 4+	Penicillins and cephalosporins
Aspirin 3+	Calcium channel blockers
Indomethacin 3+	β-Adrenergic blockers: propranolol
Rifampin 2+	Nitroglycerin
Abciximab and eptifibatide 2+	Antihistamines
Thiazides and furosemide 2+	Phenothiazines
Acyclovir 2+	Cyclic antidepressants
Procainamide 2+	
Digoxin 2+	
Cimetidine and ranitidine 2+	
Phenytoin and valproate 1+	
Penicillins/cephalosporins 1+	

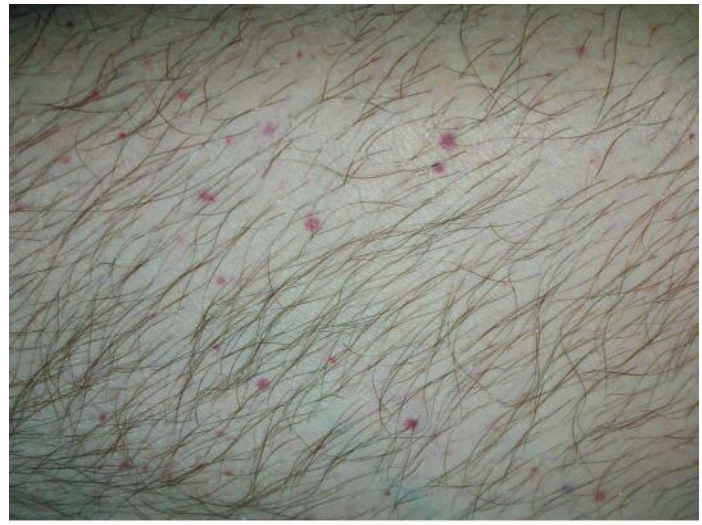
Note: 4+ to 1+ indicates relative incidence, from more frequent to less frequent, based on case reports.

cerning, particularly for intracranial hemorrhage. Additional risk factors for bleeding include age, comorbid illness (i.e, renal disease, liver disease, connective tissue disease, peptic ulcer disease, hypertension), fall risk, and lifestyle activity. With the exception of a few specific disease processes, platelet transfusion in the nonbleeding patient should be considered when counts fall below 10,000/mm^3 (10 $\times$10^9/L), or higher if other comorbid illnesses are present.[6] The cause of the platelet deficiency may also influence the risk of bleeding. At a given platelet level, patients with immune thrombocytopenia (ITP) typically bleed less than patients with aplastic anemia, as the younger platelets present in ITP are more effective in hemostasis.[7]

Immune Causes of Thrombocytopenia ITP is an acquired immune-mediated disorder in which circulating platelets typically fall to very low levels.[3,8] ITP results from antiplatelet antibodies that attack platelet surface glycoproteins such as glycoprotein IIb/IIIa, leading to peripheral platelet destruction. There is evidence that the same antibodies lead to impaired platelet production by megakaryocytes.[9] Despite very low platelet counts, the circulating platelets are not functionally impaired.

Immune thrombocytopenia may be classified as primary (formerly known as *idiopathic thrombocytopenic purpura*) or secondary when associated with other medical conditions (autoimmune disorders, infections) or drug exposures.[8] This distinction is of clinical importance, as management of the underlying disorder or discontinuation of the drug in cases of secondary ITP may lead to normalization of the platelet count.

Primary ITP may occur at any age, with equal prevalence between genders, with the exception of those age 30 to 60 years, in which women predominate. Primary ITP is classified by duration of illness: newly diagnosed (diagnosis to 3 months), persistent (3 months to 12 months), and chronic (>12 months).[8] The majority of adults with primary ITP progress to chronic illness.



The most common presenting sign of ITP is a petechial rash (**Figure 233-1A**). Mild epistaxis, gingival bleeding (**Figure 233-1B**), and menorrhagia in women of childbearing age may also be seen. Except for petechiae and bruising, the patient should have a normal physical examination.

The CBC should demonstrate normal cell lines except for the platelets. A mild anemia may be seen if bleeding is present. The peripheral smear should show large, well-granulated platelets, although they will be few in number. Bone marrow biopsy is not indicated unless clinical features are atypical. If the evaluation supports the diagnosis of primary ITP, then additional testing in the ED is not required.

Treatment for ITP is initiated based on the risk of bleeding (**Table 233-3**). Major bleeding complications in patients with platelets >50,000 /mm^3 (>50 $\times$ 10^9/L) are uncommon. As most fatal bleeding complications occur when platelet counts fall below 30,000/mm^3 (30 $\times$ 10^9/L), experts and guidelines recommend this level as the threshold for initiating treatment of ITP in adults.[5,6,9-11] Bleeding risk correlates with lower platelet counts and patient age greater than 60, a prior history of bleeding, certain chronic illnesses, and use of medications that alter hemostasis all heighten this risk. Therefore, certain patients may benefit from medical treatment despite a platelet count exceeding 30,000/mm^3 (30 $\times$ 10^9/L). For all patients with primary ITP, bleeding risk should be minimized, including avoiding use of antiplatelet medications when possible, maintenance of good blood pressure control, optimized treatment of exacerbating comorbid conditions (i.e., liver disease, renal disease), and addressing fall risks.

About two thirds of children with primary ITP will have spontaneous resolution within 6 months of diagnosis.[11] An antecedent viral infection is commonly reported. Additionally, the measles-mumps-rubella vaccination has been associated with the development of acute ITP, although this is rare and occurs in less than 1 per 25,000 doses given.[12] The risk of severe bleeding complications appears to be rare in children, regardless of their absolute platelet count.[5,8,13] Children without signs of active bleeding and good psychosocial support typically do not require hospitalization or medical treatment. Good anticipatory guidance should be provided to the family, and the child should abstain from contact sports or activities that might place them at risk for head injury.

First-line treatment for primary ITP generally includes corticosteroids, typically prednisone 1 milligram/kg per day for 4 weeks (shorter courses may be considered for children).[5,9-11,13] Initial response may not be seen for 4 to 14 days, and peak effect can be expected between 7 and 28 days. IV immunoglobulin may also be considered, either alone or in combination with corticosteroids, at a dose 1 g/kg/per day for 3 days. Initial response to IV immunoglobulin is more rapid than corticosteroids, occurring between 1 and 3 days, with peak effect seen between 2 and 7 days. Side effects of IV immunoglobulin may include aseptic meningitis, transient neutropenia, acute kidney injury, and transfusion reactions/hypotension.

A

B

FIGURE 233-1. Two patients with idiopathic thrombocytopenic purpura. **A.** Petechiae with platelet count of 3000/mm^3 (3 $\times$ 10^9/L). **B.** Gingival bleeding with platelet count of 5000/mm^3 (5 $\times$ 10^9/L). [Image used with permission of J. Stephan Stapczynski, MD.]

TABLE 233-3 Treatment of Immune Thrombocytopenia

Platelet transfusion	<10,000–20,000/mm^3 (<10–20 $\times$ 10^9/L) prophylactically to prevent bleeding <50,000/mm^3 (<50 $\times$ 10^9/L) if actively bleeding <20,000–50,000/mm^3 (<20–50 $\times$ 10^9/L) if patient requires diagnostic puncture <50,000–100,000/mm^3 (<50–100 $\times$ 10^9/L) if patient requires invasive procedure
Corticosteroids	Prednisone, 1 milligram/kg PO per day for 21 days then tapered, or dexamethasone, 20 milligrams/m^2 IV per day for 4 d
IV immunoglobulin	1 gram/kg IV per day for 3 d
Splenectomy	Considered for refractory cases

Anti-Rho(D) immunoglobulin at 50 to 75 micrograms/kg for a single dose may also be considered as a first-line treatment strategy in patients who are Rh(D) positive and have not undergone splenectomy.[14] Initial response rate and peak effect are similar to that seen with IV immunoglobulin. Mild hemolysis can be expected, and rare serious or even fatal cases of intravascular hemolysis, DIC, and renal failure have been reported with anti-Rho(D) use, prompting the U.S. Food and Drug Administration to administer a warning pertaining to its use in 2010. Second-line treatment modalities include splenectomy and use of newer agents, such as the monoclonal antibody rituximab, which blunts the autoimmune destruction of platelets, and thrombopoietin receptor agonists, which stimulate platelet production (i.e., romiplostin, eltrombopag).

In the event of life-threatening hemorrhage where hemostasis must be achieved rapidly, IV corticosteroids (such as dexamethasone) and IV immunoglobulin should be administered concomitantly.[13] Platelet transfusions should be initiated, and doses two to three times the typical dose might be required due to persistent autoimmune destruction.[6] Platelet transfusions may need to be repeated frequently until bleeding subsides or targeted treatment modalities take effect. Emergent splenectomy may be considered if all other treatment options are exhausted.

Drug-Induced Immune Thrombocytopenia Over 200 drugs have been implicated in causing immune-mediated suppression of platelet production or increased platelet destruction (Table 233-2).[3,4] The clinical presentation is similar to ITP, and the thrombocytopenia may severe. Drug-induced thrombocytopenia typically occurs 5 to 14 days following initiation of a drug, but may occur sooner if there has been recent prior exposure. A careful history should not only include prescribed medications, but also herbal remedies and food and beverage use (i.e., quinine in tonic water, alcohol use, tahini). Chronic alcohol use is a common cause of thrombocytopenia. Platelet counts typically normalize with cessation of the causative agent. Heparin-induced thrombocytopenia causes a significant drop in platelets, but patients are paradoxically hypercoagulable due to platelet activation (see chapter 239, "Thrombotics and Antithrombotics").

Nonimmune Causes of Thrombocytopenia Thrombocytopenia may occur from various non–immune-mediated causes (Table 233-1). In thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome, thrombotic microangiopathy occurs when vessel injury results in deposition of platelet-fibrin thrombi (see chapters 143 "Oncologic and Hematologic Emergencies in Children" and 237, "Acquired Hemolytic Anemia"). DIC is also a well-described cause of platelet destruction. In patients with marked hemorrhage, large-volume fluid resuscitation may lead to a dilutional thrombocytopenia. Additionally, certain bacterial, rickettsial, and viral infections can cause direct toxic destruction of platelets. Thrombocytopenia specific to pregnancy may be a result of the hemolysis–elevated liver enzymes–low platelets (HELLP) syndrome, pre-eclampsia, or gestational thrombocytopenia (see chapter 100, "Maternal Emergencies after 20 Weeks of Pregnancy and in the Postpartum Period"). Finally, an enlarged spleen can sequester a significant portion of the platelet pool.

Thrombocytopenia is present in up to 70% of patients with chronic liver disease.[15] The etiology appears multifactorial. Patients often have underlying medical conditions related to their liver disease such as alcohol use, viral hepatitis, or nutritional deficiencies that impair platelet production. Thrombopoietin, which is produced by hepatocytes, may be decreased. Portal hypertension may lead to splenic sequestration. Endotoxemia from infection may promote platelet aggregation. Some patients also demonstrate platelet autoantibodies. The degree of quantitative thrombocytopenia may be mitigated by an increased level of circulating von Willebrand factor that is typically seen, which promotes platelet adhesion. For this reason, routine platelet transfusion is not recommended in the absence of clinically significant bleeding. However, a platelet count of >50,000/mm^3 (>50 × 10^9/L) should be achieved prior to invasive procedures (i.e., lumbar puncture, surgery, liver biopsy).[16]

FUNCTIONAL PLATELET DISORDERS

Several disease processes can cause acquired qualitative or functional abnormalities of platelets (**Table 233-4**).[17] In the myeloproliferative diseases, platelets are often dysfunctional, even if the platelet count is normal or elevated. Patients can have prolonged bleeding times and clinically significant bleeding. To control acute bleeding, transfusion should be considered to raise the level of normal platelets to 50,000/mm^3 (50 × 10^9/L). In macroglobulinemia and related disorders, the elevated level of viscous proteins interferes with platelet function. Patients with clinically significant bleeding may require plasmapheresis to reduce the protein level and correct hemostatic function.

TABLE 233-4 Clinical Conditions Associated with Qualitative Platelet Abnormalities

Uremia
Liver disease
Disseminated intravascular coagulation
Antiplatelet antibodies (immune thrombocytopenia, systemic lupus erythematosus)
Cardiopulmonary bypass
Myeloproliferative disorders (thrombocytosis, polycythemia vera, chronic myeloid leukemia, acute lymphocytic or myelogenous leukemia)
Dysproteinemias (multiple myeloma, Waldenström's macroglobulinemia)
von Willebrand's disease (congenital or acquired)

Many drugs can influence platelet function (Table 233-2 and **Table 233-5**). Of these, the most commonly used are aspirin, which produces an irreversible impairment in platelet aggregation, and the nonsteroidal anti-inflammatory drugs, clopidogrel and ticlopidine, which produce temporary impairment in platelet adhesion and aggregation (see chapter 239).

Thrombocytosis, a platelet count exceeding 500,000/mm^3 (500 × 10^9/L), can be seen in many disorders including inflammatory reactions, malignancy, polycythemia, and postsplenectomy. Platelet function can be normal or abnormal depending on the underlying condition. Therefore, thrombocytosis can be associated with bleeding (mucosal, ecchymotic, GI) or thromboembolic (deep venous thrombosis, portal or mesenteric thrombosis, splenic vein thrombosis) manifestations. However, these events are unusual, even with platelet counts in excess of 1,000,000/mm^3 (1000 × 10^9/L).

ACQUIRED COAGULATION DISORDERS

Acquired coagulation disorders can result from underlying medical disease and autoimmune factor inhibitors.

LIVER DISEASE

Acute and chronic liver disease is commonly associated with laboratory tests of impaired coagulation. Hepatocytes synthesize all of the coagulation factors and related regulatory proteins, with the exception of factor VIII and von Willebrand factor. Diseases affecting the hepatic parenchyma may result in a decreased synthesis of these factors, including the vitamin K–dependent carboxylation of factors II (prothrombin), VII, IX, and X. Because vitamin K is a fat-soluble vitamin, malabsorption can occur with processes that interfere with the absorption of fat-soluble vitamins, including impaired bile acid metabolism (i.e., primary biliary cirrhosis), intrahepatic or extrahepatic cholestasis, and treatment with

TABLE 233-5 Duration of Antiplatelet Activity

Drug	Onset	Duration of Effect
Aspirin	1 h	Up to 7 d
Most nonsteroidal anti-inflammatory drugs	1 h	1 d
Piroxicam	1 h	2 d
Ticlopidine or clopidogrel	1–2 d	4–7 d

bile acid binders. Thus, prolonged prothrombin time is common in patients with decompensated hepatic function. Despite marked prolongations of prothrombin time and activated partial thromboplastin time (PTT) seen in advanced liver disease and cirrhosis, these tests poorly predict onset and severity of bleeding, including bleeding from esophageal varices or invasive procedures or surgery.[16,18-20] Although there may be marked reduction in procoagulant proteins in liver disease, there is typically a parallel decrease in the endogenous anticoagulant proteins such as protein C and antithrombin. Therefore, primary hemostasis may be relatively maintained. In fact, patients with liver disease may be susceptible to both increased bleeding and thrombosis. Patients with liver disease and cirrhosis are twice as likely to develop unprovoked deep venous thrombosis and have a relatively high incidence of portal venous thrombosis.[21]

In the actively bleeding patient with liver disease, attention to volume and circulatory status is paramount. Transfusion of packed red blood cells should be used to maintain an adequate hemoglobin and hemodynamic stability. Fresh frozen plasma transfusions or platelets should be transfused if significant hemorrhage (e.g., from esophageal varices) is associated with a coagulopathy or thrombocytopenia with a platelet count below 60,000/mm^3 (60 × 10^9/L).[16] Plasma transfusions should be used cautiously because they may incite thrombosis and expand intravascular volume, exacerbating portal hypertension and increasing the severity of variceal bleeding. There is no evidence that recombinant activated factor VII or four-factor prothrombin complex concentrate (Kcentra®) provides benefit.[22] The benefit of vitamin K in these patients has also been called into question, and its routine use is not substantiated.[22,23]

Primary prevention of bleeding in patients with liver disease should focus on medical optimization of their risk factors, rather than treatment of abnormal tests of coagulation or thrombocytopenia.[16,18] These include management and prevention of portal hypertension, treatment of esophageal varices, management of primary causes for liver disease (i.e., alcohol use, hepatitis C), optimization of renal function, and management and prevention of sepsis/infection.

RENAL DISEASE

Patients with renal disease frequently manifest disorders of hemostasis. Early renal impairment has been associated with a tendency for thrombosis relating to increased production of procoagulant factors as well as decreased formation of tissue plasminogen activator.[24] In advanced renal disease, bleeding complications are of particular concern due to qualitative platelet dysfunction from decreased ability to adhere to damaged endothelium and aggregate. Patients with chronic kidney disease are at increased risk for minor bleeding (mucosal and cutaneous) and major bleeding (intracerebral and GI hemorrhage). Serum prothrombin time, activated PTT, and platelet counts are often normal, although bleeding time will usually be prolonged. Abnormalities in platelet function can be due to direct effects of uremic toxins and impaired drug elimination. Anemia itself has been associated with platelet dysfunction. Thrombocytopenia can occur from dialysis, and the heparin used may also potentiate bleeding.

Desmopressin is the most common agent used to correct bleeding in patients with uremic platelet dysfunction, producing an increase in serum von Willebrand factor and enhancing the platelet's ability to aggregate.[25] The dose is 0.3 milligram/kg SC or IV, with a rapid onset and duration of action lasting at least 4 hours. Side effects are generally mild and include headache, flushing, minor hypotension, tachycardia, nausea, abdominal cramps, and local site reaction. Other strategies that improve platelet function include the use of cryoprecipitate, conjugated estrogens, erythropoietin to improve anemia, and hemodialysis to remove toxins.[24] Platelet transfusions alone are generally ineffective because the infused platelets quickly acquire the platelet defect. Cryoprecipitate and platelet transfusions should be reserved for life-threatening bleeding and should be used in combination with packed red blood cells, desmopressin, and conjugated estrogens.

DISSEMINATED INTRAVASCULAR COAGULATION

DIC is an acquired syndrome characterized by inappropriate and widespread activation of the coagulation system resulting in intravascular thrombin generation, small vessel thrombosis, and consumption of clotting factors and platelets.[26] Concomitant activation of the fibrinolytic system also occurs, resulting in the breakdown of fibrin clots and subsequent bleeding. DIC is associated with a wide variety of precipitating disorders (**Table 233-6**).

TABLE 233-6 Common Conditions Associated with Disseminated Intravascular Coagulation (DIC)

Clinical Setting	Comments
Infection Bacterial Viral Fungal	Probably the most common cause of DIC; 10%–20% of patients with gram-negative sepsis have DIC; endotoxins stimulate monocytes and endothelial cells to express tissue factor; Rocky Mountain spotted fever causes direct endothelial damage; DIC more likely to develop in asplenic patients or cirrhosis; septic patients are more likely to have thrombosis than bleeding.
Carcinoma Adenocarcinoma Lymphoma	Malignant cells may cause endothelial damage and allow the expression of tissue factor as well as other procoagulant materials; most adenocarcinomas tend to have thrombosis (Trousseau's syndrome), whereas prostate cancer tends to have more bleeding; DIC is often chronic and compensated.
Acute leukemia	DIC most common with promyelocytic leukemia; blast cells release procoagulant enzymes; there is excessive release at time of cell lysis (chemotherapy); more likely to have bleeding than thrombosis.
Trauma	DIC especially with brain injury, crush injury, burns, hypothermia, hyperthermia, rhabdomyolysis, fat embolism, hypoxia. Massive bleeding can occur.
Organ injury Liver disease Pancreatitis	May have chronic compensated DIC; acute DIC may occur in the setting of acute hepatic failure; tissue factor is released from the injured hepatocytes. Pancreatitis can activate the coagulation cascade.
Pregnancy	Placental abruption, amniotic fluid embolus, septic abortion, intrauterine fetal death (can be chronic DIC); can have DIC in hemolysis–elevated liver enzymes–low platelets (HELLP) syndrome.
Vascular disease	Large aortic aneurysms (chronic DIC can become acute at time of surgery), giant hemangiomas, vasculitis, multiple telangiectasias.
Envenomation	DIC can develop with bites of rattlesnakes and other vipers; the venom damages the endothelial cells; bleeding is not as serious as expected from laboratory values.
Acute lung injury (ALI) or adult respiratory distress syndrome	Microthrombi are deposited in the small pulmonary vessels; the pulmonary capillary endothelium is damaged; 20% of patients with ALI develop DIC, and 20% of patients with DIC develop ALI.
Transfusion reactions, such as acute hemolytic reaction	DIC with severe bleeding, shock, and acute renal failure.

Pathogenesis Although the diseases triggering DIC are diverse, the common pathway of these illnesses is that they lead to an inappropriate loss of localization or compensated control in the intravascular activation of coagulation (**Figure 233-2**). Immune, inflammatory, and coagulant pathways are involved. Damaged endothelial cell walls trigger activation of the intrinsic clotting cascade, leading to thrombin generation and subsequent intravascular fibrin clot deposition. Increased thrombin generation leads to consumption of anticoagulant regulatory proteins (i.e., protein C, protein S, and antithrombin), further potentiating thrombosis and ischemic tissue damage. Production of thrombin and fibrin indirectly activates tissue plasminogen activator and the counter-regulatory fibrinolytic system. When hyperfibrinolysis occurs, the hemostatic clots dissolve and bleeding ensues.

Clinical Features Clinical features of DIC vary with the underlying precipitating illness.[27] Hypercoagulation may predominate in certain conditions such as sepsis, where signs of ischemic end-organ failure are common, and physical findings in these patients may include cutaneous gangrene or thrombotic purpura. In other instances such as DIC associated

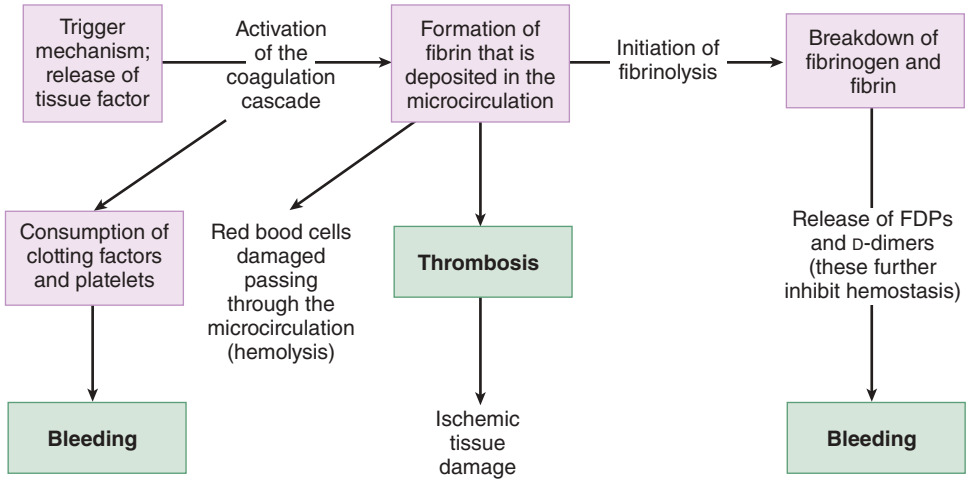


FIGURE 233-2. Pathophysiology of disseminated intravascular coagulation. Refer to "Pathogenesis" section under "Disseminated Intravascular Coagulation" for details. FDPs = fibrin/fibrinogen degradation products.

with leukemia, hyperfibrinolysis may predominate and clinical features may include petechiae, ecchymoses, oozing from catheter or venipuncture sites, or hematuria. Certain DIC-related disorders such as trauma and obstetric complications tend to have both strong hypercoagulation and hyperfibrinolysis elements and lead to major bleeding complications (i.e., wounds, intracranial, GI). Yet other conditions may be associated with mild and compensated DIC in which outward signs of thrombosis and bleeding are subclinical.

Laboratory Findings The typical laboratory results in acute DIC (**Table 233-7**) include thrombocytopenia, prolonged prothrombin time, low fibrinogen level, and elevation of fibrin-related markers (i.e., D-dimer, fibrin degradation products, soluble fibrin). The most commonly observed abnormality is thrombocytopenia; a progressive drop in the platelet count is sensitive, although not specific, for DIC. Depletion of coagulation factors is reflected by a prolonged prothrombin time. Fibrinogen is an acute-phase reactant and may be normal or elevated in early DIC. Scoring systems have been developed and validated to aid in the diagnosis (**Table 233-8**).[28,29]

Differential Diagnosis Primary fibrinolysis is a rare syndrome whereby plasmin and fibrinolysis occur without the production of thrombin. Severe liver disease will also manifest with coagulation abnormalities and low platelets. These two entities can be differentiated from DIC based on clinical history and laboratory tests. The hematologic abnormalities in liver disease should be relatively stable in contrast to the worsening abnormalities associated with acute DIC. Additionally, the D-dimer assay will usually be normal or minimally elevated in both primary fibrinolysis and liver disease, but is often significantly elevated in DIC.

Treatment Paramount to the management of DIC is the elimination of the underlying disorder whenever possible. Treatment strategies in DIC include blood product support and strategies to modulate thrombin formation (**Table 233-9**).[26,27,29] Generally speaking, blood products should only be administered when there is evidence of bleeding.

TABLE 233-7 Laboratory Abnormalities Characteristic of Disseminated Intravascular Coagulation (DIC)[28]

Studies	Result
Most Useful	
Platelet count	Usually low, or dropping
Prothrombin time	Prolonged
Fibrinogen level	Usually low (fibrinogen is an acute-phase reactant, so may actually start out elevated), fibrinogen level <100 milligrams/dL (<1 gram/L) correlates with severe DIC
Fibrin degradation products and D-dimer*	Elevated
Helpful	
Activated partial thromboplastin time	Usually prolonged
Thrombin clotting time	Prolonged (not sensitive)
Fragmented red blood cells	Should be present (not specific)
Specific factor assays	Extrinsic pathway factors are most affected (VII, X, V, and II)
Factor II, V, VII,† X	Low
Factor VIII (acute-phase reactant)	Low, normal, high
Factor IX	Low (decreases later than other factors)

*Levels may be chronically elevated in patients with liver or renal disease.

†Factor VII is usually low early because it has the shortest half-life.

TABLE 233-8 International Society on Thrombosis and Haemostasis Scoring System for DIC When Associated Condition Known to Cause Disseminated Intravascular Coagulation (DIC) Is Present[29]

Test	Points
Platelet count	
>100,000/mm^3 (>100 × 10^9/L)	0
50,000–100,000/mm^3 (50–100 × 10^9/L)	1
<50,000/mm^3 (<50 × 10^9/L)	2
Fibrin-related marker (D-dimer, fibrin degradation products)	
Normal	0
Mildly elevated	2
Markedly elevated	3
Prothrombin time prolongation	
<3 s	0
3–6 s	1
>6 s	2
Fibrinogen level	
>100 milligrams/dL (>1 gram/L)	0
<100 milligrams/dL (<1 gram/L)	1

Note. A score of ≥5 is compatible with overt DIC. A score <5 is suggestive (not affirmative) for nonovert DIC.

TABLE 233-9 Treatment of Disseminated Intravascular Coagulation (DIC)

Treat underlying precipitating disorder: volume resuscitation, antibiotics, external cooling
Platelet transfusions for thrombocytopenia <50,000/mm^3 (<50 × 10^9/L) and active bleeding
Fresh frozen plasma for prolonged PT or aPTT (>1.5) or low fibrinogen (<100 milligrams/dL [1 gram/L])
Fibrinogen concentrate for persistent low fibrinogen <100 milligrams/dL (<1 gram/L)
Vitamin K for prolonged PT
Consider LMWH when thrombotic events dominate clinical picture
Consider tranexamic acid for trauma-related DIC

Abbreviations: aPTT = activated partial thromboplastin time; LMWH = low molecular weight heparin; PT = prothrombin time.

Platelet transfusions are recommended in actively bleeding patients who have platelet counts below 50,000/mm^3 (50 × 10^9/L) and may be considered in those considered to be at high risk for bleeding (such as DIC resulting from chemotherapy) when platelet counts fall below 10,000 to 20,000/mm^3 (10 to 20 × 10^9/L). Plasma should be administered in bleeding patients when prothrombin time/activated PTT exceeds 1.5 times normal or when fibrinogen levels fall below 150 milligrams/dL (1.5 grams/L). The initial recommended dose is 15 mL/kg, although there is some evidence that 30 mL/kg may be superior when volume overload is not of concern. Fibrinogen concentrate should be considered when hypofibrinogenemia persists despite use of plasma. Patients with a prolonged prothrombin time should receive parenteral vitamin K.

There is no proven benefit in DIC with other coagulation factor products, such as three- or four-factor prothrombin complex concentrate or recombinant factor VIIa. Although there is no evidence demonstrating improved outcomes, low-molecular-weight heparin may be considered in patients with DIC where thrombotic complications predominate the clinical picture or in patients with evidence of early compensated DIC.[29] Patients with DIC are at very high risk for developing venous thromboembolism, and routine prophylaxis with low-molecular-weight heparin, in the absence of major bleeding, is recommended. Antifibrinolytic medications (i.e., tranexamic acid) should generally be avoided in patients with DIC. One notable exception is in trauma-related DIC, where their use reduces mortality.[30]

CIRCULATING INHIBITORS OF COAGULATION

Acquired inhibitors of blood coagulation, also known as *circulating anticoagulants*, are antibodies directed against one or more of the coagulation factors. Although inhibitors may develop spontaneously in previously healthy patients with normal hemostasis, most inhibitors develop in patients with hereditary bleeding disorders who receive transfusion of plasma products. Inhibitors have been described for most of the coagulation factors; the two most common inhibitors are factor VIII inhibitors and antiphospholipid antibodies. Factor VIII inhibitors are "specific" inhibitors, directed only against factor VIII, as opposed to antiphospholipid antibodies, including lupus anticoagulant and anticardiolipin antibodies, which are "nonspecific" inhibitors directed against several of the coagulation factors. Lupus anticoagulant and anticardiolipin antibodies often result in thrombosis (see chapter 234, "Clotting Disorders").

Factor VIII Inhibitors Factor VIII inhibitors most commonly develop in patients with hemophilia A (see chapter 235, "Hemophilias and von Willebrand's Disease"), but can also develop spontaneously in patients with previously normal hemostasis, a condition termed *acquired hemophilia*.[31,32] The incidence of spontaneously arising inhibitors is rare—estimated at 1.4 cases per 1 million persons per year. Although uncommon, it is important to recognize this clinical entity because the mortality rate approaches 22%. The majority of acquired hemophilia cases, approximately 85%, occur in the elderly. In about half of cases, inhibitors develop in association with preexisting disorders, such as autoimmune disorders (systemic lupus erythematosus, rheumatoid arthritis, ulcerative colitis) and lymphoproliferative disorders (multiple myeloma, Waldenström's macroglobulinemia, benign monoclonal gammopathy of uncertain significance), and in patients with allergic drug reactions (penicillins, sulfonamides, phenytoin).

Patients without a prior bleeding history who develop factor VIII inhibitors can present with massive spontaneous ecchymoses, hematomas, and hematuria. Laboratory studies classically show a normal prothrombin time, normal thrombin clotting time, and a greatly prolonged activated PTT that does not correct with mixing. A factor VIII–specific assay will show very low or absent factor VIII activity. Other factor-specific assays should be normal or only slightly decreased. Quantitative measurement of the inhibitor by the Bethesda inhibitor assay is important for the emergency management of bleeding episodes. Long-term management of acquired factor VIII inhibitors is with steroids, IV immunoglobulin, cytotoxic agents, or rituximab to suppress antibody production. A hematologist should direct the management of an acute, clinically significant bleeding episode.

There is no proven therapy to control bleeding episodes in patients with acquired factor VIII inhibitors.[33] Treatment options include administration of factor VIII, three- or four-factor prothrombin complex, recombinant factor VIIa, desmopressin acetate, and plasmapheresis. Additionally, the use of aspirin, nonsteroidal anti-inflammatory drugs, and intramuscular injections should be avoided and conservative therapies should be considered, including compression and immobilization of the bleeding site.[31,32]

CHAPTER 234

Clotting Disorders

Jessie G. Nelson
Robin R. Hemphill

INTRODUCTION

Most patients who develop an arterial or venous thrombosis do so because of local factors (e.g., a focal atherosclerotic lesion producing a thrombus in an coronary artery) or major systemic events (e.g., trauma, surgery, or prolonged immobilization). However, several inherited genetic mutations predispose patients to venous thromboembolism with some studies finding up to 50% of patients with venous thromboembolism having a thrombophilia (**Table 234-1**).[1] Importantly, risk for clotting from genetic, acquired, and environmental factors is additive or even multiplicative; a patient with mild deficiency may develop a deep venous thrombosis when started on estrogen.[2]

PATHOPHYSIOLOGY

Several physiologic systems ensure that blood clots do not extend beyond the necessary area. The two most clinically important pathways involve antithrombin and protein C (see Figures 232-1 and 232-2 and **Table 234-2**). Antithrombin is a plasma-based protein that inhibits several activated coagulation factors, primarily thrombin, factor Xa, and factor IXa. Both unfractionated heparin and low-molecular-weight heparin possess anticoagulant activity by increasing the rate by which antithrombin inhibits these factors: approximately 2000- to 4000-fold for thrombin, about 500- to 1000-fold for factor Xa, and about a million-fold for factor IXa. Protein C is a vitamin K–dependent plasma protein that binds to the endothelial cell surface and is activated by thrombin. Activated protein C cleaves both factor Va and factor VIIIa, inhibiting both the common pathway and the intrinsic pathway. Protein S, another vitamin K–dependent plasma protein, is a cofactor that increases the inhibitory action of activated protein C by about 20-fold.

TABLE 234-1 Hypercoagulable States

Inherited	Acquired
Activated protein C resistance due to factor V Leiden mutation	Pregnancy
	Oral contraceptives/hormone replacement therapy
Prothrombin gene mutation 20210A	Malignancy
Protein C deficiency	Heparin-induced thrombocytopenia
Protein S deficiency	Antiphospholipid syndrome
Antithrombin deficiency	Warfarin-induced skin necrosis
Hyperhomocysteinemia, severe	Hyperviscosity syndromes
	Human immunodeficiency virus (HIV)

CLINICAL FEATURES

Thrombophilic disorders are rarely diagnosed in the ED. Instead, the emergency physician's primary responsibilities are to (1) recognize higher risk of thrombosis in patients with a known thrombophilia, and (2) obtain pertinent information to suspect an undiagnosed hypercoagulable state (**Table 234-3**).[3]

DIAGNOSIS

Laboratory testing specific for hypercoagulable conditions is not helpful in an ED setting.[4,5] Some factor levels cannot be reliably measured in the setting of acute thrombosis or while the patient is taking a vitamin K antagonist such as warfarin. The focus is to suspect the thrombophilia, refer for evaluation, and appropriately manage acute thrombosis. The ED diagnostic approach to individual episodes of suspected thrombosis in a thrombophilic patient is site specific (e.g., cerebral circulation, coronary circulation, or peripheral venous system). **Using a normal serum D-dimer level to exclude venous thromboembolism in patients with known hypercoagulable disorders has not been validated.**

TABLE 234-2 Functions of Coagulation Proteins in Protein C and Antithrombin Systems

Factor	Function	Pertinent Disorders
Prothrombin (factor II)	Precursor to thrombin, which converts fibrinogen to fibrin.	Prothrombin mutations, 20210A and others
Factor V, activated	Complexes with Factor Xa, calcium, and phospholipid to convert prothrombin to thrombin.	Activated protein C resistance due to factor V Leiden mutation
Protein C, activated	Cleaves activated factors Va and VIIIa.	Congenital protein C deficiency Activated protein C resistance due to factor V Leiden mutation Neonatal purpura fulminans Warfarin-induced skin necrosis
Protein S	Cofactor for activated protein C. Cofactor for tissue factor pathway inhibitor (which inhibits extrinsic pathway of coagulation). Counteracts factor Xa's protection of factor Va from degradation.	Congenital protein S deficiency Neonatal purpura fulminans Warfarin-induced skin necrosis
Antithrombin	Inhibits thrombin, factor Xa, and factor IXa. Binds heparins, leading to increased antithrombin activity.	Antithrombin deficiency
Phospholipids	Present on cell membranes of endothelial cells that line blood vessels. The activity of several proteins in the coagulation cascade is enhanced when bound to phospholipids.	Antiphospholipid syndrome

TABLE 234-3 Features Suggestive of Thrombophilia

Early thrombosis (age 45 y and younger)
Recurrent thrombotic events or fetal loss
Family history of thrombosis or recurrent fetal loss
Thrombosis in unusual location (mesenteric, cerebral, axillary, or portal veins)

TREATMENT AND DISPOSITION

Initial management and disposition of individual episodes of confirmed thrombosis in a patient with thrombophilia is similar to that of a patient without known thrombophilia. Duration of treatment does differ (**Table 234-4**).

Patients not currently on anticoagulation should consider prophylactic anticoagulants for high-risk situations such as surgery, pregnancy and the postpartum period, and prolonged travel. Estrogen-based oral contraceptive pills and hormone replacement therapy should be avoided in patients with known thrombophilia because of the thrombotic risk.

SPECIFIC CONDITIONS ASSOCIATED WITH THROMBOPHILIA

INHERITED CLOTTING DISORDERS

ACTIVATED PROTEIN C RESISTANCE (FACTOR V LEIDEN)

Activated protein C resistance caused by the factor V Leiden mutation is the most prevalent inherited hypercoagulable disorder; approximately 5% of the U.S. population of European descent is heterozygous for this mutation.[6] In this disorder, the gene for factor V has a single point mutation that makes factor Va resistant to inhibition by activated protein C (factor V Leiden). This leads to overabundant conversion of prothrombin to thrombin. Factor V Leiden is inherited in an autosomal dominant pattern, with most patients being heterozygous for the mutation. Heterozygotes for factor V Leiden have a sevenfold increased risk of deep venous thrombosis compared with noncarriers, with homozygotes having a 20-fold increase in risk. Factor V Leiden is more highly associated with deep vein thrombosis than pulmonary embolism[6] and has been observed in up to 21% of patients with first-time deep venous thrombosis.[7] Activated protein C resistance also produces pregnancy complications such as

TABLE 234-4 Management of Inherited and Acquired Thrombophilias

Situation	Management
First episode of thrombosis	Unfractionated heparin or low-molecular-weight heparin for 5 d and/or until therapeutic anticoagulation achieved with an oral anticoagulant. Continue anticoagulation for 6 mo to 2 y; some advocate lifelong treatment.
Second episode of thrombosis	Lifelong anticoagulation.
Pregnancy	Begin unfractionated heparin or low-molecular-weight heparin at diagnosis of pregnancy. May use warfarin in postpartum period.
Active malignancy	Use low-molecular weight heparin for treatment of venous thromboembolic events
Oral contraception	Avoid.
Hormone replacement therapy	Avoid.

severe pre-eclampsia, placental abruption, fetal growth restriction, and stillbirth.

PROTHROMBIN GENE MUTATION

The most common mutation of the prothrombin gene (20210A) leads to increased prothrombin biosynthesis with about a 30% increase in circulating prothrombin levels, creating a hypercoagulable state. Prothrombin mutations are inherited in an autosomal dominant manner with mutations in the prothrombin gene present in about 2% of Caucasians.[2] Heterozygotes account for up to 10% of patients with initial episodes of deep venous thrombosis.[7] Patients with prothrombin gene mutation present with increased risk of venous thromboembolism and pregnancy complications, similar to activated protein C resistance from factor V Leiden.

ANTITHROMBIN DEFICIENCY

Several mutations to the antithrombin gene exist, many leading to antithrombin deficiency. Two percent of patients with a history of thrombosis have an antithrombin deficiency,[8] and it is more prevalent in Asian populations. Antithrombin deficiency is classified into two main groups. In type 1, the measured level of antithrombin is diminished, whereas patients with type 2 have a normal amount of antithrombin, but the function is greatly diminished due to conformational changes in the protein. Antithrombin deficiency is inherited in an autosomal dominant fashion. Heterozygous patients have a fivefold increased risk of thrombotic events, typically pregnancy complications and venous thromboembolism. Homozygous antithrombin deficiency is incompatible with life.

PROTEIN C AND S DEFICIENCIES

Protein C and protein S deficiencies, like antithrombin deficiency, are transmitted in an autosomal dominant fashion, but with more varied clinical presentations. Prevalence can only be estimated, because not all patients with heterozygous defects develop inappropriate thrombosis. Heterozygous protein C deficiency is thought to be present in 1:250 to 1:500 people, and heterozygous protein S deficiency is estimated to occur in about 1:500 individuals.[9] Homozygous protein C or S deficiency is rare and presents as neonatal purpura fulminans. Patients with heterozygous protein C or S deficiency are at higher risk for venous thromboembolism, and like antithrombin deficiency, these disorders can be associated with either decreased total amount of protein C or S or decreased functional activity. In general, lower protein function is associated with higher risk and frequency of thrombotic events. Protein C and S deficiency, like antithrombin deficiency, is more prevalent in the Japanese and Chinese populations with up to 65% percent of adults with venous thromboembolism having a deficiency of protein C, protein S, or antithrombin.[9]

Patients with heterozygous protein C or S deficiency are at higher risk for warfarin-induced skin necrosis because warfarin inhibits protein C and S synthesis. Warfarin-induced skin necrosis is rare and is prevented by both avoiding loading doses of warfarin and continuing heparin products until the INR is therapeutic. Therefore, any patient who develops warfarin-induced skin necrosis should be evaluated for protein C or S deficiency.

HYPERHOMOCYSTEINEMIA

Three enzymes are involved in the metabolism of homocysteine: methylenetetrahydrofolate reductase, cystathionine β-synthase, and methionine synthase. Inherited functional deficiency in the first two enzymes is associated with an increased risk of both arterial and venous thrombosis, as well as atherosclerosis.[2] The presence of elevated homocysteine in the blood is a marker of the functional enzyme deficiency. Heterozygotes for a variant mutation in either methylenetetrahydrofolate reductase or cystathionine β-synthase are found in approximately 15% of individuals with European, Middle Eastern, and Asian ancestry, compared with approximately 1% to 2% of African Americans.

Patients with profound hyperhomocysteinemia, generally because of homozygous inheritance of a dysfunctional enzyme, have the condition termed *congenital homocystinuria*, and have significant skeletal and ocular problems as well as mental retardation, developmental delay, and thrombotic events. Heterozygotes for a dysfunctional enzyme do not have the skeletal, ocular, or mental complications, but have a two- to fourfold increased risk for venous thrombosis. As with other hypercoagulable disorders, the presence of hyperhomocysteinemia can combine with other thrombotic conditions to greatly increase the risk of venous thrombosis; factor V Leiden mutation combined with hyperhomocysteinemia produces about a 20-fold increase in the risk for venous thrombosis.[2,10]

ACQUIRED CLOTTING DISORDERS

PREGNANCY AND ESTROGEN USE

The coagulation changes in pregnancy (**Table 234-5**) represent an adaptive measure to prevent excessive hemorrhage with delivery.[11] Many of these changes are anatomic in nature, whereas some are related to the relatively high estrogen state. These changes promoting thrombosis are similar but less profound in women taking oral contraceptive and hormone replacement therapy.

The exact mechanism of how exogenous estrogen therapy leads to a hypercoagulable state is complex and not completely understood, but higher doses of estrogen clearly confer a higher risk for clotting. The current low doses for estrogens in oral contraceptives are associated with a smaller but still clinically significantly increased risk of thrombosis. Estrogen use has been associated with modest increases in several procoagulant proteins (factors VII, VIII, X, prothrombin, and fibrinogen) as well as decreases in anticoagulant proteins (antithrombin, protein S, protein C). Use of oral contraceptives or hormone replacement therapy in a patient with known heterozygosity for factor V Leiden puts the patient at an even higher risk for thrombosis, approximately a 15-fold increase.

MALIGNANCY

Malignancy is associated with increased risk for thrombus formation, but the exact mechanisms are not completely understood.[12,13] For patients with the new diagnosis of cancer, the risk of venous thromboembolism is highest in the first 3 months after diagnosis, with an odds ratio of about 50. Some types of cancers are more likely to promote thrombosis than others, with pancreatic, brain, acute myelogenous leukemia, gastric, esophageal, gynecologic, kidney, and lung cancers having the highest association with thrombosis. Cancer also increases the incidence of arterial thrombotic events, such as myocardial infarction and ischemic stroke.[12] Other manifestations of hypercoagulability in cancer patients include chronic disseminated intravascular coagulation, nonbacterial thrombotic endocarditis, migratory superficial thrombophlebitis, and thrombotic microangiopathy. Chemotherapy itself can also affect coagulation in many ways, such as downregulation of proteins C and S, induction of tissue factor production by endothelial cells, and direct cell damage.

Use low-molecular-weight heparin for the initial treatment of venous thromboembolism in patients with active cancer.[13] Long-term anticoagulation following the diagnosis of venous thromboembolism in these patients should be with a low-molecular-weight heparin for 6 months as opposed to warfarin.[13] Prophylactic anticoagulation for primary prevention

TABLE 234-5 Factors Contributing to Hypercoagulable State in Pregnancy

Anatomic	Hematologic
Venous occlusion from gravid uterus.	Increased thrombin generation from placental secretion of tissue factor
Trauma to pelvic veins during delivery.	
Tissue injury during surgical delivery.	Increased production of procoagulant proteins
Left iliac vein crosses over left iliac artery, leading to relative compression (left leg deep venous thrombosis is three times more likely than right in pregnant patients).	Decreased free and total protein C
	Increased platelet activation and platelet turnover

of venous thromboembolism in ambulatory medical oncology patients is not recommended.[13]

HEPARIN-INDUCED THROMBOCYTOPENIA

Heparin-induced thrombocytopenia is a consumptive coagulopathy in which components of the clotting cascade are inappropriately activated, forming arterial and venous thrombus.[14] Platelet factor 4 is a cell-signaling molecule that plays a central role in this syndrome. Platelet factor 4 neutralizes heparin and heparin-like endogenous compounds, and the heparin–platelet factor 4 combination inhibits local antithrombin activity, thereby promoting coagulation. Heparin-induced thrombocytopenia develops when patients develop antibodies against the heparin–platelet factor 4 complex. A complex of heparin, platelet factor 4, and the antibody binds to platelets, activating them. The platelets then form small microparticles that initiate clot formation. The measured platelet count falls because platelets are bound in both small and large clots. Also, the heparin–platelet factor 4 antibody complex can stimulate endothelial cells and monocytes to release tissue factor, which further triggers the coagulation cascade.

The typical presentation of heparin-induced thrombocytopenia has the platelet count falling to 50,000 to 60,000/mm^3 (50 to 60 × 10^9/L) within 5 to 15 days after starting heparin treatment. Despite the low platelet counts, the patient is hypercoagulable for days to weeks, even after heparin is stopped. Rarely, patients can develop a rapid-onset presentation within hours of initiation of heparin.

With more outpatients being treated with heparin products for venous thromboembolism or other thrombophilias, patients with heparin-induced thrombocytopenia may present to the ED with this syndrome.[14] The diagnosis of heparin-induced thrombocytopenia hinges on laboratory findings and cannot be definitely diagnosed on clinical grounds alone.[15] Thrombocytopenia is almost universally present (with the exception being patients with preexisting thrombocytosis). Suspect the syndrome when platelets have dropped approximately 50% from a recent value in a patient currently or recently taking a heparin product. All heparin products, both unfractionated and low-molecular-weight, must be stopped. These patients need anticoagulation because the risk for thrombosis is highest in the first week after diagnosis.[14] Vitamin K antagonists, such as warfarin, should be avoided in acute heparin-induced thrombocytopenia because these can increase the risk of microvascular thrombosis acutely due to transient relative protein C deficiency. Hematology consultation should be sought.

WARFARIN-INDUCED SKIN NECROSIS

Warfarin inhibits the production of vitamin K–dependent coagulation factors, with the serum levels of the individual factors decreasing according to their half-life. Upon initiation of warfarin, protein C is decreased before most of the procoagulant proteins. This decrease in protein C leads to a transient relative protein C deficiency, which can lead to clinically significant hypercoagulability.

Warfarin-induced skin necrosis presents with painful, red lesions usually located over the extremities, breasts, trunk, or penis.[16] Lesions typically start with an initial central erythematous macule, extending over hours to a localized edema, developing central purpuric zones and then necrosis. Prevention of this complication is one of the reasons loading doses of warfarin are avoided. Thrombin inhibitors, such as low-molecular-weight heparin, should be administered and continued until therapeutic anticoagulation is achieved with warfarin.[16] Rarely, warfarin-induced skin necrosis occurs despite appropriate initiation of heparin treatment. When it does, approximately one-third of patients will prove to have an inherited protein C deficiency.

ANTIPHOSPHOLIPID SYNDROME

Antiphospholipid syndrome (APS) is an autoimmune disorder that is a cause of acquired thrombophilia.[17] Many of the specific antibodies discovered have targets that are not phospholipids, but rather proteins that interact with phospholipids, such as prothrombin, protein C, and protein S. The most common specific antibodies associated with APS are β_2-glycoprotein I and lupus anticoagulant. Lupus anticoagulant was initially discovered in patients with systemic lupus erythematosus and prolongation of the activated thromboplastin time; hence, the name *lupus anticoagulant*. However, in vivo, the lupus anticoagulant acts as a procoagulant and is associated with thrombosis.[17]

Prevalence of APS is about 40 to 50 cases per 100,000 persons. Up to 5% of normal, healthy young people have antiphospholipid antibodies; this number increases with age and comorbid conditions, but only a minority of these patients develops APS. Antiphospholipid antibodies are positive in approximately 13% of patients with stroke, 11% with myocardial infarction, and 9.5% with deep venous thrombosis.[18] As with most autoimmune disorders, APS is more common in women and is diagnosed from a combination of laboratory findings and clinical findings (**Table 234-6**).

TABLE 234-6 Clinical Manifestations of Antiphospholipid Syndrome

System	Examples
Venous	Deep venous thrombosis: extremities, cerebral, portal, hepatic, renal, retinal
Arterial	Premature atherosclerosis Acute coronary syndrome Ischemic stroke Vascular stenosis or occlusion: extremities, aorta, renal, retinal
Obstetric	Fetal loss: often after 10-wk gestation Preterm labor Low birth weight Pre-eclampsia
Neurologic	Stroke Migraine Sneddon's syndrome—clinical triad of stroke, hypertension, and livedo reticularis Cognitive dysfunction Subcortical dementia Chorea Dysphagia Guillain-Barré syndrome Seizures Optic neuritis
Skin	Livedo reticularis
Cardiac	Valvular abnormalities (Libman-Sacks endocarditis) Syndrome X (angina-like chest pain, cardiac stress test positive for ischemia, normal coronary angiography)
Skeletal	Osteonecrosis
Renal	Thrombotic microangiopathy Renal artery or vein thrombosis Renal artery stenosis with hypertension
Pulmonary	Pulmonary embolus Pulmonary hypertension (from recurrent emboli)
GI	Budd-Chiari syndrome (hepatic vein thrombosis) Mesenteric ischemia Hepatic infarction Acalculous cholecystitis with gallbladder necrosis
Hematologic (other than thrombosis)	Bleeding diathesis (rare) Acquired hypoprothrombinemia Thrombocytopenia Hemolytic anemia
Catastrophic antiphospholipid syndrome	Fulminant multisystem organ failure

Most patients with APS have no other predisposing conditions (primary APS). However, many patients with APS also have other conditions thought to be associated with their APS (secondary APS). Typical conditions include other rheumatologic or autoimmune disorders such as systemic lupus, infections, and drug exposures (e.g., phenytoin, hydralazine, cocaine).

Although most patients with APS present with isolated, recurrent thrombotic events, about 1% have a rapidly progressive form known as *catastrophic antiphospholipid syndrome,* representing acceleration in the pathophysiologic processes of APS with widespread small-vessel occlusions in multiple organs.[19] It is unknown why some APS patients develop such a severe course. Common triggers include infection, trauma, anticoagulation problems, and cancer. However, 40% of the time, no obvious trigger can be found. Mortality of catastrophic APS is approximately 50% despite treatment.

Obviously, APS patients with recurrent thrombotic events need lifelong anticoagulation. Pregnant women with APS need anticoagulation with subcutaneous unfractionated or low-molecular-weight heparin or low-dose aspirin therapy. Because many normal healthy patients have antiphospholipid antibodies, prophylaxis without a personal history of thrombosis is not recommended. In the rare event of catastrophic APS, a multipronged approach involving anticoagulation, steroids, plasmapheresis, and/or IV γ-globulin is typically used.

HYPERCOAGULABILITY ASSOCIATED WITH OTHER DISORDERS

Many other conditions are associated with increased risk of clotting. Patients with **nephrotic syndrome** have an increased risk of hypercoagulability for complex reasons. In several cases, this is simply a matter of increased urinary excretion of anticoagulant proteins. The nephrotic syndrome can also lead to increased endothelial injury and platelet aggregation. Patients with several different forms of **vasculitis**, such as Behçet's syndrome, antineutrophil cytoplasmic antibody–associated vasculitis, and granulomatosis with polyangiitis have a slightly increased risk of thrombosis. **Hyperviscosity syndromes,** such as essential thrombocythemia, polycythemia vera, Waldenström's macroglobulinemia, multiple myeloma, and sickle cell disease, also place patients at increased risk for thrombosis. Most risk factors for cardiovascular disease, such as smoking and diabetes, are also risk factors for venous thromboembolism to varying degrees.[20] **Diabetes** alone slightly increases the risk for thrombosis in younger patients without other obvious risks for thrombosis.[21] Patients with **human immunodeficiency virus** have a 2- to 10-fold increased risk for venous thromboembolism compared to the general population.[22]

CHAPTER 235

Hemophilias and von Willebrand's Disease

Robin R. Hemphill

INTRODUCTION

Hemophilias are bleeding disorders due to deficiency in one of the factors present in the clotting cascade.[1,2] The most common factor abnormalities are of factor VIII (**hemophilia A**) or factor IX (**hemophilia B**). **von Willebrand's disease** is a related defect of the von Willebrand factor.[3]

These hereditary bleeding disorders typically appear early in life, and adult patients will usually be able to relate a history of a bleeding problem. However, patients with mild forms of inherited disease may be unaware of a bleeding disorder until stressed by significant trauma or development of another hemostatic problem.

Systemic bleeding disorders should be suspected in patients with severe bleeding related to trivial trauma or minor surgery, or spontaneous bleeding, particularly when the bleeding occurs in joints or muscle. Unusual bleeding or bruising at multiple areas should also raise concern about a coagulopathy. Medications can be responsible for unmasking a mild bleeding diathesis.

The pattern of bleeding can suggest a likely cause. Patients with easy bruising, gingival bleeding, epistaxis, hematuria, GI bleeding, or heavy menses are more likely to have a deficiency or dysfunction of the platelets. Conversely, patients with spontaneous deep bruises, hemarthrosis, retroperitoneal bleeding, or intracranial bleeding are more likely to have a coagulation factor deficiency. In factor-deficient patients, bleeding associated with trauma may be delayed, due to inadequate fibrin clot formation that inadequately stabilizes the initial platelet thrombus. Patients with von Willebrand's disease may present with features of both platelet and clotting factor problems.

HEMOPHILIA

EPIDEMIOLOGY

The genes that encode factors VIII and IX are located on the long arm of the X chromosome. A genetic mutation in the factor VIII gene produces hemophilia A, occurring in about 1 in 5000 male births in the United States. A mutation in the factor IX gene causes hemophilia B, affecting approximately 1 in 25,000 male births in the United States. Together, these two forms of hemophilia make up about 99% of patients with inherited coagulation factor deficiencies. Hemophilia A and B are clinically indistinguishable from each other, and specific factor testing is required to identify the type.

Because hemophilia A and B are X-linked disorders, hemophilia is overwhelmingly a disease of men, with women typically being asymptomatic carriers. Only rarely do women have severe disease. While these disorders are genetic and usually inherited, a family history of bleeding may be absent because approximately one third of new cases of hemophilia arise from a spontaneous gene mutation.

PATHOPHYSIOLOGY

Bleeding manifestations in patients with all forms of hemophilia are directly attributable to the decreased plasma activity levels of either factor VIII or IX (**Table 235-1**). Those with factor activity levels of 0.3 to 0.4 IU/mL (30% to 40% of normal) may never be aware that they have hemophilia, or they might manifest unusual bleeding only after major surgery or severe trauma. Unless there is another underlying disease, patients with hemophilia do not have problems with minor cuts and abrasions, as hemostasis from these injuries is achieved by platelet activation and the formation of the primary hemostatic plug (see chapter 232, "Tests of Hemostasis").

Bleeding is the major complication of hemophilia, but as a result of frequent exposure to blood products, many hemophiliacs in the past were infected with viral hepatitis or human immunodeficiency virus, and had, in addition, complications related to these chronic infections; currently available factor replacement products have essentially eliminated the risk of seroconversion.

CLINICAL FEATURES

Depending on the severity of the disease, both hemophilia A and B are characterized by easy bruising and spontaneous recurrent bleeding into the joints and muscles.[1,2] Although the joints and muscles are the most common areas into which bleeding occurs, hemorrhage may also occur in other areas (**Table 235-2**). Trauma or a surgical procedure can result in prolonged and difficult-to-control bleeding.

Although adults often know that they have hemophilia, young children may not have been diagnosed before they present to the ED with a bleeding episode. Family history may reveal a bleeding disorder on the mother's side. Hemophilia should be suspected in an infant or child who presents with excessive bruising or with bleeding into the joints, muscles, or CNS that is spontaneous or out of proportion to the history of trauma. Because factor level determines the severity of disease, those

TABLE 235-1 Hemophilia Severity

Disease Severity	Percentage of Factor VIII or IX Activity (% of Normal)	Clinical Features
Severe	<0.01 IU/mL (<1%)	Severe spontaneous bleeding, difficult to control if trauma
Moderate	0.01–0.05 IU/mL (1%–5%)	Usually bleeding from trauma; may bleed spontaneously
Mild	0.06–0.40 IU/mL (6%–40%)	Bleeding after trauma

with mild hemophilia may come to medical attention only when they have a significant surgical procedure or trauma or have started a medication with antihemostatic effects.

Congenital hemophilia in neonates can be manifest as excess bleeding after circumcision or as intracranial hemorrhage, usually associated with traumatic delivery.[4,5] In infants and mobile children, nonpatterned bruising can suggest hemophilia. An irritable infant with hemophilia can be difficult to evaluate; if no other source is found, there should be a presumption of occult bleeding.

DIAGNOSIS

Hemophilia is diagnosed starting with the clinical suspicion of a bleeding disorder. Screening tests, such as the **prothrombin time**, which measures the extrinsic coagulation cascade, will be normal, whereas the **activated partial thromboplastin time**, which measures the intrinsic coagulation cascade, is usually abnormal. However, patients with mild hemophilia and factor levels above 0.3 to 0.4 IU/mL (30% to 40% of normal) may have an activated thromboplastin time within the test reference range. **Bleeding time in both forms of hemophilia will be normal and therefore not helpful**. The diagnosis is confirmed by quantitative measurement of factor VIII or IX levels below 0.50 IU/mL (<50% normal). If mild hemophilia A is suspected, a variant of von Willebrand's disease characterized by abnormal binding of factor VIII and von Willebrand factor should be excluded by special binding tests or genetic analysis.

For patients with established hemophilia, hemostatic testing (e.g., prothrombin time, activated partial thromboplastin time) is unlikely to yield new information and is not routinely indicated. Female carriers of a hemophilic gene can be suspected by family history and confirmed by DNA mutation analysis performed at specialized centers. Prenatal diagnosis is possible using chorionic villus sampling performed between 9 and 14 weeks of gestation or amniocentesis done at 15 to 17 weeks to detect the genetic mutation.

TABLE 235-2 Hemophilia Bleeding Manifestations

Site	Comments
Hemarthroses	Most common site, more frequent in hinged joints (elbows, knees, ankles) than in multiaxial joints.
Soft tissue	Bleeding into soft tissues or muscle; bleeding can dissect along fascial planes; most dangerous in the neck (airway compromise), limbs (compartment syndromes), eye (retro-orbital hematoma), spine (epidural hematoma), and retroperitoneum (circulatory shock).
Mucocutaneous bleeding	Delayed bleeding after dental extractions; spontaneous bleeding from the nose, pharynx, GI tract, or lungs is uncommon.
CNS	Intracranial bleeding is the most common cause of hemorrhagic death in hemophiliacs of all age groups; subdural hematomas occur spontaneously or with minimal trauma.
Hematuria	Common, usually not serious, and a specific bleeding site is rarely found.
Hemophilic pseudotumor	Unresolved or undertreated hematomas erode into adjacent bones resembling bone cysts or malignancy; may compress adjacent nerves and vessels.

HEMOPHILIA TREATMENT

General Principles Treatment of patients with hemophilia relies on either the early replacement of missing factors or, for those who have mild factor VIII deficiency, stimulating the body to secrete clotting factor from intracellular stores. **Begin replacement before or at the same time as other resuscitative and diagnostic maneuvers for intracranial, intrathoracic, intra-abdominal, retroperitoneal, ocular, or airway bleeding, as sustained bleeding raises the risk for morbidity and death (Table 235-2).** Bleeding into the neck, tongue, or retropharynx can compromise the airway. Suspected intracranial hemorrhage, either spontaneous with an acute severe headache or following blunt head injury, should receive immediate factor replacement therapy followed by noncontrast head CT. Complaints of back, thigh, groin, or abdominal pain may be symptoms of retroperitoneal bleeding. Hemorrhage into the iliopsoas muscle is a common form of retroperitoneal bleeding seen in hemophiliacs, and patients may describe hip pain and have difficulty straightening their leg, preferring to keep it in a flexed, externally rotated position. An **iliopsoas muscle bleed** can compress and damage the femoral nerve, cause anemia of blood loss, or produce circulatory shock.

The initial manifestations of bleeding can be subtle. Simple injuries, such as ankle and wrist sprains, may at first appear benign, and several hours may pass before hemarthrosis is apparent. **So, while there may not be physical signs of bleeding into a joint, patients reliably report when bleeding is occurring.** Prompt treatment of hemarthroses can prevent or reduce the long-term sequelae of hemophilic arthropathy. If a large hemarthrosis is already present, consultation with an orthopedist for appropriate splinting and rehabilitation may improve the outcome once the bleeding has been controlled.[6]

Compartment syndromes can result from bleeds within the fascial compartments of the extremities. Compartment pressures can be safely measured **after** the patient has received factor replacement.

Many patients and their families administer factor concentrate therapy at home. Patients are taught to self-treat or seek care at the first symptom before little outward evidence develops. Take patient concerns seriously. Many patients will have an established management plan for acute bleeding episodes in the medical record. Regional hemophilia foundations, associations, and centers often maintain a database that can be contacted for patient-specific information.

Bleeding episodes are terribly painful, so provide adequate pain control whether or not there is a history of opiate abuse.

When treating patients with hemophilia for other reasons, some general principles apply. Do not place central venous access or arterial lines without factor replacement. Similar rules apply to arterial blood gases, lumbar puncture, and other invasive procedures. Do not give IM injections unless factor replacement is given and maintained for several days. As a general rule, do not give compounds that contain aspirin or nonsteroidal anti-inflammatory drugs for pain relief. If a hemophiliac patient requires interhospital transfer, initiate factor replacement **before** transfer, and do not delay factor replacement with attempts to obtain imaging. Most hemophilia centers prefer to be consulted **anytime** a patient with hemophilia presents to the ED, especially if there is an uncertainty about the need for factor replacement.

Hemophilia Factor Replacement Therapy For patients with hemophilia, there are two sources for factor replacement therapy: recombinant technology from hamster cell lines and purification from human plasma (**Table 235-3**).[1,2,7,8] The highest level of purity and the lowest risk for human viral contamination are found with the recombinant factor concentrates: no transmission of human immunodeficiency virus, hepatitis B virus, or hepatitis C virus has been reported with the current products available in the United States. However, recombinant products may have a higher risk for the development of inhibitor antibodies than plasma-derived products.[9-11] It remains possible for even the highly treated and purified plasma-derived products to potentially transmit viruses such as hepatitis A and the highly heat-resistant parvovirus B19.[1,2,7,8] Opinions vary as to the preferred product,[12,13] and

TABLE 235-3 Hemophilia Replacement Factor Products

Hemophilia Type	Available Products* (Manufacturer/Distributor)
Hemophilia A	*Recombinant Factor VIII Concentrates*
	Advate® (Baxter)
	Helixate FS® (Bayer/CSL Behring)
	Kogenate FS® (Bayer)
	Recombinate® (Baxter)
	Xyntha® (Pfizer)
	Human Plasma-Derived Factor VIII Concentrates
	Hemofil M® (Baxter)
	Monoclate-P® (CSL Behring)
	Human Plasma-Derived Factor VIII Concentrates That Contain von Willebrand Factor
	Alphanate® (Grifols)
	Humate-P® (CSL Behring GmbH)
	Koate-DVI® (Grifols/Kedrion Biopharma)
Hemophilia B	*Recombinant Factor IX Concentrate*
	BeneFIX® (Pfizer)
	Human Plasma-Derived Factor IX Concentrates
	AlphaNine SD® (Grifols)
	Mononine® (CSL Behring)

*Commercial trade names provided for ease of specific identification.

current World Federation of Hemophilia guidelines do not express a preference.[2] In the United States, the National Hemophilia Foundation position is that recombinant factor concentrates are the preferred treatment for hemophilia despite a cost higher than plasma-derived products.[14] **Where possible, the treating physician should use the product that the patient uses at home.**

The dosing regimen used in the hemophilic patient is empiric based on the clotting factor volume of distribution, the half-life of the factor, and the hemostatic level of factor required to control the bleeding (**Table 235-4**).[15,16] Clotting factor is dosed in units of activity; 1 IU of factor represents the amount present in 1 mL of normal plasma. In hemophilia A, 1 IU of factor VIII per kilogram of body weight raises the plasma level by approximately 0.02 IU/mL (2%). The half-life of factor VIII is approximately 8 to 12 hours. For hemophilia B, 1 IU of factor IX per kilogram of body weight will raise the plasma level by approximately 0.01 IU/mL (1%). The half-life of factor IX is approximately 16 to 24 hours.

Factor concentrates are supplied as lyophilized powder in single-use glass vials containing a range of amounts, from 250 to 4000 IU per vial. Calculation of the amount of factor is done using the patient's weight, baseline factor level, the desired factor level, and, to avoid wasting factor, rounding up doses to the next vial. For patients with moderate and severe hemophilia and baseline factor levels below 0.05 IU/mL (5%), the presence of such low levels can be discounted when calculating initial dosing guided by these formulae:

Factor VIII dose = Desired factor VIII level × weight (kg) × 0.5
Factor IX dose = Desired factor IX level × weight (kg)

For major bleeding, high levels of factor replacement are required and continued until bleeding stops (**Table 235-4**). Repeat doses are usually given as intermittent bolus therapy every 8 to 24 hours, or 6 to 12 hours in patients under 6 years of age.

For less severe bleeding in soft tissue, muscle, or joints, a lesser amount of factor replacement is necessary; usually three doses over 1 to 2 days are sufficient to control bleeding. In addition to factor replacement, extremity and joint bleeding may benefit from splinting followed by physical therapy.[6] Cryotherapy has no proven benefit in hemarthroses.[17]

There may be rare instances in which a patient presents with what appears to be a previously undiagnosed bleeding disorder. In these cases, treatment with **fresh frozen plasma** is appropriate to control bleeding until definitive studies can be done. Fresh frozen plasma contains all of the plasma clotting factors, with an average concentration of 1 IU/mL. However, one bag (about 200 mL) of fresh frozen plasma will only raise the factor levels by 3% to 5% in an average adult, so volume overload can complicate extensive factor replacement using this product.

Special Considerations • *Oral and Mucosal Bleeding* Oral bleeding from hemophilia is more common in children than in adults. For an oral bleed, the area should be identified, cleaned of inadequate clot, and solution of **topical bovine thrombin** sprayed on to the site or applied in conjunction with a saturated absorbable gelatin sponge. Repeat doses should be limited because repetitive application of topical bovine thrombin can induce antibodies to factor V, resulting in a syndrome of severe bleeding and thrombosis, which can rarely be fatal. Factor replacement may be required, dosed according to the severity of bleeding. Antifibrinolytic agents, such as **aminocaproic acid** and **tranexamic acid**, are useful adjunctive therapies with a low rate of adverse effects.[2] For very superficial mucosal injuries, it may be possible to manage the bleeding with antifibrinolytic therapy alone. The dose of aminocaproic acid is 75 to 100 milligrams/kg every 6 hours for children, and 6 grams every 6 hours for adults, given PO or IV. The dose of tranexamic acid is 10 milligrams/kg IV three times per day for 1 to 7 days. Tranexamic acid should be used with caution if hematuria is present because ureteral obstruction due to clot formation has been reported.[7]

Mild Hemophilia A Patients with **mild hemophilia A** (factor levels of 5% of normal or greater) who have mild bleeding may not always require factor replacement.[1,2,18] Rather, they may be treated with desmopressin, which

TABLE 235-4 Initial Factor Replacement Guidelines in Moderate and Severe Hemophilia

Severity and Site	Desired Factor Level to Control Bleeding	Hemophilia A Initial Dose (IU/kg)	Hemophilia B Initial Dose (IU/kg)	Comments
Minor: skin (deep laceration)	—	—	—	Abrasions and superficial lacerations usually do not require factor replacement. Treat with pressure and topical thrombin.
Minor: early hemarthrosis, mild muscle bleeding, mild oral bleeding	0.2–0.4 IU/mL (20%–40%)	10–20	20–30	Repeat dose every 12–24 h for 1–3 d until bleeding episode is resolved. Typical duration of replacement is 1–3 d.
Moderate: definite hemarthrosis, moderate muscle bleeding, moderate oral bleeding	0.3–0.6 IU/mL (30%–60%)	15–30	25–50	Orthopedic consult may be required for splinting, physical therapy, and follow-up. Typical duration of replacement is 3–5 d.
Major: retropharyngeal, GI, intra-abdominal, intrathoracic, retroperitoneal	0.6–1.0 IU/mL (60%–100%)	30–50	30–50	Repeat dose every 8–24 h until resolution of bleeding episode. May require replacement for up to 10 d.
CNS	1.0 IU/mL (100%)	50	50–100	Treat before CT. Early neurosurgical consultation.

TABLE 235-5 Desmopressin Treatment of Mild Hemophilia A and von Willebrand Disease

Patient	IV Preparation	Nasal Preparation
<2 y	Not recommended	Not recommended
<50 kg weight	0.3 micrograms/kg IV over 30 min	Single spray 150 micrograms in one nostril
>50 kg weight	0.3 micrograms/kg IV over 30 min; maximum dose, 20 micrograms	One spray 150 micrograms in each nostril (total dose, 300 micrograms)

stimulates the release of von Willebrand factor from endothelial storage sites promoting an increase of factor VIII in the plasma (**Table 235-5**).[19,20] A concentrated intranasal preparation is available and can be used at home.[21] IV or intranasal desmopressin will increase the factor VIII level by two to four times. Desmopressin treatment can be repeated in 24 hours, but with repetitive use, the patient's stores of factor VIII will become depleted, and subsequently, the effect will be less. Desmopressin is an antidiuretic agent, and fluid restriction may be needed during use.[19]

Hematuria **Hematuria** is common in hemophilia but is typically not severe.[22] Rest and hydration are important to ameliorate the degree of bleeding. Factor replacement is indicated for gross hematuria. There is evidence that hemophiliacs are at increased risk for nephrolithiasis, suggesting that renal imaging is indicated for patients with symptoms of renal colic or new-onset hematuria.[23]

Factor Inhibitors **Factor inhibitors**, antibodies against replacement factors, tend to occur most commonly in severe hemophiliacs.[2] Inhibitors not only interfere with the effectiveness of factor replacement therapy, but also can cause anaphylaxis during factor administration in patients with hemophilia B.[24] The use of factor replacement in hemophilic patients with inhibitors is guided by the concentration of inhibitor (measured in Bethesda inhibitor assay units) and the type of response the patient has to factor concentrates. ED physicians should query hemophiliacs about whether they have known inhibitors.

The overriding principle in treating patients with inhibitors is close consultation with a hematologist. In patients with an inhibitor titer <5 Bethesda inhibitor assay units and who are not vigorous antibody responders, some hematologists may recommend giving an increased dose of factor in an attempt to overwhelm the existing antibody. Alternative therapies include human plasma-derived activated prothrombin complex concentrates and recombinant activated factor VII (**Table 235-6**).[25-27] Activated prothrombin complex concentrate contains factors II, IX, and X, mostly nonactivated, and factor VII, primarily in the activated form. Activated factor VII, either from human plasma or recombinant, when complexed with tissue factor, activates factor X. Factor Xa, in concert with factor Va, calcium, and phospholipid, promotes the conversion of prothrombin to thrombin, which ultimately leads to the formation of a hemostatic plug composed of cross-linked fibrin. Even without tissue factor, activated factor VII can bind to the surface of activated platelets stimulating the conversion of factor X to factor Xa.

TABLE 235-6 Replacement Therapy for Hemophilia A and B in Patients With Inhibitors

Type of Product*	Initial Dose	Dosing Interval	Comments
Human plasma-derived activated prothrombin complex concentrate FEIBA NF® (Baxter)	50–100 units/kg	6–12 h	Total daily doses should not normally exceed 200 units/kg
Recombinant activated factor VII NovoSeven RT® (Novo Nordisk)	90 micrograms/kg	2 h	Repeat until hemostasis achieved or therapy judged ineffective

*Commercial trade names provided for ease of specific identification.

Acquired Hemophilia **Acquired hemophilia** occurs when autoantibodies are created against factor VIII, resulting in inactivation of this factor and a hemorrhagic tendency.[28,29] This rare disorder is associated other conditions in about 40% of reported cases, such as autoimmune diseases, cancer, drugs (e.g., penicillin, sulfonamides, ciprofloxacin, phenytoin, clopidogrel), or the postpartum period. Acquired hemophilia occurs equally in both genders with a median age of 60 to 70 years. The bleeding pattern in acquired hemophilia is usually widespread cutaneous purpura and internal bleeding, with hemarthroses being less common, a difference from congenital hemophilia.

The autoantibodies are typically polyclonal IgG4 antibodies that form complexes with factor VIII in a manner that enables some residual factor VIII activity, causing a poor correlation between measured factor activity and bleeding severity. The laboratory findings include a prolonged activated partial thromboplastin time and a low factor VII level.[30] The autoantibody of acquired hemophilia has different kinetics of interaction with factor VII, enabling a differentiation between the inhibitor antibody sometimes seen in congenital hemophilia and antiphospholipid antibodies by mixing studies (see chapter 232).

Treatment of acute bleeding is with activated prothrombin complex concentrates or recombinant activated factor VII (**Table 235-6**).[30,31] Suppression of antibody formation is initiated with prednisone plus either cyclophosphamide or azathioprine. Most patients respond and maintain remission after the immunosuppressives are tapered and discontinued; relapse occurs in about 20%.[32]

Postpartum Acquired Hemophilia **Postpartum acquired hemophilia** is a rare condition with severe hemorrhagic potential.[33] The risk is highest with the first pregnancy, and presentation is typically 2 months after delivery with persistent vaginal bleeding being the most common presenting symptom. Treatment for hemorrhage is with activated prothrombin complex concentrates or recombinant activated factor VII (**Table 235-6**). Production of the autoantibodies will spontaneously cease over many months, achieving complete remission. Immunosuppressants will reduce time to remission. Recurrence with subsequent pregnancies is uncommon.

DISPOSITION AND FOLLOW-UP

Many hemophilic patients are able to judge the severity of bleeding, self-administer replacement therapy, and monitor the response at home.[1,2] Such patients may likely be discharged after initial treatment in the ED for typical joint, soft tissue, or nasal hemorrhage. Relative indications for hospital admission include treatment requiring multiple factor replacement doses or necessity for parenteral pain management. Patients with bleeding in the CNS, neck, pharynx, retropharynx, or retroperitoneum, or those with a potential compartment syndrome should be admitted. Given the complexity of treatment, consultation or transfer to a hemophilia treatment center is recommended.

VON WILLEBRAND'S DISEASE

EPIDEMIOLOGY

von Willebrand's disease is the most common inherited bleeding disorder, present in 1% of the population.[27] However, most patients have a mild defect, and clinically significant bleeding occurs in only about 1% of those with the disease. Congenital von Willebrand's disease is heterogeneously inherited and variably expressed, and although there are multiple variants, it can be classified into three major groups (**Table 235-7**).[34,35] An acquired form of von Willebrand's disease occurs when autoantibodies develop against von Willebrand factor, resulting in rapid clearance of the antibody–von Willebrand factor complex from the circulation.

PATHOPHYSIOLOGY

von Willebrand factor is a glycoprotein that, unlike most other coagulation factors, is synthesized, stored, and then secreted by the vascular endothelial cells. von Willebrand factor serves two key roles in normal

TABLE 235-7 von Willebrand Disease Classification and Treatment

Type	Frequency	Defect	Treatment
1	70%–80% of cases	Normal vWF is present, but in decreased quantity (approximately 20%–50% normal levels)	Desmopressin and, if no response, consider the measures below
2	10%–15% of cases	The vWF is abnormal and dysfunctional	vWF-containing concentrate or cryoprecipitate if vWF-containing product is not available
3	<10% of cases	Almost no vWF is present	vWF-containing concentrate or cryoprecipitate if vWF-containing concentrate is not available

Abbreviation: vWF = von Willebrand factor.

hemostasis: as a cofactor for platelet adhesion and as the carrier protein for factor VIII.[3,36] Circulating von Willebrand factor does not bind directly to platelets, but, when exposed to the subendothelial matrix, von Willebrand factor undergoes a structural change, allowing it to bind to platelet glycoprotein Ib. This interaction between von Willebrand factor and platelet glycoprotein Ib leads to platelet activation and adhesion to other platelets, as well as to the damaged endothelium. As a carrier protein, von Willebrand factor protects factor VIII from proteolytic degradation within the plasma. A defect in von Willebrand factor that diminishes factor VIII binding can produce a clinical presentation similar to mild hemophilia A.

CLINICAL FEATURES

Skin and mucosal bleeding is common in people with von Willebrand's disease, particularly in children and adolescents.[35] Examples of bleeding include recurrent epistaxis, gingival bleeding, unusual bruising, GI bleeding, and menorrhagia in young women. Hemarthrosis is not typical unless severe disease is present. In mild cases of von Willebrand's disease, the patient may be unaware of the disease until after a surgical procedure or injury when unexpected bleeding occurs.

DIAGNOSIS

Tests used to diagnose von Willebrand's disease include bleeding time, activated partial thromboplastin time, factor VIII coagulant activity, von Willebrand factor antigen level, and von Willebrand factor activity.[37,38] The common abnormalities seen in von Willebrand's disease include prolonged bleeding time, low or normal von Willebrand factor antigen, and low von Willebrand factor activity. The prothrombin time should be normal, and about half of patients have a mildly prolonged activated partial thromboplastin time. Diagnostic testing can be complicated, and misdiagnosis can occur from errors in specimen handling, storage, processing, and laboratory testing proficiency. Also, variability in von Willebrand factor levels can sometimes make von Willebrand's disease difficult to differentiate from mild hemophilia A.

TREATMENT

Desmopressin: Nontransfusional Therapy **Desmopressin** has become the primary therapy for many patients with type 1 von Willebrand's disease.[20,21,39,40] For other types of von Willebrand's disease, desmopressin may still work in conjunction with plasma products that contain von Willebrand factor, but hematologists tend to recommend either one or the other. Desmopressin induces the release of von Willebrand factor from storage sites within the endothelium. In responsive individuals, it causes a transient two- to four-fold increase in von Willebrand factor. Desmopressin also has an effect on the endothelium that promotes hemostasis. IV and concentrated nasal spray preparations of desmopressin are available (**Table 235-5**).[21] Desmopressin may be repeated in 24 hours, but the response to subsequent doses diminishes as vWF stores become depleted. Fluid restriction for 24 hours after desmopressin administration is important to prevent hyponatremia.[39] Medications with known antiplatelet effects should be avoided, including aspirin, nonsteroidal anti-inflammatory drugs, antiplatelet agents, heparin, and some antibiotics.

Transfusional Therapies Plasma derivatives that contain von Willebrand factor are used for those type I patients who do not (or no longer) respond to desmopressin or have type II or III von Willebrand's disease.[14,40,41] Because of the risk of viral contamination, factor VIII concentrates that contain multimeric von Willebrand factor and have undergone viral inactivation processes are preferred at a dose of 30 to 50 IU/kg (**Table 235-3**). Cryoprecipitate also contains von Willebrand factor, but because it does not undergo viral inactivation, cryoprecipitate should only be used in life-threatening emergencies when appropriate factor VIII concentrates are not available.[14] Platelet transfusions may benefit patients with certain types of von Willebrand's disease (type III) who do not respond to von Willebrand factor–containing plasma products.[42]

Additional Therapy Patients with von Willebrand's disease with significant epistaxis should be treated with desmopressin or transfusion therapy as needed to control bleeding. If unsuccessful, intranasal topical therapy or cauterization may be necessary (see chapter 244, "Nose and Sinuses") in some cases. Menorrhagia is a common complaint in young women with von Willebrand's disease. Oral contraceptives can help raise von Willebrand factor levels and limit the degree of menstrual bleeding. For dental injury or planned procedures in the oral cavity, an antifibrinolytic agent can be used. **Aminocaproic acid** can be taken orally and **tranexamic acid** can be made into a mouthwash, to be used for 5 to 10 days after the injury or surgical procedure.

DISPOSITION AND FOLLOW-UP

In most patients with von Willebrand's disease, the acute bleeding episodes can be controlled with local measures and desmopressin; such patients can usually be discharged. The unusual von Willebrand's disease patient with almost no von Willebrand factor activity is typically handled like a patient with hemophilia. Relative indications for hospital admission include treatment requiring multiple factor replacement doses or necessity for parenteral pain management. Patients with bleeding in the CNS, neck, pharynx, retropharynx, or retroperitoneum or those with a potential compartment syndrome should be admitted.

CHAPTER 236

Sickle Cell Disease and Hereditary Hemolytic Anemias

Jean Williams-Johnson
Eric Williams

INTRODUCTION

Hereditary anemias result from defects in hemoglobin production, abnormalities in red blood cell (RBC) metabolism, or changes within RBC membrane structure. Increased hemolysis occurs because the RBCs produced are either abnormal or sustain damage after release from the bone marrow, and are removed from the circulation, primarily by the spleen. Depending on the compensatory rate of production, the concentration of circulating erythrocytes may decrease, resulting in anemia.

Inherited hemoglobin disorders are comprised of two main groups: disorders with abnormal hemoglobin structure (e.g., sickle cell disease) and disorders of abnormal hemoglobin production (e.g., the thalassemias). These disorders are widely prevalent; an estimated 7% of the world's population are carriers of an abnormal hemoglobin gene.[1] These genetic abnormalities result in hemoglobin that tends to gel or crystallize, possesses abnormal oxygen-binding properties, or is readily oxidized to methemoglobin, rendering the RBC susceptible to hemolysis.

SICKLE CELL DISEASE

Sickle cell disease (SCD) is a worldwide public health problem.[2] An estimated 250 million people (approximately 4.5% of the world population) are carriers of the sickle cell gene,[3] with 60 million new carriers of sickle cell and 1.2 million new individuals with SCD diagnosed every year.[4] SCD affects predominantly people of African Equatorial descent, although it is also found in persons of Mediterranean, Indian, and Middle Eastern origin.[5,6] SCD affects approximately 70,000 people in the United States, and about 2 million Americans are sickle cell gene carriers.[7]

The overall life expectancy of patients in the United States with SCD is now >50 years,[8] an improvement attributed to early diagnosis (antenatal and neonatal screening), parental education about complications, close monitoring in clinics and follow-up, immunizations, prophylactic penicillin to prevent pneumococcal septicemia, and increased use of drugs such as hydroxyurea.[9]

PATHOPHYSIOLOGY

The normal adult RBC contains three forms of hemoglobin: HbA, HbA_2, and fetal hemoglobin (HbF) (**Table 236-1**). Normal hemoglobin consists of a tetramer of four polypeptide chains, which are pairs of dissimilar chains (two α-globin chains and two non–α-globin chains). HbA accounts for approximately 96% to 98% of adult hemoglobin and consists of two α- and two β-globin chains. HbA_2 accounts for approximately 2.0% to 3.5% of adult hemoglobin and is composed of two α- and two δ-globin chains. HbF is composed of two α- and two γ-globin chains. HbF production peaks in utero and starts declining just before birth, reaching a baseline of <1% at approximately 48 weeks of age. Because of the 120-day life span of the normal RBC, HbF is the predominant form in the circulation for approximately the first 4 months of life. The α-globin chains are coded by four genes, two each on chromosomes 16, whereas the β-, γ-, and δ-globin chains are coded by two genes, one each on chromosomes 11.

SCD is caused by the presence of an abnormal β-globin chain.[10] The specific mutation is an adenine-to-thymine substitution in the codon that results in the hydrophobic amino acid, valine, replacing the hydrophilic amino acid glutamic acid in the sixth amino acid position of the β-globin chain. As a result, under deoxygenated conditions, valine becomes buried in a hydrophobic pocket on an adjacent chain. The globin chains then join together, and HbS polymerizes, deforming the RBC and producing the characteristic sickled appearance (**Figure 236-1**).

The distorted sickle cell results in premature RBC destruction (life span of about 20 days) and also increases the viscosity of blood, leading to obstruction within the microvasculature (Figure 236-1). The overall effect is chronic, ongoing hemolysis and episodic periods of vascular occlusion, resulting in tissue ischemia affecting many organ systems. Although the sickle cell gene results from a single base substitution, there is tremendous variability in the phenotypic expression of this mutation.[6,11,12]

SCD is seen in patients who are homozygous for the sickle gene or who are double heterozygous with another hemoglobin variant (e.g., HbSC). **Sickle cell anemia** refers to homozygosity of the mutation, also termed *HbSS* or *SS disease*.

People with **sickle cell trait** (HbAS, heterozygous with one gene for the sickle mutation) have a normal life span and usually are asymptomatic, although complications occur, grouped as definite, probable, or possible.[13] Definite associations include renal medullary carcinoma, hematuria and renal papillary necrosis, hyposthenuria, splenic infarcts, and exercise-related deaths. Probable associations include venous thromboembolic events, pregnancy-related complications, and complicated

TABLE 236-1 Composition of Normal Human Hemoglobin and Hemoglobin Variants

Syndrome	Types of Hemoglobin (Hb) Present	Percentage within the Red Blood Cell	Hemoglobin Tetramer Composition (globin chains)
Normal adults	HbA	96–98	Two α-chains and two β-chains
	HbA_2	3.0–3.5	Two α-chains and two δ-chains
	HbF	0.5–0.8	Two α-chains and two γ-chains
Sickle cell trait (heterozygous)	HbA	60–65	Two α-chains and two β-chains
	HbAS	35–40	Two α-chains, one normal β-chain, and one sickle β-chain
	HbF	0.5–0.8	Two α-chains and two γ-chains
Sickle cell disease (homozygous)	HbS	80–90	Two α-chains and two sickle β-chains
	HbA_2	2–4	Two α-chains and two γ-chains
	HbF	2–20	Two α-chains and two γ-chains

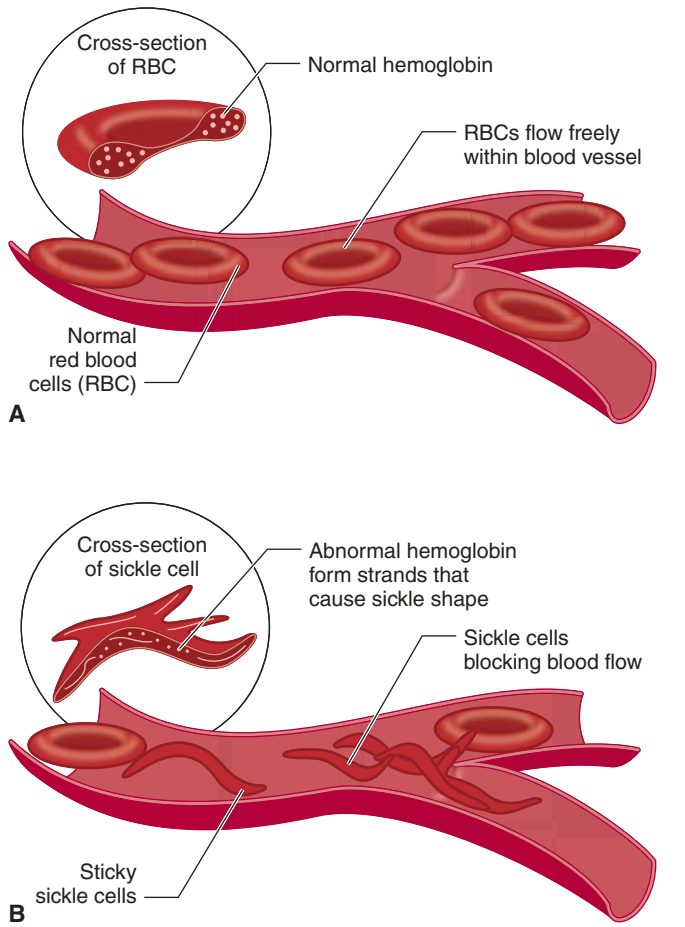

FIGURE 236-1. Intravascular blood flow of normal and sickle red blood cells (RBCs). **A.** Normal RBCs flowing freely in a blood vessel. **B.** Abnormal, sickled RBCs clumping and blocking blood flow in a blood vessel. (Other cells also may play a role in this clumping process.)

hyphema. Possible associations include retinopathy, acute chest syndrome, and asymptomatic bacteruria.[13] Many of the associations are seen only under conditions of severe tissue hypoxia, acidosis, dehydration, or hypothermia.

Polymerization of deoxygenated HbS, deforming the red cell into a sickled shape that causes microvascular sludging and obstruction (vaso-occlusion), is the major pathophysiologic process in SCD.[10] Vascular obstruction worsens hypoxia and causes acidosis in the microcirculation that contributes to further sickling. The sickling process is initially reversible when the HbS is reoxygenated, but with repeated episodes of sickling, the red cell membrane is permanently damaged, and the cell remains irreversibly sickled. Anywhere from 5% to 50% of the circulating erythrocytes in a patient with SCD can be irreversibly sickled cells. The sickling process is inhibited by the presence of HbF and other hemoglobin variants.[14] Structural and antigenic changes on the RBC membrane cause an abnormal tendency for the erythrocyte to catalyze plasma coagulation factors and adhere to vascular endothelium in SCD.

CLINICAL FEATURES

Because newborn screening occurs in the United States and in most developed countries, the majority of patients who present to the ED will already know that they have the sickle cell trait or disease. Although SCD can produce a wide spectrum of manifestations, vaso-occlusive crisis accounts for the majority of ED presentations as the sickled RBCs restrict the blood flow to various organs, thus causing ischemic pain and organ damage.[10,15,16] Patients may also present to the ED with life-threatening complications such as stroke, aplastic crisis, acute chest syndrome, and sepsis[17,18] (**Table 236-2**).

TABLE 236-2 Complications of Sickle Cell Anemia

Neurologic	Ischemic or hemorrhagic stroke
	Cerebral aneurysm
	Chronic pain syndrome
	Neuropathic pain syndrome
Eye	Retinopathy
Pulmonary	Acute chest syndrome
	Pulmonary hypertension
Cardiac	Cardiomegaly
Abdominal, GI	Mesenteric ischemia
	Hepatic infarction
	Cholelithiasis
	Intrahepatic cholestasis
	Splenic sequestration
Renal, GU	Hematuria
	Renal infarction
	Papillary necrosis
	Renal failure
	Priapism
Musculoskeletal	Acute vaso-occlusive pain crisis; bone, joint, and muscle pain
	Osteomyelitis
	Avascular necrosis of femoral head
Dermatologic	Leg ulcers
Infection	Osteomyelitis
	Pneumonia
	Urinary tract infection
Hematologic	Chronic hemolysis
	Acute hemolytic crisis
	Aplastic crisis
	Hypercoagulability: pulmonary embolism and venous thrombosis

Vaso-Occlusive Pain Crisis Acute vaso-occlusive pain crisis is a common problem in patients with SCD.[10,16] The initiating event may not be identifiable, but stressors such as infection, cold, dehydration, and altitude have been implicated. As a result of intravascular sickling and small-vessel occlusion, infarction of bone, viscera, and soft tissue occurs. This is manifested as diffuse bone, muscle, and joint pain and, in some cases, symptoms related to a specific affected organ. **Initial management of these patients includes aggressive pain management, appropriate hydration, and an assessment for a treatable cause of the current crisis as well as a search for additional complications (Table 236-3).**[1,18-20]

The CBC and reticulocyte count assess the degree of anemia and whether the marrow is still producing red cells. If the reticulocyte count is not available, the presence of polychromasia in the peripheral blood smear can be used to provide evidence of continued RBC production. It is common for SCD patients to have a low-grade temperature as well as a modestly elevated leukocyte count during a painful crisis, potentially confounding detection of an infection. A leukocyte count >20,000/mm^3 (> 20 × 10^9/L) with an increased number of bands is not typical for sickle crisis alone; this combination suggests a potential infection. Mild elevations in serum bilirubin and lactate dehydrogenase levels are common due to chronic hemolysis.

Supplemental oxygen has no proven benefit, unless the patient is systemically hypoxemic.[18,20] SCD patients during a painful crisis may be hypovolemic due to their disease (deficient renal concentrating ability) or crisis (anorexia, vomiting, or fever), so PO or IV rehydration may be necessary. No hydration regimen has proven capable of shortening the duration or severity of a painful sickle cell attack.[21] After rehydration, maintenance PO or IV (5% dextrose in 0.5 normal saline) should be provided.

Treatment of acute, moderate to severe pain usually requires opioids,[1,10,16,18-20] usually parenteral, but sustained-release oral morphine may be as effective as parenteral morphine.[22] Potent opioids, such as morphine or hydromorphone, are recommended, but meperidine, with the potential for neurotoxicity (seizures) from accumulation of the metabolite normeperidine, is not.[20] Some patients, because of prior opioid treatment, may be very tolerant, and large doses may be required to achieve adequate analgesia. Regular doses of analgesics for a few hours to several days typically are required. Patient-controlled analgesia has been used in selected patients. Nonsteroidal anti-inflammatory drugs can be used for their probable additive effect in pain management of sickle cell crisis.[18] Low-dose ketamine by continuous IV infusion is a potential adjuvant analgesic in acute pain crisis.[23]

Tinzaparin, a low-molecular-weight heparin that has antithrombotic, anti-inflammatory, and endovascular effects may be considered in protracted vaso-occlusive crises[1,24]; the recommended dose is 175 IU/kg SC daily for 2 to 7 days.

A recommended practice is to develop an individualized assessment and treatment protocol for specific patients who frequently present to the ED with painful crises.[20]

RBC transfusion to reduce the concentration of HbS-containing erythrocytes does not shorten the duration or reduce the risk of complications of routine acute vaso-occlusive painful crisis.[25] Furthermore, transfusion involves significant expense, the risk of bloodborne disease transmission, and the potential for iron overload and exposes the patient to the minor RBC antigens, with the potential to induce antibodies that prevent or complicate future transfusions (see chapter 238, "Transfusion Therapy").[26,27] Transfusion for sickle cell crisis or complications is reserved for specific indications such as aplastic crisis, pregnancy, stroke, respiratory failure, and general surgery.[10,28,29] Transfusion protocols in SCD are categorized as aggressive (decreasing HbS to <30%) and conservative (increasing hemoglobin to >10 grams/dL or 100 g/L); for most indications, there is no clinical difference between aggressive or conservative protocols.[29]

Hydroxyurea (hydroxycarbamide) successfully reduces the frequency and severity of painful crises in SCD.[8,30-33] Hydroxyurea blocks the synthesis of DNA and impairs cell division. It also increases the production of HbF to levels that are protective and preventive of RBC sickling. Hydroxyurea is indicated for young adults who have three or more

TABLE 236-3 Guidelines for the Assessment and Management of Acute Vaso-Occlusive Crisis

History	Duration and location of pain History of fever Presence of focal swelling or redness Precipitation factors for acute episode Medications taken for pain relief
Physical examination	Assess degree of pain Inspect sites of pain, looking for swelling, warmth, redness General: respiratory distress, pallor, hydration, jaundice, rash Vital signs: especially temperature, pulse oximetry Respiratory: lung sounds Heart: cardiomegaly and systolic murmur common with chronic anemia Abdomen: tenderness, organomegaly
Ancillary tests	Obtain if moderate to severe pain, focal pathology is present, or pain is atypical for acute episode CBC, leukocyte differential, reticulocyte count, urinalysis Chest radiograph, if signs of lower respiratory tract pathology Blood cultures and additional blood tests: as indicated by clinical condition
General management	Bed rest, provide warmth and a calm, relaxing atmosphere Distractions where appropriate: television, music, etc. Oral fluids: typically about 3 L/d IV fluids to correct dehydration or if reluctant to drink or vomiting is present Oxygen: not routinely required unless hypoxemia is present Encourage deep breathing, incentive spirometry
Pain management	Use analgesics appropriate to degree of pain Acetaminophen for mild pain Nonsteroidal anti-inflammatory drug for mild to moderate pain (avoid if renal insufficiency is present) Opioids for moderate to severe pain; typical initial doses include: Morphine, 0.3 milligram/kg PO or 0.1–0.15 milligram/kg IV Hydromorphone, 0.06–0.08 milligram/kg PO or 0.015–0.020 milligram/kg IV Reassess response in 15–30 min; may repeat with one fourth to one half of the initial dose
Consider adjuvant therapy	Medication to prevent constipation Antiemetic Anxiolytic Tinzaparin
Disposition and follow-up	Consider admission to the hospital if: Acute chest syndrome is suspected Sepsis, osteomyelitis, or other serious infection is suspected WBC count is >30,000/mm^3 Hemoglobin level is <5 grams/dL Platelet count is <100,000/mm^3 Pain is not under control after 2 to 3 rounds of analgesics in the ED
	Consider discharge if: Pain is under control and patient can take oral fluids and medications Appropriate oral analgesics are available Patient is able to comply with home care instructions Patient has resources for follow-up

hospitalizations for vaso-occlusive crisis in the preceding 12 months.[8,31] Daily prophylactic penicillin V reduces the incidence of infections and reduces mortality from sepsis in children but with little benefit in adults.[34]

Bone Pain Bone pain is common during a sickle cell crisis and is usually located in the back and the extremities.[35] The pain will be diffuse, without focal signs of inflammation; therefore redness, warmth, or swelling suggests infection such as cellulitis or osteomyelitis. Localized hip pain with difficulty ambulating suggests aseptic necrosis of the femoral head; approximately 30% of SCD patients develop femoral head damage by age 30 years old. Joint effusions are occasionally seen in painful sickle cell crisis, and arthrocentesis is often necessary to differentiate this complication from infection. Plain radiographs may show evidence of aseptic necrosis or osteomyelitis, whereas bone infarcts usually are not visible on radiographs. A radionuclide bone scan or MRI may be necessary to differentiate infection from infarction.

Acute Chest Syndrome **Acute chest syndrome** is defined as a new infiltrate on chest radiograph in association with one other new sign or symptom: fever >38.5°C (101.3°F), cough, wheezing, tachypnea, or chest pains.[36-38] In adults, acute chest syndrome occurs most commonly 1 to 3 days after hospitalization for an acute pain crisis. Acute chest syndrome is the leading cause of death in patients with SCD in the United States.[39] Although this phenomenon occurs most often as a single episode, some patients may experience multiple attacks, resulting in chronic lung disease.[40] Also, symptoms may vary with repeated episodes.

Acute chest syndrome has multiple potential etiologies; most commonly, the syndrome is precipitated by pulmonary infections, fat emboli, and rib infarction.[37,38,40] Acute chest syndrome may also result from iatrogenic causes, such as aggressive hydration for sickle cell painful crisis producing pulmonary edema and opioid use depressing inspiratory effort and promoting atelectasis.

Infectious pathogens were identified in patients admitted to the hospital with acute chest syndrome in a national study.[36] The two most common organisms identified were the atypical pneumonia pathogens *Chlamydia pneumoniae* and *Mycoplasma pneumoniae*.[36] Other organisms associated with acute chest syndrome include *Staphylococcus aureus*, *Haemophilus influenzae*, *Klebsiella pneumoniae*, adenoviruses, influenza viruses, parainfluenza viruses, respiratory syncytial viruses, cytomegalovirus, and parvovirus B19.[36] Traditionally, *Streptococcus pneumoniae* was considered the most frequent cause of pulmonary infection in SCD patients, but this pathogen is now rare in cases of acute chest syndrome, presumably due to the use of pneumococcal immunization and prophylactic penicillin therapy.

Abundant evidence for fat embolism as a possible cause for acute chest syndrome includes bony slivers and marrow fat found in the pulmonary vasculature at autopsy, fat droplets within endothelial cells identified in lung biopsy specimens collected via bronchoscopy in living patients, and elevated serum levels of free fatty acids and circulating secretory phospholipase A_2, a potent inflammatory mediator originating from the bone marrow.[41] It is postulated that reduced blood flow to the bone marrow during a vaso-occlusive crisis results in ischemia and necrosis, so that pieces of necrotic marrow embolize and become lodged in the pulmonary vasculature, playing a role in the pathophysiology of acute chest syndrome.

The combination of both ischemia and hypoxia in the pulmonary circulation promotes the production of free radicals, which further results in the upregulation of endothelial adhesion molecules such as vascular cell adhesion molecule-1. This activation causes binding of sickled RBC and leukocytes to the endothelium, which further increases the cycle of vaso-occlusion. The acute chest syndrome is the final result of several pathogenic processes exerting their effects individually and collectively in a vicious cycle, creating regional hypoxia, acidosis, and lung injury (**Figure 236-2**).

Respiratory symptoms are usually present, including cough, shortness of breath, chest pain, and fever, although the clinical presentation may vary.[37,38] Chest radiographs are important to identify the presence of a new patchy infiltrate; any lobe can be affected. The radiographic changes often lag behind the clinical features, so the radiograph may be initially normal, and the clinical severity of disease and the extent of hypoxia may not correlate with radiographs.

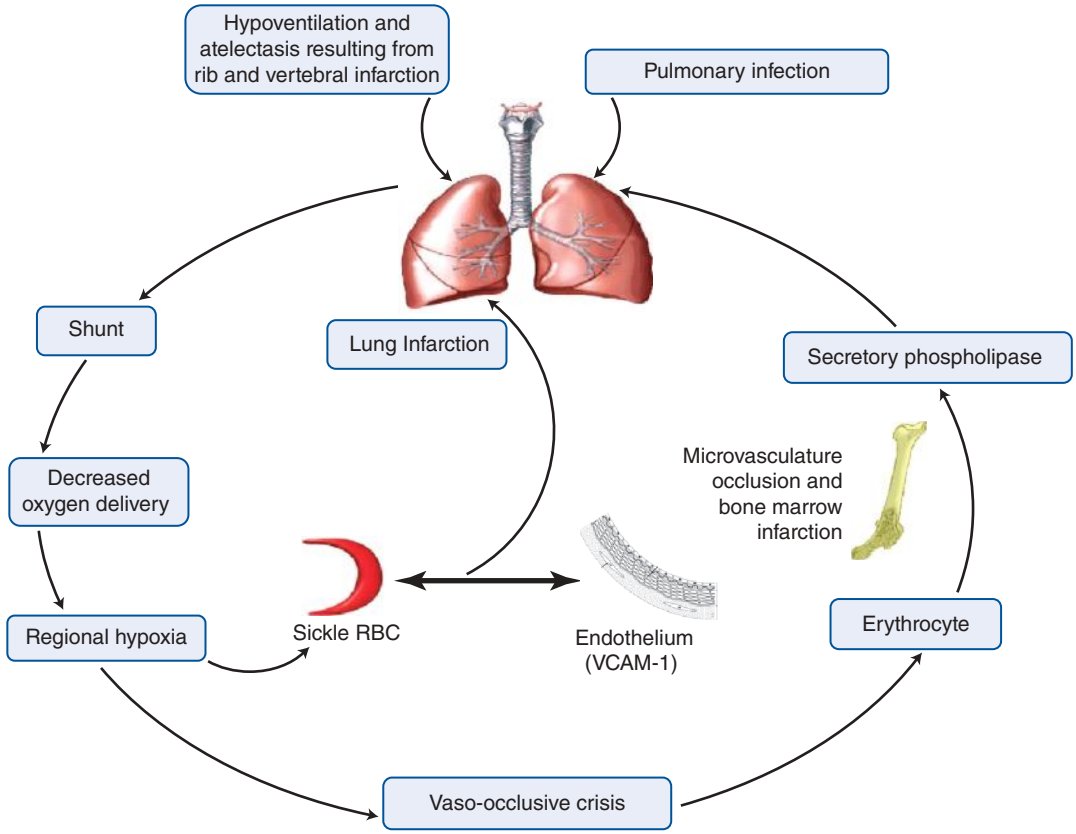

FIGURE 236-2. Pathogenesis of acute chest syndrome. NO = nitric oxide; RBC = red blood cell; VCAM-1 = vascular cell adhesion Molecule-1.

Acute chest syndrome is treated with supportive care (oxygen, analgesics, hydration), antibiotics, and exchange transfusion (**Table 236-4**).[37,38,40] Oxygen should be administered, especially if hypoxemia is demonstrated. Pain control initially requires high doses of parenteral opioids but requires careful monitoring to prevent both oversedation and hypoventilation. Dehydration results in increased plasma osmolarity and intracellular dehydration of RBCs, resulting in the further propagation of the sickling phenomenon. Supportive IV fluid therapy (up to 1.5 times maintenance) in the form of hypotonic solution facilitates free water passage into the relatively hypertonic red cells so that the resultant osmotic swelling decreases the mean corpuscular hemoglobin concentration and reduces the tendency for sickling.

Antibiotics are recommended irrespective of cultures, and many experts believe that patients with acute chest syndrome should receive a full course of empirical broad-spectrum antibiotics to treat pathogens commonly associated with community-acquired pneumonia,[37,38] but no specific regimen has proven superior.[42] Bronchospasm may accompany acute chest syndrome and can persist after recovery, indicating that bronchial hyperactivity can be a marker of lung injury in some patients. Inhaled β_2-adrenergenic agents can be used if wheezing occurs.[43]

Transfusion therapy is believed to be lifesaving in acute chest syndrome, but there are no firm evidence-based recommendations for its use,[44] and currently accepted indications for exchange transfusion in acute chest syndrome are based on empirical observations.[37,38,40] Exchange transfusion appears more advantageous, particularly in patients with relatively high hemoglobin (>9.0 grams/dL or 90 grams/L). Exchange transfusion decreases the concentration of sickled hemoglobin while maintaining an unchanged whole-blood viscosity and resulting in little iron gain. Exchange transfusion is usually reserved for severe crises signaled by deterioration of the patient's partial pressure of arterial oxygen (Pao_2) to <60 mm Hg (<8 kPa) with the goal to decrease the HbS level to <30%.

Hydroxyurea reduces the occurrence of acute chest syndrome primarily by stimulating an increase in HbF, with other therapeutic effects such as inhibiting sickle polymerization, increasing the deformability of RBC, and reducing the adhesion of sickle cells to vascular endothelium.[30-32,37,38]

Inhaled nitric oxide is beneficial in acute chest syndrome,[37,40] apparently due to its vasodilatory effects that improve the coordination between ventilation and perfusion in the damaged lung regions with minimal systemic absorption. In addition, nitric oxide reduces adhesion of RBCs and leukocytes to endothelial cells by decreasing the activity of vascular cell adhesion molecule-1.

Abdominal Crisis Generalized and constant abdominal pain is a common complaint during an acute sickle cell crisis, and it may be difficult to distinguish from focal abdominal problem, such as cholecystitis or appendicitis. **With a vaso-occlusive crisis, there should be accompanying musculoskeletal pain, the patient can frequently identify that the pain is similar to prior episodes, and there should not be physical evidence of peritonitis.** Repeated abdominal examinations should be done to assess for progression of tenderness and development of peritoneal signs.

Hepatic infarction may produce jaundice and abdominal pain, which can be difficult to distinguish from hepatitis or cholecystitis. Biliary disease is common because pigment-related cholelithiasis is seen in 30% to 70% of SCD patients. Severe right upper quadrant pain and marked elevations of bilirubin may be due to intrahepatic cholestasis, which rarely may progress to hepatic failure.

GU System Vaso-occlusive events involving the kidneys are often asymptomatic and likely account for the frequent finding of microscopic hematuria seen in SCD patients.[45] Infarction in the renal medulla may cause flank pain, renal colic–type pain, and costovertebral angle tenderness, mimicking pyelonephritis.[46] Papillary necrosis may result in either gross or microscopic hematuria, but RBC casts are uncommon. Renal imaging studies generally are necessary for correct diagnosis. Both renal medulla infarction and papillary necrosis are treated with IV fluids to maintain urine flow and close monitoring of hemoglobin levels to ensure that anemia does not worsen. Urinary tract infections are common in SCD patients, and routine urinalysis is recommended when these patients present to the ED.

TABLE 236-4 Assessment and Treatment of Acute Chest Syndrome

History	Major presenting symptoms: dyspnea, fever, cough Accompanying chest, rib, bone, or joint pain Assess degree or severity of pain Recent or previous sepsis, infection, pneumonia, or hospitalization Prior history of acute chest syndrome, especially if required intubation and ventilatory support Potentially infectious contacts Current medications Immunization history: especially pneumococcal and *Haemophilus influenzae* type b Baseline hemoglobin level and arterial oxygenation saturation
Physical examination	General: respiratory distress, pallor, hydration, jaundice, rash Vital signs: especially temperature, pulse oximetry Respiratory: chest wall, lung sounds Heart: cardiomegaly and systolic murmur common with chronic anemia Abdomen: tenderness, organomegaly
Ancillary tests	CBC, leukocyte differential, reticulocyte count, serum electrolytes, renal function, urinalysis Cross-match sample: if RBC transfusion is contemplated Arterial blood gas: if moderate to severe respiratory distress and/or hypoxemia on pulse oximetry Chest radiography Blood cultures Additional blood tests: as indicated by clinical condition
Treatment	Oxygen: adjust according to pulse oximetry Oral hydration: preferable IV hydration: use hypotonic fluids, use a rate and dose at approximately 1.5 times maintenance (aggressive IV fluids can worsen acute chest syndrome) Analgesics: if needed, generally potent parenteral opioids are used, monitor for signs of respiratory suppression Antibiotics: empiric antibiotics recommended to cover community-acquired pneumonia pathogens Transfusion: use if severe acute anemia is present
Exchange transfusion	Consider when Severe acute chest syndrome on admission and past history of requiring ventilatory support: useful to prevent intubation Deterioration despite above management: useful to prevent intensive care unit admission Patient already intubated and on ventilatory support: useful to shorten duration of ventilatory need Suspected or confirmed fat or bone marrow embolism

Priapism occurs in up to 30% of males with SCD. Patients with stuttering priapism (recurrent episodes that last <3 hours often with a pattern of increasing frequency and severity) are treated with oral adrenergic agents or hormonal analogues.[47] Patients with a major episode (sustained erection lasting >4 hours) are treated with fluid hydration, pain control, corporal aspiration, and intracorporal installation of a dilute α-adrenergic agonist solution (see chapter 93, "Male Genital Problems"). Transfusions, either simple or exchange, have no proven benefit for sickle cell–associated priapism.[47]

ADDITIONAL SYSTEMIC MANIFESTATIONS OF SICKLE CELL DISEASE

Splenic Infarction The spleen is particularly susceptible to the vaso-occlusive effects of sickled cells, and over time, microinfarctions result in a spleen that is essentially nonfunctional by age 5.[48] This renders these patients at risk for serious infections and sepsis from encapsulated organisms. Therefore, immunizations, prophylactic penicillin therapy, and parental education are critical to minimize the risk of infection and prompt early evaluation of fever in these patients. As SCD patients grow into teenage years, their risk of overwhelming sepsis decreases, but they remain predisposed to infection.

Splenic Sequestration Splenic sequestration is an important cause of significant morbidity and occasional mortality in SCD, with its occurrence being more common in children than in adults.[49] This syndrome manifests by the sudden enlargement of the spleen with an acute fall in the hemoglobin level due to sequestration of the blood volume within the spleen. Left upper quadrant pain may or may not be present. Symptoms include tachycardia, hypotension, pallor, and lethargy, and the spleen is usually enlarged and firm. Platelets also may be sequestered, resulting in moderate thrombocytopenia. The reticulocyte count should remain elevated.

Therapy includes volume resuscitation, which may mobilize some of the RBCs trapped within the spleen. Simple RBC transfusion or exchange transfusion may be necessary. An investigation for a precipitating infection should be done. Rarely, splenectomy is necessary. Unfortunately, recurrence of this syndrome is common.

Hemolytic Anemia Patients with SCD have a chronic hemolytic state due to the shape of the red cells. The baseline hemoglobin level is often between 6 and 9 grams/dL (60 to 90 grams/L), and the reticulocyte count is between 5% and 15%. With infections, the hemolytic process may worsen, and hemoglobin may drop from the previous baseline. Typically, erythrocyte production will increase in response to the increased RBC destruction, but it may not be enough to compensate for the increased hemolysis. Acutely, the patient may notice symptoms of worsening fatigue, shortness of breath, dyspnea on exertion, and scleral icterus. These symptoms may be worsened if other comorbid diseases are present. It is uncommon for the hemolysis to be so severe as to require transfusion.

Aplastic Crisis Aplastic crisis results when the production of RBCs declines significantly, producing a rapid decrease in the hemoglobin level with reticulocytopenia.[15] The most common cause of aplastic crisis appears to be infection, specifically from human parvovirus B19. Folate deficiency and bone marrow necrosis also may play a role. Aplastic crisis is more common in children than in adults. Patients generally will present with increasing fatigue and pallor and no evidence of increased hemolysis. The hemoglobin level will be unusually low, and few or no reticulocytes will be present; reticulocyte count is typically <0.5%. The leukocyte and platelet levels are usually normal. This syndrome is usually self-limiting, and the marrow will begin producing RBCs spontaneously within 1 week. Transfusion may be required in the interim.

Neurologic Disorders Ischemic and hemorrhagic stroke, as well as subarachnoid hemorrhage, are more common in patients with SCD.[50] The risk of stroke in children with SCD is >200 times greater than those without SCD,[51] and approximately 10% of patients with SCD experience a stroke before age 20 years old. The cause of stroke in most patients is cerebral infarction due to occlusion or narrowing of large cerebral vessels.[52] Silent cerebral infarcts visible on MRI have been observed in over a third of SCD patients by age 14, associated with decreased intellectual ability, poor academic achievement, and risk of progression to overt stroke.[53] Hemorrhagic strokes and subarachnoid hemorrhage most commonly occur in the third decade of life.[51] Cerebral aneurysms are also more common in SCD patients, perhaps due to local vessel occlusion or ischemia.

Acute stroke in a SCD patient is treated with emergent simple or partial exchange transfusion. Unfortunately, children who suffer a stroke are at 70% to 90% risk for recurrence, so chronic transfusion therapy is indicated to prevent recurrent stoke after the initial event.[53]

Chronic pain syndromes in SCD patients are associated with avascular necrosis and leg ulcers.[54] Neuropathic pain has been reported in SCD patients; the most commonly reported location is the mental nerve, with numbness of the chin and mandibular bone pain.[54]

Infections Patients with SCD are functionally asplenic after early childhood, rendering them susceptible to infections from encapsulated organisms, such as *H. influenzae* and *S. pneumoniae*.[48,55] Other common infections associated with SCD include pneumonia caused by these

organisms as well as *M. pneumoniae*, meningitis, and osteomyelitis due to *Salmonella typhimurium*, *S. aureus*, and *Escherichia coli*. Although low-grade fever is not uncommon during an acute crisis, unexplained fevers of >38°C (100.4°F) require evaluation for bacterial infection and consideration for early treatment with broad-spectrum antibiotics. In addition to *H. influenzae* immunization, patients with SCD should be encouraged to receive yearly influenza vaccinations and remain up to date with pneumococcal immunization, and children should be maintained on prophylactic daily oral penicillin.[34]

Cardiac Complications Cardiomegaly is common and correlates with the degree of chronic anemia. Additionally, cardiac dysfunction may occur from microinfarcts and hemosiderin deposition from hemolysis and blood transfusion.[56] Cardiac contractility is enhanced to maintain adequate systemic oxygen delivery, producing a widely radiating systolic ejection murmur. SCD patients have laboratory evidence of coagulation overactivation, and there appears to be increased risk for pulmonary embolism and venous thrombosis.[57,58] Baseline D-dimer levels are increased in the steady-state in SCD patients, and levels are much higher during pain crisis.[59]

Dermatologic Chronic, poorly healing leg ulcers around the malleoli are common in older sickle cell patients.[60] Minor injury, impaired microcirculation due to repeated sickling episodes and microinfarcts, and infections all contribute to the development and persistence of these ulcers. No systemic or topical therapy has proven superior to achieve complete healing.[61]

VARIANTS OF SICKLE CELL DISEASE

SICKLE CELL–HEMOGLOBIN C DISEASE

HbC results from a single point mutation in the β-globin chain gene; lysine is substituted for glutamic acid at the sixth position. The prevalence of the HbC gene is approximately 1 per 5000 in African Americans but is as high as 16% in parts of West Africa.[62] Deoxygenated HbC has the tendency to precipitate inside the RBC, forming crystals that decrease cell deformability and increase blood viscosity. Patients with HbC trait (heterozygous for the HbC gene, or *HbAC*) are asymptomatic, and those with HbC disease (homozygous for the HbC gene, or *HbCC*) typically have a mild hemolytic anemia, abundant target cells,[63] and sporadic episodes of musculoskeletal pain, splenomegaly, dental infarctions, and angioid retinopathy.[64]

The heterozygous sickle cell variant, sickle cell–hemoglobin C (*HbSC*), results when the gene for HbS is inherited from one parent and the gene for HbC is inherited from the other parent. These individuals have almost equal amounts of HbS and HbC but no HbA. Because HbC does not polymerize as readily as HbS, HbSC disease generally has less severe clinical consequences than sickle cell anemia (HbSS).[65] These patients have a milder chronic hemolytic anemia and, as a consequence, milder reticulocytosis. The peripheral smear shows abundant target cells and a few sickle cells.

The complications of HbSC disease are similar to sickle cell anemia, although usually less severe. As opposed to sickle cell anemia, adult patients with HbSC disease often have splenomegaly. HbSC disease patients are susceptible to a proliferative retinitis that is visible on funduscopy as angioid streaks (jagged, reddish brown, subretinal lines that taper outward from the optic nerve), representing breaks in the brittle Bruch membrane.[64] Cracks in the membrane lead to impairment of the choriocapillaries that may produce loss of photoreceptor cells and lead to impaired vision.

SICKLE CELL–HEMOGLOBIN O-ARAB DISEASE

Hemoglobin O-Arab is a hemoglobin variant resulting from substitution of lysine for glutamic acid at position 121 of the β-globin chain. Hemoglobin O-Arab is widespread in the Middle East, is present in the Balkans, and occasionally occurs in African Americans.[6] Patients heterozygous for hemoglobin O-Arab (*HbAO-Arab*) have no clinical problems. Patients homozygous for hemoglobin O-Arab (*HbOO-Arab*) or heterozygous for sickle cell–hemoglobin O-Arab (*HbSO-Arab*) are clinically similar to patients with sickle cell anemia, having severe hemolytic anemia and recurrent vaso-occlusive crises, and children have the potential to develop sickle cell dactylitis and splenic sequestration crises.

THALASSEMIA

The thalassemias are a diverse group of hereditary disorders caused by defective synthesis of globin chains, resulting in an inability to produce normal adult hemoglobin.[66-68] The hallmark of these disorders is a microcytic, hypochromic, hemolytic anemia. These disorders are most common in those of Mediterranean, Middle Eastern, African, and Southeast Asian descent. Globalization as a result of migration has led to changing demographics, and persons who have thalassemia syndromes and heterozygote carriers now reside in all parts of the world. Similar to other hemoglobin disorders, namely SCD and glucose-6-phosphokinase deficiency, the high prevalence of thalassemia phenotypes is thought to be protective against malaria.[69]

The thalassemia syndromes are categorized depending on the globin chain affected or the abnormal hemoglobin produced. Thus, β-globin gene mutations give rise to **β-thalassemia** and α-globin mutations cause **α-thalassemia**.[68]

The β-thalassemias have diminished production of the β-globin chain, which allows unmatched α-globin chains to accumulate as α-tetramers in the immature RBC. These tetramers are very insoluble, and their precipitation damages the developing erythroid precursor cells, resulting in early death. The cells that are produced have decreased hemoglobin, which accounts for the hypochromia and target cell formation seen in thalassemias. Over 200 different mutations with variable impact on β-globin production have been identified associated with β-thalassemia.

Patients with α-thalassemia develop an excess of β-globin chains that accumulate as β-tetramers called *hemoglobin H*. Hemoglobin H is more soluble and stable so that in severe α-thalassemia, ineffective erythropoiesis is less of a problem, and increased destruction of the cells due to the structural abnormality is more prominent.

Both forms of thalassemia are characterized by varying degrees of anemia depending on the amount of ineffective erythropoiesis and premature destruction of the circulating RBCs. The hypoxia associated with severe anemia triggers compensatory mechanisms in an attempt to increase RBC production. This causes enlargement of the reticuloendothelial organs and expansion of the bone marrow cavity, leading to osteopenia.

β-Thalassemia has three clinical syndromes representing mutations in one or both β-globin genes: β-thalassemia major (Cooley's anemia), β-thalassemia intermedia, and β-thalassemia minor.[66,67,70-72] Because there are four α-globin genes, two each inherited from the individual parents, the genetics and clinical consequences of the α-thalassemias are determined by five genotypic possibilities.[73] A normal individual has four functioning α-globin genes, the silent α-thalassemia carrier has three normal functioning α-globin genes and one dysfunctional gene, the patient with α-thalassemia trait has two normal functioning α-globin genes and two dysfunctional genes, and the patient with hemoglobin H disease has one normal functioning α-globin gene and three dysfunctional genes. Individuals with a defect in all four α-globin genes, called *Hb Bart's*, have a disorder that is incompatible with life, producing stillborn or severely distressed infants. Outside of this most severe form, individuals with either α- or β-thalassemia can be minimally to severely affected due to the specific genotype and whether the mutation produces complete or partial reduction in globin chain production.[66,67]

α-THALASSEMIA CARRIER AND TRAIT

Patients who are α-thalassemia carriers and with α-thalassemia trait have no clinical symptoms or physical findings, and patients with α-thalassemia trait are detected by the finding of microcytic RBCs and a borderline to slightly low hemoglobin level.[67]

HEMOGLOBIN H DISEASE

Hemoglobin H disease is a disorder with one functional α-globin chain gene.[73] Hemoglobin H disease usually presents in the neonatal period

TABLE 236-5 Drugs That Produce Oxidative Stress on Red Blood Cells at Therapeutic Doses

	Definite Association	Possible Association
Sulfonamides	Sulfacetamide Sulfamethoxazole Sulfanilamide	Sulfasalazine Sulfadimidine Glibenclamide
Antimalarials	Primaquine Pamaquine	Chloroquine
Urinary agents	Nitrofurantoin Nalidixic acid Phenazopyridine	
Miscellaneous antibiotics	Dapsone	Ciprofloxacin Chloramphenicol
Mothballs	Naphthalene	
Miscellaneous drugs	Methylthionium chloride (methylene blue)	Vitamin K analogues Ascorbic acid

with a severe hypochromic anemia. Later in life, the clinical picture includes a hypochromic, microcytic anemia with jaundice and hepatosplenomegaly. These patients may not require regular transfusions, but under conditions of increased oxidative stress, which may cause precipitation of the unstable hemoglobin H resulting in hemolysis, a transfusion may be necessary. Most affected individuals will know their diagnosis, and the emergency physician needs only to provide supportive care and blood transfusion when necessary. Medications that may precipitate hemolysis should be avoided in this population (**Table 236-5**).

β-THALASSEMIA MINOR (β-THALASSEMIA TRAIT)

Patients with β-thalassemia minor are heterozygous for the β-globin mutation and have only mild microcytic anemia.[66,67] Splenomegaly may be present but is not common. On blood smear, these patients may have microcytosis and hypochromia as well as basophilic stippling. An elevated HbA_2 level, typically 4% to 6%, confirms the diagnosis. These patients generally will not have clinical manifestations and may only come to attention during an evaluation for a mild anemia.

β-THALASSEMIA INTERMEDIA

β-Thalassemia is the result of genetic combination of β-gene mutations producing microcytic moderate anemia (blood hemoglobin usually >7 g/dL), splenomegaly, and intense bone marrow hyperplasia. HbF levels are elevated.[70,71] Clinical symptoms tend to be milder and delayed compared to thalassemia major. Transfusion requirements are variable and complications from iron overload are less extreme.

β-THALASSEMIA MAJOR (COOLEY'S ANEMIA)

In β-thalassemia major, both β-globin genes are defective, and production of β-globin chains is severely impaired. Newborn infants with β-thalassemia major are usually well because HbF is predominant during the first few months of life. Symptoms emerge during the second 6 months of life when β-globin production would be expected. The RBCs of these children show a low mean corpuscular volume with microcytic and hypochromic cells. Variation in size and shape of the RBCs will be notable (increased RBC distribution width), as will be the presence of nucleated cells. HbF levels remain elevated, often >90% in untransfused individuals. This diagnosis should be considered in any child with a severe microcytic anemia and the appropriate ethnic background.

Affected children develop hepatosplenomegaly, jaundice, and expansion of the erythroid marrow causing bone changes and osteoporosis, and possess increased susceptibility to infection.[72] The anemia is severe and requires regular, lifelong blood transfusions, with resultant challenges of alloimmunization.[27] Transfusions and enhanced iron absorption eventually cause iron overload that is the etiology of most of the morbidity and mortality associated with the thalassemia. Untreated iron overload results in hemochromatosis with cardiac, hepatic, and endocrine dysfunction.[66,67,72,74] Treatment is chelation, with parenteral (desferrioxamine)[75] or oral (deferiprone and deferasirox)[76,77] agents.

For those with a known diagnosis who present to the ED with significant symptoms related to anemia or hemolysis, consider transfusion along with a search for precipitating events.

SICKLE CELL–β-THALASSEMIA DISEASE

Sickle cell–β-thalassemia disease, a heterozygous sickle cell variant, occurs when the gene for sickle hemoglobin is inherited from one parent and a gene for β-thalassemia is inherited from the other parent. The frequency of sickle cell–β-thalassemia disease is about 1 per 1600 African American births. The severity of the disease depends on the functionality of inherited β-thalassemia gene. Between 80% and 90% of affected individuals have a β-thalassemia gene that results in the production of some normal β-chains; thus, some normal HbA is made. Such patients have a mild hemolytic anemia with near-normal hemoglobin levels, few crises, and minimal organ damage. Those 10% to 20% of patients who inherit a β-thalassemia gene that inhibits all β-globin production have severe hemolytic anemia and vaso-occlusive symptoms comparable with patients with SCD.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common enzymopathy of RBCs in humans; worldwide it affects >400 million people.[78] Although the deficiency affects all ethnicities, it has been found mainly among persons of African, Asian, or Mediterranean ancestry, a distribution suggestive of an ability to protect against malaria.[79] The disease has many forms, with >400 variants.[78]

G6PD deficiency is an X-linked inherited disorder that primarily affects males. Females must have two defective genes to be severely affected, but because expression of this gene is variable, women with one abnormal gene may still show some symptoms. Most adults are usually asymptomatic, but some may have intermittent hemolytic anemia, and a few have chronic hemolysis.

G6PD is an enzyme that catalyzes the oxidation of glucose 6-phosphogluconate while concomitantly being responsible for the production of nicotinamide adenine dinucleotide phosphate, a required cofactor for maintaining glutathione in its reduced state. Glutathione in the reduced state acts as a scavenger for harmful oxidative cell metabolites and, with the help of the enzyme glutathione peroxidase, converts harmful peroxide to water. G6PD-deficient RBCs are therefore susceptible to oxidative stress; oxidization of the sulfhydryl groups causes hemoglobin to precipitate within the cell. The precipitated hemoglobin is recognized by the presence of **Heinz bodies** on the peripheral blood smear (**Figure 236-3**). The affected RBCs are removed from the circulation by the spleen. Oxidant damage also occurs at the RBC membrane, producing both extravascular and intravascular hemolysis.

CLINICAL FEATURES

The clinical expression of G6PD variants encompasses a spectrum of hemolytic syndromes. The likelihood of developing hemolysis and disease severity are determined by the degree of the enzyme deficiency (**Table 236-6**).

A serious complication of G6PD deficiency is neonatal jaundice occurring during the first week of life. The elevated bilirubin induces neurotoxicity that can result in permanent neurologic sequelae (kernicterus). Phototherapy can be used to lower the serum bilirubin concentration.

Class III variants are the most prevalent G6PD mutations, with acute hemolytic events that are usually self-limited and well tolerated, so the variant condition may remain undetectable.[78]

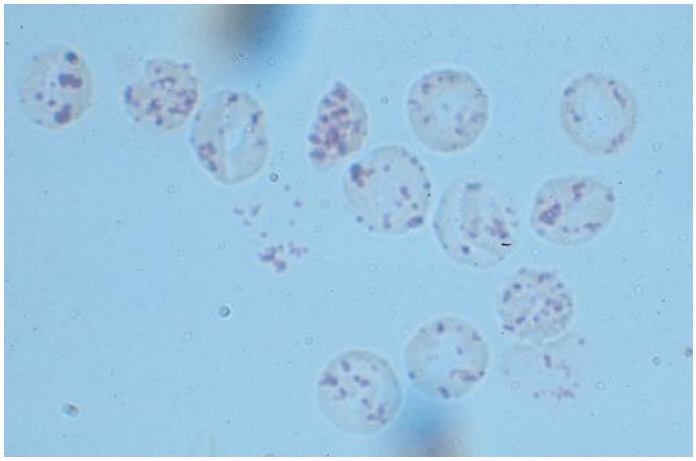

FIGURE 236-3. Heinz bodies. Blood mixed with hypotonic solution of crystal violet. Precipitates of denatured hemoglobin within the cells. [Reproduced with permission from Lichtman M, Beutler E, Kaushansky K, et al: *Williams Hematology*, 7th ed. Copyright © 2006, McGraw-Hill Inc., New York.]

Aside from favism and drug-induced hemolytic anemia, infection is the most common cause of hemolysis in G6PD-deficient individuals. There is also an increased incidence of pigmented gallstones and splenomegaly in patients with G6PD deficiency.

DIAGNOSIS

G6PD deficiency should be established by the demonstration of decreased enzyme activity through quantitative assay rather than the amount of enzyme protein present. In societies with a high prevalence of G6PD deficiency, neonatal screening programs for this disorder are appropriate.

Helpful ancillary tests to evaluate patients with acute symptoms include a CBC and reticulocyte count (to evaluate level of anemia and bone marrow function), serum bilirubin levels, serum aminotransferases (to exclude other causes of jaundice), and lactate dehydrogenase (elevated in hemolysis and a marker of hemolytic severity).

TREATMENT

Treatment of the patient with G6PD deficiency is determined by the patient's overall clinical condition. If the illness is severe, then blood transfusion with packed RBCs may be warranted.

In patients with known G6PD deficiency, infections should be treated aggressively and oxidant drugs avoided. **There is solid evidence to implicate seven currently used medications as causing acute hemolysis in patients with G6PD deficiency: dapsone, phenazopyridine, nitrofurantoin, primaquine, rasburicase, methylthioninium chloride (methylene blue), and tolonium chloride (toluidine blue).**[80] There is no evidence that other oxidant drugs (Table 236-5) in therapeutic doses are associated with increased hemolysis in G6PD-deficient patients.[80] Human immunodeficiency virus–positive patients should be screened for G6PD deficiency before dapsone is used for prophylaxis of *Pneumocystis jiroveci* pneumonia.

TABLE 236-6 World Health Organization Classification of Glucose-6-Phosphate Dehydrogenase (G6PD) Variants

Class I variants: severe enzyme deficiency (<1% of normal activity) and have chronic hemolytic anemia.
Class II variants, such as G6PD Mediterranean: severe enzyme deficiency (1%–10% normal activity), associated with acute intermittent hemolytic episodes.
Class III variants, such as G6PD A–: moderate enzyme deficiency (10%–60% of normal activity) with intermittent hemolysis usually associated with stressors such as infection or drugs.
Class IV variants: no enzyme deficiency (60%–150% normal activity), no hemolysis or other clinical significance.
Class V variants: increased enzyme activity (>150% normal activity), no clinical significance.

HEREDITARY SPHEROCYTOSIS

Hereditary spherocytosis is the result of an erythrocyte membrane defect and is the most prevalent hereditary hemolytic anemia among people of northern European descent.[81] The disease typically is inherited in an autosomal dominant pattern, although a less common autosomal recessive variant exists, and up to 20% of hereditary spherocytosis patients are the result of an apparent spontaneous mutation. The abnormal shape of the RBC results from molecular abnormalities in the cytoskeleton of the cell membrane, most commonly from mutations in the genes for the proteins spectrin and ankyrin.[82,83] These abnormalities result in RBCs with a microspherocytic shape that is not pliable enough to pass through the spleen. This results in an increased rate of destruction and a compensatory increase in RBC production.

CLINICAL FEATURES

The clinical spectrum of hereditary spherocytosis is divided into those with (1) mild disease, occurring in about 20% with an autosomal dominant inheritance; (2) moderate disease, occurring in about 75% with primarily autosomal dominant inheritance; and (3) severe, occurring in approximately 5% with an autosomal recessive inheritance.[84,85] The main complications include aplastic or megaloblastic crises, hemolytic crisis, cholecystitis or cholelithiasis, and neonatal hemolysis with jaundice.[84,85]

Neonatal jaundice during the first week of life occurs in 30% to 50% of those with hereditary spherocytosis. After the neonatal period, the symptoms and signs depend on the severity of ongoing hemolysis. Patients with mild disease usually have a normal hemoglobin level and little or no splenomegaly but are susceptible to hemolytic or aplastic episodes triggered by infection. Patients with moderate disease have mild to moderate anemia, modest splenomegaly, periodic episodes of hemolysis with jaundice, and an increased incidence of pigmented gallstones. The rare patient with severe hereditary spherocytosis has significant hemolytic anemia requiring episodic blood transfusions, chronic jaundice, and an enlarged spleen.

DIAGNOSIS

The peripheral blood smear shows spherocytes with a normal to low mean corpuscular volume and increased mean corpuscular hemoglobin concentration (>36%). The diagnosis of hereditary spherocytosis is usually established by a combination of clinical history and examination, family history, and RBC indices and morphology.[86] In unclear or atypical cases, initial screening tests (cryohemolysis test and eosin-5-maleimide–binding test) are performed, followed by confirmatory tests (gel electrophoresis analysis of RBC membranes).[87]

TREATMENT

In severe cases, splenectomy generally will reverse the anemia,[83,88] except in the unusual cases of autosomal recessive variants. After splenectomy, spherocytes are still present. Patients with severe anemia may need blood transfusions.[84]

CHAPTER 237

Acquired Hemolytic Anemia

Laurie Ann Dixon
Robin R. Hemphill

INTRODUCTION

Acquired hemolytic anemias are a group of disorders characterized by hemolysis of red blood cells (RBCs) not due to congenital or inherited disorders of hemoglobin synthesis or of the RBC membrane. Hemolysis of RBCs can take place within the intravascular space or in the extravascular spaces of the spleen and liver and can produce a spectrum of disease from mild, asymptomatic illness to severe hemodynamic compromise leading to critical ED encounters.

Presenting symptoms and signs of hemolytic anemia include those common to anemia in general: weakness, fatigue, dizziness, shortness of breath, dyspnea on exertion, tachycardia, palpitations, chest pain, new or accentuated cardiac murmur, and pallor. RBC destruction generates free hemoglobin that is then broken down into bilirubin. When bilirubin production exceeds the liver's ability to conjugate it for biliary and fecal excretion, jaundice and darkened urine may develop. Splenic enlargement may promote the storage and extravascular breakdown of RBCs.

The laboratory findings characteristic of acquired hemolytic anemia demonstrate hemolysis of RBCs, hemoglobin breakdown, and compensatory RBC production (**Table 237-1**). The peripheral blood smear displays abnormal RBC morphology consistent with hemolysis: schistocytes generated by intravascular shearing of RBCs and spherocytes produced by extravascular phagocytosis of RBCs within the liver and spleen.

Intravascular hemolysis of RBCs releases hemoglobin into the bloodstream that then binds to haptoglobin and other serum proteins. The hemoglobin–haptoglobin complex travels to the liver for processing, thus decreasing the amount of free haptoglobin in the serum—an important laboratory finding of intravascular hemolysis. Breakdown of RBCs releases lactate dehydrogenase and potassium, leading to elevation of both in serum. With excessive hemoglobin breakdown comes increased bilirubin production that cannot be conjugated by the liver for biliary and fecal excretion. Laboratory findings associated with excess bilirubin production include elevated total bilirubin; elevated indirect or unconjugated bilirubin; and increased urinary urobilinogen, a by-product of bilirubin breakdown formed by the intestine and passed into the urine. Excess free hemoglobin may escape binding by serum haptoglobin as well as reabsorption by the renal tubules, creating hemoglobinuria and darkened urine.

TABLE 237-1 Basic Tests and Findings in the Evaluation of Hemolytic Anemia

Purpose	Test	Finding
Confirm anemia/blood loss	Hemoglobin	Decreased
	Hematocrit	Decreased
Confirm compensatory RBC production	Reticulocyte count	Increased
Confirm hemolysis	Peripheral smear	Schistocytes—intravascular hemolysis, RBCs fragmented by shear mechanism
		Spherocytes—extravascular hemolysis, RBC phagocytosis by macrophages
Confirm hemolysis	Lactate dehydrogenase	Increased, released by RBCs
	Potassium	Increased, released by RBCs
Confirm hemolysis	Haptoglobin	Decreased, indicative of intravascular hemolysis
	Free hemoglobin	Increased, indicative of intravascular hemolysis
	Hemoglobinuria	Present
Confirm hemoglobin breakdown	Total bilirubin	Increased
	Indirect (unconjugated) bilirubin	Increased (hepatic conjugation of bilirubin overwhelmed)
	Urinary urobilinogen	Increased

Abbreviation: RBC = red blood cell.

IMMUNE-MEDIATED ACQUIRED HEMOLYTIC ANEMIA

Immune-mediated acquired hemolytic anemia encompasses three main categories: autoimmune, alloimmune, and drug induced.

AUTOIMMUNE HEMOLYTIC ANEMIA

Individuals with autoimmune hemolytic anemia make antibodies against their own RBCs.[1] Diagnosis requires evidence of an antibody on the patient's RBCs, usually accompanied by an autoantibody in the plasma. The direct antigen test, also known as the **direct Coombs test**, is performed by combining the patient's anticoagulated, washed RBCs with anti–immunoglobulin G and anti-C3d (complement) antibodies to detect the presence of immunoglobulin G and/or complement on the RBC surface. A positive direct antigen test consists of the detection of either immunoglobulin G or complement on the RBC surface; it does not require the detection of both.[2] A positive direct antigen test is not specific for a diagnosis of autoimmune hemolytic anemia (**Table 237-2**), nor does the presence of immunoglobulin G and/or complement on a patient's RBCs indicate the severity of disease; the direct antigen test is, however, a critical confirmatory screen. The **indirect Coombs test** looks for the presence of autoantibodies in the patient's serum, testing against a panel of RBCs bearing specific surface antigens. Hemolysis can take place within the vascular space or extravascularly within the liver or spleen.

Autoimmune hemolytic anemia can be divided into primary and secondary disease; primary, or idiopathic, disease occurs without a known underlying etiology, whereas secondary disease is associated with an underlying disorder.[1] Primary disease is more common in women, with peak incidence during the fourth and fifth decades. Many cases initially designated as primary are later found to be associated with lymphoproliferative, autoimmune, or infectious diseases. In children, the disorder is commonly associated with viral or respiratory infections and can cause acute, fulminant hemolysis. Pregnancy can increase the risk of autoantibody development fivefold, but significant RBC destruction is not common. Autoimmune hemolytic anemia is further divided into autoantibody type: warm type, cold type, and mixed type (**Table 237-3**).[1]

Warm Antibody Autoimmune Hemolytic Anemia Warm autoantibody–mediated hemolysis is predominantly extravascular, with antibody-coated RBCs consumed mostly by splenic macrophages

TABLE 237-2 Differential Diagnosis of Positive Direct Antigen (Direct Coombs) Test

Autoimmune hemolytic anemia
Hemolytic transfusion reaction, acute or delayed
Hemolytic disease of newborn
Transplantation
Drug-related hemolytic anemia
IV immunoglobulin therapy
Rh(D) immunoglobulin therapy
Antilymphocyte globulin therapy
Antithymocyte globulin therapy
Sickle cell disease
β-Thalassemia
Renal disease
Multiple myeloma
Hodgkin's disease
Systemic lupus erythematosus
Human immunodeficiency virus/acquired immunodeficiency syndrome

TABLE 237-3 Categories of Autoimmune Hemolytic Anemia (AIHA)

Warm antibody AIHA: Autoantibodies adhere most strongly to RBCs at 37°C (98.6°F).	70%–80% of AIHA cases
	2:1 female predominance
	50% primary (idiopathic) disease
	50% secondary disease: lymphoproliferative, autoimmune disease, postinfection (transient)
	Usually immunoglobulin G (IgG) autoantibody against Rh(D) antigen
	Hemolysis usually extravascular
	Steroid responsive: 70%–80%
Cold antibody AIHA: Autoantibodies adhere most strongly to RBCs at 0–4°C (32–39.2°F).	**Cold agglutinin disease: IgM autoantibody against I antigen**
	Primary disease: older females
	Secondary disease: lymphoproliferative disorders, postinfection (transient)
	Raynaud's phenomenon, livedo reticularis, vascular occlusion
	Attacks precipitated by cold exposure
	Rarely intravascular hemolysis
	Not steroid responsive
	Paroxysmal cold hemoglobinuria: IgG autoantibody against P antigen
	Primary disease: rare, in adults
	Secondary disease: usually in children after upper respiratory infection
	Intravascular hemolysis during cold weather
	Usually not steroid responsive
Mixed-type antibody AIHA: Autoantibodies have variable temperature-dependent RBC adherence.	Primary disease: more common in older females
	Secondary disease: lymphoproliferative and autoimmune disorders
	Usually chronic course with severe exacerbations
	Usually steroid responsive

Abbreviation: RBC = red blood cell.

and, to a lesser degree, by hepatic macrophages known as *Kupffer cells*. Partial phagocytosis of the original RBC membrane structure leads to the formation of the more rigid, fragmentation-prone spherocyte. Increased spherocytosis found on peripheral blood smear correlates positively with severity of extravascular hemolysis.

Autoimmune hemolytic anemia is initially treated with high-dose corticosteroids, typically oral at 1 to 2 milligrams/kg per day for 3 to 4 weeks, with improvement expected in 80% to 85% of patients but complete remission in only up to 30% of patients.[3]

Monoclonal antibodies (e.g., rituximab), immunosuppressive agents (e.g., azathioprine, mycophenolate mofetil, cyclosporine, cyclophosphamide), or semisynthetic androgens (e.g., danazol) can be used to decrease autoantibody production.[3,4] Splenectomy removes both the main site of extravascular hemolysis in IgG-mediated disease and a major site of general autoantibody production. Splenectomy shows clinical benefit in up to 60% of patients, with potential for long-term remission or a complete cure. A serious complication of splenectomy is overwhelming postsplenectomy infection due to sepsis with encapsulated bacteria.[5] Such **patients should receive regular pneumococcal and meningococcal vaccinations** and may benefit from daily penicillin prophylaxis.

Severe hemolysis in cases of warm antibody autoimmune hemolytic anemia may be treated with plasma exchange as a transient stabilizing measure while waiting for steroids or immunosuppressive agents to take effect. IV immunoglobulin has been used as an adjunctive treatment in children who cannot tolerate the side effects of chronic high-dose steroids or immunosuppressive agents.[6]

For a patient with life-threatening anemia, the goal is to transfuse allogeneic RBCs without producing potentially harmful transfusion reactions. Laboratory personnel must determine whether the patient's blood contains alloantibodies against RBC antigens, but first, autoantibodies—usually directed against more commonly occurring or higher prevalence RBC antigens, and thus typically panreactive against RBC panels—must be identified and sifted out because the presence of autoantibodies can hide the existence of alloantibodies.[7] The testing process can be both labor and time intensive, sometimes requiring 6 hours or longer. Once completed, however, antigen-free, compatible RBC units can then be selected in hopes of providing safe and effective transfusion for the patient. If emergently needed, transfusion of the *least incompatible* units may be administered slowly and in the smallest amounts necessary with close monitoring.[8]

Cold Antibody Autoimmune Hemolytic Anemia Cold autoantibodies lead to clumping or agglutination of RBCs on peripheral smear at cooler temperatures. Cold antibody autoimmune hemolytic anemia is associated with complement fixation on the RBC surface and triggering of the complement cascade. Hemolysis occurs in both the extravascular and intravascular spaces. Instead of splenic macrophages, the hepatic macrophages known as *Kupffer cells* are responsible for most of the extravascular RBC destruction. The two major cold antibody disorders are **cold agglutinin disease** and **paroxysmal cold hemoglobinuria**. Fifty percent of secondary cold antibody cases are associated with lymphoproliferative disorders, with underlying infection as the next leading cause.

Cold agglutinin disease is exacerbated by the cold, so more episodes of acute hemolysis are seen during winter.[9] Because the peripheral circulation is typically cooler than the central circulation, secondary Raynaud's phenomenon and vascular occlusion can complicate cold agglutinin disease, leading to acrocyanosis and tissue necrosis/gangrene. Painful discoloration and mottling of the skin consistent with livedo reticularis may be seen.[10] Less commonly, cold urticaria and hemorrhagic vesicles may develop.[11]

Primary cold agglutinin disease causes chronic, recurrent hemolysis in older adults, particularly females, with a peak incidence at age 70 years old. As with all of the idiopathic autoimmune hemolytic anemias, an associated underlying disease process may be discovered well after initial presentation of cold agglutinin disease; in particular, an occult lymphoproliferative disorder may be the source of the aberrant cold autoantibodies.

Secondary cold agglutinin disease may present after infection with *Mycoplasma pneumoniae*, Epstein-Barr virus, or infectious mononucleosis, adenovirus, cytomegalovirus, influenza, varicella-zoster virus, human immunodeficiency virus, *Escherichia coli*, *Listeria monocytogenes*, or *Treponema pallidum*. Hemolysis typically begins 2 to 3 weeks after the onset of illness, corresponding with peak antibody development against the infectious agent, and resolves about 2 to 3 weeks after resolution of the infectious illness. Many patients with *Mycoplasma* pneumonia and infectious mononucleosis will have measurable cold agglutinin titers, but far fewer will develop symptoms and signs of hemolytic anemia. Conversely, cold agglutinin disease associated with lymphoproliferative diseases such as chronic lymphocytic leukemia and lymphoma produces high autoantibody levels with the potential for significant hemolysis.

Agglutination of RBCs can confound an automated CBC device; the mean corpuscular volume may be falsely elevated, whereas the hemoglobin registers spuriously low. Holding the blood tube in warm hands may decrease RBC clumping for more reliable CBC results. A CBC with confusing or bizarre results should undergo peripheral smear examination. Peripheral smear findings of cold agglutinin disease include spherocytosis, anisocytosis, poikilocytosis, polychromasia, and agglutination.[12] The direct antigen test demonstrates adherence of complement to patient RBCs, but cold autoantibodies are typically washed off the RBCs during the elution process and thus are not identified. Other laboratory findings correspond with those routinely seen in cases of hemolytic anemia, including findings consistent with intravascular hemolysis in some cold agglutinin disease cases (Table 237-1).

An important principle in treating cold agglutinin disease is keeping the extremities and appendages, particularly the nose and ears, warm in cold weather. Patients should take a daily folate supplement for healthy RBC production. Cold agglutinin disease is less likely to respond to steroids, with response rates as low as 35%.[9] Splenectomy is less effective in treating cold agglutinin disease because splenic macrophages play a lesser role in IgM-mediated cold antibody disease. Severe

hemolysis has been treated successfully with immunosuppressive agents such as chlorambucil, cyclophosphamide, interferon-α, fludarabine, or rituximab.[9] Because immunoglobulin M autoantibodies have an intravascular distribution, plasmapheresis may assist by removing autoantibodies from the circulation when combined with immunosuppressive agents.

Infection-related cold antibody disease does not require immunosuppressive therapy because the hemolytic anemia is usually self-limited. RBC transfusion can be performed for patients at risk for significant cardiac or cerebrovascular ischemia, but transfused blood should be infused at 37°C (98.6°F) using a blood warmer. Transfusions should be limited as they may worsen ongoing hemolysis because most cold antibodies act against the I/i group antigens that are found on most donor RBCs. Donor complement in the transfused product also may exacerbate ongoing hemolysis.

Paroxysmal cold hemoglobinuria is caused by a biphasic hemolysin immunoglobulin G autoantibody called the *Donath-Landsteiner (D-L) antibody* that is directed against the P antigen system found on most RBCs.[13] This potent autoantibody binds to RBCs and fixes early complement cascade proteins at low temperatures, whereas terminal complement components adhere and produce intravascular lysis of RBCs at warmer, physiologic temperatures.

Bursts of cold weather–induced intravascular hemolysis lead to bouts of dark urine or hemoglobinuria for which the disease is named. Other presenting symptoms include attacks of high fever, chills, headache, abdominal cramps, nausea and vomiting, diarrhea, and leg and back pain, all exacerbated by cold weather. Cold urticaria may develop as well as extremity paresthesias and Raynaud's phenomenon.

Primary paroxysmal cold hemoglobinuria is a rare, idiopathic, chronic condition occurring in adults, characterized by cold-induced episodes of massive hemolysis. Secondary disease occurs predominantly in children, usually seen after a preceding upper respiratory infection. Most pediatric cases are self-limited and nonrecurring, but severe cases may take weeks to resolve. With severe hemolysis, hemoglobinuria is common, and methemoglobinemia may be seen. Acute renal failure may develop as a complication. Pediatric paroxysmal cold hemoglobinuria may occur after infections with measles, mumps, Epstein-Barr virus, cytomegalovirus, varicella, adenovirus, influenza A, *M. pneumoniae*, *Haemophilus influenzae*, and *E. coli*. Adult patients with chronic, relapsing disease should be tested for syphilis, because cold-provoked hemolysis has been associated with tertiary or late syphilis as well as with congenital syphilis.

During an attack of paroxysmal cold hemoglobinuria, acutely low hemoglobin may be seen on CBC due to sudden, severe hemolysis. The peripheral smear may demonstrate erythrophagocytosis, the engulfment of RBCs by neutrophils.[12] Presence of the biphasic D-L immunoglobulin G antibody on laboratory testing is pathognomonic. Patient serum is added to two tubes containing human type O RBCs. The first tube, the control, is incubated at 37°C (98.6°F) or physiologic temperature, whereas the second tube is incubated first at 0°C (32°F) and then at 37°C (98.6°F). The D-L test is positive if hemolysis is present in the second tube, indicating presence of the biphasic D-L antibody, while absent in the control tube.[14] The direct antigen test is usually positive for complement just before or after a paroxysm but often negative in between paroxysms in patients with chronic, relapsing disease.

Patients with paroxysmal cold hemoglobinuria should be kept warm. Steroids can be considered in children with severe hemolytic anemia, but because infection-related disease tends to be self-limited, benefit is uncertain. Disease secondary to syphilis responds to effective antibiotic treatment. Splenectomy is not helpful, and plasmapheresis should be used only as a temporizing measure in life-threatening cases. RBC transfusion using a blood warmer should be limited to cases of severe hemolysis because most donor units are P antigen positive and may stimulate further production of antibodies. Rituximab can successfully treat primary paroxysmal cold hemoglobinuria in adults.[15]

Mixed-Type Autoimmune Hemolytic Anemia Mixed-type autoimmune hemolytic anemia, with both warm and cold autoantibodies to RBCs, presents as primary or secondary disease, most commonly associated with lymphoproliferative and autoimmune diseases, particularly systemic lupus.[1] The course of illness is usually chronic with severe exacerbations. Like the warm antibody disorder, the mixed type is usually steroid responsive, can be treated with splenectomy, and responds to immunosuppressive therapy.

ALLOIMMUNE HEMOLYTIC ANEMIA

Alloimmune hemolytic anemia requires exposure to allogeneic RBCs with subsequent alloantibody formation. In the laboratory, alloantibodies react specifically with the allogeneic RBCs that triggered their production; these antibodies do not react against a patient's own RBCs. A well-known example of this is when the Rh(D)-negative maternal immune system develops immunoglobulin G alloantibodies on exposure to Rh(D)-positive fetal RBCs. The maternal alloantibodies can then cross the placenta, leading to fetal RBC destruction in a condition known as *hemolytic disease of the newborn*.[16] Anemia can range from mild to potentially fatal, producing intrauterine fetal death. The term *hydrops fetalis* has been used to describe the anasarca seen in severe cases. Transplacental or fetomaternal hemorrhage, the inciting stimulus for maternal alloantibody formation, may occur during amniocentesis, chorionic villus sampling, delivery, or abortion (threatened or otherwise) or even during external cephalic version. Administration of anti-D immunoglobulin G with any fetomaternal hemorrhage event and soon after delivery will suppress maternal alloantibody formation and prevent hemolytic disease of the newborn. Treatment of established hemolytic disease of the newborn employs intrauterine and intravascular fetal transfusion and may include plasma exchange and/or IV immunoglobulin therapy.

Most adults who develop alloimmune hemolytic anemia have a history of RBC transfusion, which sensitizes patients to allogeneic RBC antigens. A subsequent transfusion can result in immediate alloantibody production, resulting in the fever, chest and flank pain, tachypnea, tachycardia, hypotension, hemoglobinuria, and oliguria seen in the hemolytic transfusion reaction (see chapter 238, "Transfusion Therapy"). In patients with high alloantibody titers, the hemolytic reaction can be immediate. Delayed alloantibody-mediated hemolysis is possible, with hemolytic transfusion reaction symptoms presenting 3 to 7 days after transfusion (see chapter 238).

DRUG-INDUCED HEMOLYTIC ANEMIA

Drug-induced hemolytic anemia is rare, estimated at 1 in 1,000,000 patients, where drug exposure induces antibody formation leading to the destruction of RBCs.[17] More than 100 drugs are known to induce autoantibody production against patient RBCs (**Table 237-4**).[18]

TABLE 237-4 Most Often Cited Drugs Inducing Hemolytic Anemia

Cephalosporins	Cefotetan
	Ceftriaxone
	Cephalothin
Chemotherapeutic agents	Fludarabine
	Interferon
	Oxaliplatin
Nonsteroidal anti-inflammatory drugs	Diclofenac
	Mefenamic acid
	Phenacetin
	Tolmetin
Penicillins	Penicillin G
	Piperacillin
Miscellaneous	Catechin (antidiarrheal)
	Levodopa (antiparkinsonian)
	Methyldopa (antihypertensive)
	Nomifensine (antidepressant)
	Quinidine (antiarrhythmic)
	Rifampin (antibiotic)

Drug-induced hemolytic anemia can result in either a positive or negative direct antigen test and can be difficult to distinguish from autoimmune hemolytic anemia, so a careful review of current medications is important in patients with a new hemolytic anemia.

Patients with severe hemolysis and anemia require hospitalization and further evaluation. In all cases, stop the offending drug immediately. In the event that medications are required for treatment of patients in the ED who have evidence of ongoing hemolysis, refrain if possible from using listed agents (Table 237-4). Steroids can be used in cases of drug-related severe hemolysis.

MICROANGIOPATHIC SYNDROMES

The two classic syndromes associated with microangiopathic hemolytic anemia are thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome (HUS).[19,20] Both syndromes involve platelet aggregation in the microvascular circulation via mediation of von Willebrand factor. Microangiopathic hemolytic anemia or schistocyte-forming hemolysis occurs from fragmentation of RBCs during travel through these partially occluded arterioles and capillaries. Although TTP and HUS are clinical syndromes with characteristic features, overlap does occur, sometimes making differentiation difficult. TTP is more common in adults, whereas HUS is more common in children. TTP typically induces more prominent neurologic effects, with deposition of platelet aggregates in a broader distribution, whereas HUS more specifically affects the renal system.

THROMBOTIC THROMBOCYTOPENIC PURPURA

The classic pentad for TTP includes CNS abnormalities, renal pathology, fever, microangiopathic hemolytic anemia, and thrombocytopenia. Untreated TTP carries a high mortality rate, but plasma exchange therapy can achieve remission of disease in >80% of patients.[20-22] Groups at higher risk for TTP include women, patients age 30 to 50 years old, individuals of African descent, and Hispanics.

Pathophysiology The pathophysiology of TTP is connected to a specific metalloprotease ADAMTS-13 (*a d*isintegrin *a*nd *m*etalloproteinase with a *t*hrombo*s*pondin type 1 motif, member 13, also known as *von Willebrand factor–cleaving protease*). ADAMTS-13 is made by hepatic stellate cells, glomerular podocytes, and vascular endothelial cells. Its function is to cleave von Willebrand factor that has been unfolded by shear stress within the microvasculature of arterioles and capillaries. Without this cleavage function, unfolded von Willebrand factor monomers can form large multimers that lead to formation of intravascular microthrombi. TTP has been associated with ADAMTS-13 activity at levels <10% of normal.[23] Severely deficient ADAMTS-13 activity alone does not reliably trigger TTP; often other precipitating or contributing factors are important, including pregnancy, infection, inflammation, and medication use.

ADAMTS-13 activity levels typically decrease by up to 30% during pregnancy, although not usually to the severely low levels associated with TTP.[23] It is hypothesized that the hypercoagulable state of pregnancy combined with the decreased ADAMTS-13 activity level may set the stage for TTP in pregnancy. TTP is rare during pregnancy, seen in <1 per 100,000. Published literature offers conflicting opinions as to when TTP most commonly occurs during pregnancy—either during the second trimester or early in the third trimester,[24-26] or at term or postpartum.[27] TTP shares many clinical and laboratory features with pre-eclampsia–eclampsia, HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelet count), and acute fatty liver of pregnancy.[20] Still, symptoms of severe pre-eclampsia or HELLP before 24 weeks of gestation should raise suspicion for TTP.

Human immunodeficiency virus infection, particularly with progression to acquired immunodeficiency syndrome, is associated with the microangiopathic anemia and thrombocytopenia that characterize TTP. On testing, some human immunodeficiency virus patients with TTP-like illness have severely deficient ADAMTS-13 activity levels and thus may benefit from plasma exchange therapy. However, others with microangiopathic hemolytic anemia and thrombocytopenia in the setting of human immunodeficiency virus/acquired immunodeficiency syndrome have normal ADAMTS-13 activity levels, questioning whether the TTP label and plasma exchange therapy should be applied.[28,29]

Influenza vaccination has been implicated as a TTP trigger, leading to production of autoantibody against ADAMTS-13.[30] Acute pancreatitis, capable of inducing a systemic inflammatory response, has also been associated with TTP, although moderately rather than severely low ADAMTS-13 activity levels lead to uncertainty about a TTP diagnosis versus some other thrombotic microangiopathic process.[31,32]

Drugs associated with TTP include ciprofloxacin, ofloxacin, levofloxacin, quinine, sirolimus when used with calcineurin inhibitors such as cyclosporine, risperidone, clopidogrel, lansoprazole, valacyclovir, mitomycin, infliximab, and ticlopidine.[20] Ticlopidine in particular is thought to induce autoantibody formation against ADAMTS-13 as well as microvascular endothelial cell injury in genetically susceptible individuals within 2 to 12 weeks of starting the medication. Clopidogrel use can also incite microvascular endothelial cell injury within 2 weeks of use. Ticlopidine has been associated with more severe thrombocytopenia and microangiopathic hemolysis than clopidogrel, whereas clopidogrel has produced more significant renal insufficiency not readily responsive to plasma exchange therapy.[33] Days to weeks may be required to achieve remission in ticlopidine/clopidogrel-associated TTP cases.

Clinical Features Shearing of RBCs across these microthrombi produces the microangiopathic hemolytic anemia. Platelet aggregation in TTP leads to systemic platelet depletion or thrombocytopenia. When these microthrombi are concentrated in the CNS and renal arterioles and capillaries (though notably not found in venules), they promote tissue ischemia and necrosis, with resultant end-organ damage such as seizure, stroke, other focal neurologic deficits, coma, and acute renal injury.

Along with findings of severe anemia and thrombocytopenia of <20,000/mm^3 (<20 × 10^9/L), serum and urine tests may corroborate ongoing intravascular hemolysis (Table 237-1) with renal injury or failure. Because TTP thrombi do not incorporate fibrin, TTP can be distinguished from disseminated intravascular coagulation by normal coagulation studies.

Treatment Plasma exchange therapy is very effective in TTP with the goal to achieve a normal platelet count.[20,21] Daily plasmapheresis (plasma exchange) of 40 mL/kg or up to 1.0 to 1.5 times a patient's plasma volume is performed and then either weaned in frequency or stopped once normal counts are reached for 2 to 3 consecutive days. Infusion of plasma replaces defective or insufficient ADAMTS-13, and removal of plasma rids the body of defective ADAMTS-13, autoantibodies against the metalloprotease, and large von Willebrand factor multimers.

If plasmapheresis cannot be performed immediately, fresh frozen plasma infusion can be initiated, with pheresis occurring later.[20] Infusion with factor VIII concentrate containing ADAMTS-13 activity can be considered for patients with plasma allergy after specialist consultation and review.

Severe TTP may require additional interventions such as RBC transfusion, anticonvulsants, antihypertensives, and hemodialysis. **Avoid platelet transfusions**, except in life-threatening bleeding or intracranial hemorrhage, because acutely worsened thrombosis can lead to renal failure and, potentially, death. **Aspirin** can exacerbate hemorrhagic complications in the setting of severe thrombocytopenia but can still be used for cerebrovascular and cardiovascular indications in patients with adequate platelet counts. Heparin is not beneficial in TTP. Corticosteroids, rituximab, and cyclosporine may play a role in the treatment of autoimmune TTP.[20,21] Discontinue the inciting drug in all cases of drug-associated TTP.

Outcome TTP relapse, defined as a new case onset >30 days after completion of remission-achieving plasma exchange therapy, is seen in 20% to 50% of cases, most often within 2 years after the initial episode. Patients with ADAMTS-13 activity levels <10% are at increased risk for relapse.[23] Triggers for relapse may be the same as those inciting original cases. Relapses may present with milder symptoms and less severe hematologic findings. Patients with multiple relapses may experience them farther and farther apart, and total volume and duration

requirements for plasma exchange therapy are lessened in subsequent cases.[34]

The maternal mortality rate from TTP has been reduced significantly with the use of plasma exchange therapy, but fetal mortality has remained high secondary to placental microvascular occlusion, ischemia, and infarction. TTP may relapse with subsequent pregnancy, so affected women should be counseled accordingly. Because of this association, females of child-bearing age presenting with microangiopathic hemolytic anemia and thrombocytopenia should be assessed for an unsuspected pregnancy.

HEMOLYTIC-UREMIC SYNDROME

HUS, a common cause of acute renal failure in childhood, consists of microangiopathic hemolytic anemia, acute nephropathy or renal failure, and thrombocytopenia.[19,20,35] HUS can be classified as typical or atypical, with prognosis favoring typical cases.[34] Typical HUS occurs in children about 1 week into a case of infectious diarrhea, often bloody and without associated fever. The causative agent of typical HUS is Shiga toxin–producing *E. coli*, with serotype O157:H7 predominating in North America.[35,36] Shiga toxin is sometimes alternatively labeled *verocytotoxin* in the literature. Other less common causes of diarrhea-associated HUS include *Shigella*, *Yersinia*, *Campylobacter*, and *Salmonella*. Atypical HUS occurs in older children and adults; may be difficult to distinguish from TTP because of extrarenal involvement; is caused by other infectious organisms, such as *Streptococcus pneumoniae* and Epstein-Barr virus; or may have a noninfectious source, such as bone marrow transplantation or the administration of immunosuppressant or chemotherapeutic agents.[35]

Store-bought refrigerated ground beef and frozen ground beef patties, frozen pepperoni pizza, bagged fresh spinach, prepackaged raw cookie dough, as well as lettuce, cheddar, and ground beef found in fast food have been implicated in multistate *E. coli* O157:H7 infection outbreaks with HUS occurring as a complication of each of the outbreaks.[36] HUS has also occurred after drinking water from a municipal source contaminated by *E. coli* O157:H7.

Pathophysiology Ingested via contaminated food or water, Shiga toxin–producing *E. coli* O157:H7 possesses potent virulence factors that allow invasion of intestinal epithelial cells and subsequent transmural intestinal migration.[35] The ensuing colonic inflammation produces the characteristic hemorrhagic colitis associated with *E. coli* O157:H7 and other Shiga toxin–producing bacteria. Shiga toxin, once absorbed into the systemic circulation, binds with greatest affinity to receptors found on the surfaces of glomerular and renal tubular epithelial and endothelial cells and, to a lesser extent, to receptors lining cerebral and colonic epithelial and endothelial cells and pancreas. Molecular mimicry may exist between human CD36, an antigen found on endothelial cells and platelets, and Shiga toxin, so that antibody formed against the toxin may bind to CD36 and incite the pathologic processes leading to HUS.[37]

Toxin-mediated microvascular injury promotes platelet aggregation (and therefore, systemic depletion, leading to thrombocytopenia) and thrombus formation at the injury site. Further upregulation of epithelial and endothelial cell receptors with high affinity for Shiga toxin creates a vicious cycle of thrombosis, and microangiopathic hemolytic anemia via shearing of RBCs over microthrombi contributes to tissue ischemia and necrosis. Microthrombi within the pancreas have been postulated to cause pancreatic β-cell death and subsequent deficits in insulin secretion. Thus, patients with HUS may present with hyperglycemia consistent with new-onset diabetes mellitus. Some may even go on to have chronic insulin requirements with increased morbidity and mortality rates.[38]

Clinical Features Onset of HUS is typically 2 to 14 days after diarrhea develops, so patients may present during the diarrheal illness phase, with abdominal cramps, with or without bloody diarrhea, and, often, without fever. For the patient with nonbloody diarrhea, testing stool for fecal leukocytes can reveal occult inflammatory colitis, thereby prompting stool culture, specifically for *E. coli* O157:H7.[35] For the patient with bloody diarrhea, the results of stool testing for Shiga toxin–producing bacteria, including *E. coli* O157:H7, can guide medical treatment, alert providers that the complication of HUS should be anticipated, and aid in the cause of public health disease monitoring and outbreak prevention. In addition to the studies required for diagnosing hemolytic anemia, electrolyte and renal function panels should be obtained to detect nephropathy and associated electrolyte disturbances, while urinalysis should be examined for RBCs, RBC casts, protein, and other evidence of acute nephropathy.[35]

Treatment Typical HUS is treated with supportive care, with focus on hydration, pain control, and RBC or platelet transfusion in cases of significant anemia or profound thrombocytopenia associated with active bleeding.[39] Should acute renal failure develop, hemodialysis may be required. Infection with *E. coli* O157:H7 should not be treated with antimotility drugs because these agents appear to increase the risk of developing HUS.[40] Antibiotics for the treatment of *E. coli* O157:H7 diarrhea is controversial because in vitro studies have found that antibiotics may increase Shiga toxin expression from the bacteria, and case-control human studies have found that antibiotic treatment of the diarrheal illness may increase the risk of developing HUS.[40,41] Atypical HUS is treated with eculizumab.[42]

Outcome Acute renal failure occurs in 55% to 70% of patients with typical HUS, but most, up to 85%, recover kidney function.[35] Mortality in typical HUS is about 5% to 15%. Historically, patients with atypical HUS had a poor outcome, with permanent renal failure or neurologic damage occurring in about half of patients and a morality rate approaching 25%. Aggressive treatment, including eculizumab, appears to significantly reduce the incidence of permanent renal failure and lower the death rate in atypical HUS.[42]

MACROVASCULAR HEMOLYSIS

A **prosthetic heart valve** may create turbulent blood flow with high shear stress across the valve. Older generation mechanical heart valves were subject to deterioration that produced subsequent hemolysis, but hemolysis associated with current prosthetic heart valve models is most often attributed to paravalvular leak. Such leaks may occur at the time of valve placement or develop later in the life of the prosthetic valve if infection or calcification promotes dehiscence.[43] Particularly after mitral valve replacement, hemolysis may occur at both clinically insignificant and significant levels.

Macrovascular hemolysis can also occur after **intracardiac patch repair** or **aortofemoral bypass**; in patients with **coarctation of the aorta, severe aortic valve disease, or ventricular assist devices**; and in patients requiring the use of extracorporeal circulation such as during cardiopulmonary bypass, plasma exchange, or hemodialysis.[44-46] Although the mechanics and shear stress applied to blood through extracorporeal circulatory interventions may drive hemolysis, the composition or contamination of diluents and dialysates may also contribute.[45]

RBCs hemolyzed in the macrocirculation bear the characteristic fragmented appearance of schistocytes seen on peripheral smear. Increased schistocytosis correlates with more severe hemolysis.[43] Other laboratory findings are consistent with intravascular hemolysis (Table 237-1).

Patients with ongoing mild macrovascular hemolysis should receive supplemental iron and folate to promote healthy reticulocytosis. By reducing the heart rate, β-blocker therapy may decrease RBC shear stress in the presence of a prosthetic valve and thereby mitigate hemolysis. Pentoxifylline, a xanthine derivative that reduces blood viscosity and improves RBC flexibility and deformability, can reduce hemolysis associated with prosthetic heart valves.[43] Hemolysis associated with extracorporeal circulation typically begins during the procedure, but such patients may or may not exhibit symptoms until hours afterward. In particular, dialysis patients treated in the outpatient setting may present to the ED for evaluation and treatment of symptoms caused by hemolysis. Severe macrovascular hemolysis may necessitate blood transfusion, whether during an isolated episode or repeat episodes.

ADDITIONAL CAUSES OF HEMOLYSIS

Infection, envenomation, chemical exposure, and trauma can also result in hemolysis (**Table 237-5**).

TABLE 237-5 Additional Causes of Hemolysis

Cause	Disorder	Comments
Infection		
	Malaria	Blackwater fever or hemoglobinuria
	Babesiosis	Protozoan infects and damages with RBC
	Clostridium perfringens	Toxin lyses RBCs
	Leptospirosis	Weil's syndrome; toxin lyses RBCs
Envenomation		
	Hymenoptera stings	Requires massive venom injection
	Brown recluse spider	Part of systemic loxoscelism
	Pit viper; Crotalinae; Elapidae; Viperinae	Intravascular RBC destruction
Chemical exposure		
	Arsine	Hemolysis can present 24 h after exposure
	Naphthalene	Mothballs; well water contaminated by toxic dumps; can affect fetus in utero and neonates; patients with G6PD deficiency at higher risk[47,48]
Direct impact trauma		
	March hemoglobinuria	Runners, soldiers, karate, conga drummers[49,50]; hemoglobinuria but usually not anemia

Abbreviations: G6PD = glucose-6-phosphate dehydrogenase; RBC = red blood cell.

CHAPTER 238

Transfusion Therapy

Clinton J. Coil
Sally A. Santen

INTRODUCTION

Modern transfusion practice uses blood that has been separated into specific components (**Table 238-1**). Coagulation factors, either derived from human plasma or manufactured with recombinant technology, are used treat hemorrhage associated with a deficiency of one or more factors (**Table 238-2**). Transfusion in the ED typically is done for acute blood loss and/or circulatory shock. As medical care is moved to outpatient settings, emergency physicians may be responsible for transfusion therapy or complications previously relegated to inpatient settings.[1]

Blood products are provided using standardized preparations as "units" (Table 238-1). Provide information to patients about the risks, benefits, and alternatives to transfusion prior to the initial infusion of red blood cells, plasma, or platelets.[2,3] Obtain informed consent or document that the patient was unable to consent if a medical emergency exists.[2] Use great care to assure that the correct blood product is delivered to the correct patient because of the consequences of transfusing the wrong unit; use two individuals to verify the identification of the patient and the unit before transfusion. Bar-code identification along with verification by one individual is an alternative to two-person verification.[4]

TRANSFUSION OF BLOOD PRODUCTS

PACKED RED BLOOD CELLS

Adult total blood volume is approximately 2.5 L/m^2, 75 mL/kg, or about 5 L in a 70-kg person. Whole blood transfusion would seem ideal to replace acute blood loss; however, storage of whole blood inactivates platelets and other factors. Therefore, whole blood is fractionated to its components for storage and transfusion. Packed red blood cells (PRBCs) are prepared by the centrifugation of whole blood to remove approximately 80% of the plasma; then a preservative solution is added (most commonly, citrate-phosphate-dextrose) with the additional nutrients adenosine, and mannitol (Table 238-1).

The primary reason for PRBC transfusion is to increase oxygen-carrying capacity.[1,4] Emergency PRBC transfusion is usually performed for acute blood loss or, occasionally, profound anemia with impaired oxygen delivery. Transfusion thresholds assist the physician in assessing whether PRBC transfusion will benefit the patient. Current evidence is substantial that a restrictive threshold for PRBC transfusion is appropriate for most patients.[5-9] In previously healthy adults, transfusion should be considered at hemoglobin concentrations less than 7 grams/dL (70 grams/L), and for patients with sepsis or ischemic heart or brain injury, transfusion should be considered at a hemoglobin concentration less than 8 to 9 grams/dL (80 to 90 grams/L).[10-13] Transfusion threshold values for children may be higher and depend on the etiology of their anemia.[14] Some patients with severe sepsis receiving early, goal-directed therapy may benefit from transfusion up to a hemoglobin of 10 grams/dL (100 grams/L) when the central venous oxygen saturation is less than 70%.[15]

For actively bleeding patients, transfusion is based on clinically estimated blood loss rather than hemoglobin levels, because the fall in measured hemoglobin will lag behind the clinical impact of acute blood loss. A loss of about 30% blood volume (1500 mL in an adult) generally produces symptoms and signs, but young, healthy patients can tolerate this degree of loss when treated with crystalloid. However, patients with chronic illness such as underlying anemia, cardiac diseases, or pacemakers or those on β-blockers or similar medications may not tolerate blood loss. Consider emergency PRBC transfusion for unstable trauma patients based on an inadequate response to an initial 2-L bolus of IV crystalloid or 40 mL/kg in children. The anticipated clinical course also guides the decision to transfuse the patient with acute hemorrhage; the transfusion threshold is lower if the source of bleeding cannot be controlled immediately compared to a patient whose acute hemorrhage has stopped.

Use the minimum amount of PRBCs to accomplish the desired clinical outcome.[7,12] **A single PRBC unit will raise the hemoglobin by 1 gram/dL (10 grams/L) and hematocrit by 3% in adults. In children, 10 to 15 mL/kg of PRBCs will raise the hematocrit by 6% to 9% and the hemoglobin level by approximately 2 to 3 grams/dL (20 to 30 grams/L).**[14]

One unit of PRBCs, approximately 250 mL in volume, is generally transfused over 1 to 2 hours. PRBCs should be transfused more rapidly in patients with hemodynamic instability. Single-unit PRBC transfusions should not exceed 4 hours to prevent contamination. If a slow transfusion is desired (e.g., in a patient at risk for volume overload), the blood bank should be asked to split a unit so that the first half can be transfused over 4 hours while the second half waits in the blood bank refrigerator. During standard transfusions, the initial infusion rate is slower over the first 30 minutes so that if there is a transfusion reaction, the infusion may be stopped.

Type and Cross-Match PRBC transfusion requires matching the recipient's and donor's red blood cells according to blood type (ABO and Rh) and screening the recipient's plasma for antibodies to the minor red blood cell antigens. Screening is done using a mixture of commercially available red blood cells that have all of the important minor antigens.[12] If the screen is positive, then the recipient's plasma is cross-matched against the specific PRBC unit intended for transfusion. Blood type can be determined in approximately 15 minutes, whereas it takes about 45 to 60 minutes to perform a serologic cross-match. If an anti–red blood cell antibody is found in the recipient's plasma, cross-matching may take longer and require additional blood specimens from the patient. For most patients with no antibodies detected on the screen, serologic cross-matching can be foregone and ABO-Rh–compatible PRBC units can be released by the blood bank using a process termed *electronic* (or *computerized*) *cross-match*. This process has computer-based verifications to ensure the patient receives ABO-Rh–compatible blood.[12] Electronic cross-matching typically takes 5 minutes or less to perform.

Type O Rh-negative (universal donor) blood may be used in critical circumstances because these transfused red cells do not contain major

TABLE 238-1 Characteristics of Blood Products

Component	Shelf Life	Volume/Unit (mL)	Approximate Content/Unit*	Initial Dose	Dosage Effect
Packed red blood cells (PRBCs)	21–42 d	250–350	Red cells 65%–80% Plasma 10–20 mL	Adult: 2 units Pediatrics: 10–15 mL/kg	Raises hemoglobin concentration approximately 2 grams/dL (20 grams/L) or hematocrit by 6% in adults (2–3 grams/dL [20–30 grams/L] or 7%–9% in children)
Platelets (apheresis-collected single-donor platelet concentrate)	5 d	250–300	Platelets $3–6 \times 10^{11}$	1 unit or 5 mL/kg	Raises platelet count by up to 50,000/mm^3 (50×10^9/L), but less in many cases
Platelets (pooled donor platelet concentrate, rarely used in the United States)	5 d	50–60	Platelets $8–9 \times 10^{10}$	6 units or 5 mL/kg	Raises platelet count by up to 50,000/mm^3 (50×10^9/L), but less in many cases
Fresh frozen plasma (FFP)	1 y frozen and up to 5 d after thawing	200–250	Each coagulation factor about 200–250 units Fibrinogen 400–500 milligrams	Four units or 15 mL/kg	Raises most coagulation factors levels approximately 20%; volume issues may make factor correction difficult; benefits are transient
Cryoprecipitate	1 y frozen and 4 h thawed	20–50	Factor VIII 80–140 units Fibrinogen 225–420 milligrams von Willebrand factor in variable amounts Factor XIII and fibronectin in some amounts	0.2 units/kg or 10–15 units in an adult	Increases fibrinogen 50–100 milligrams/dL (0.5– 1.0 grams/L)

*Unless specifically prepared, most blood-derived products contain some small amount of WBCs, red blood cells, platelets, and plasma in addition to the specific component.

blood group antigens (A or B). Type O Rh-positive blood may be used if type O Rh-negative is not available, but should be avoided in girls and women of childbearing potential. Approximately 20% of Rh-negative patients transfused with 1 unit of Rh-positive PRBCs will develop anti-Rh(D) antibodies, creating the risk for hemolytic disease of the newborn with subsequent pregnancies. This is usually clinically inconsequential for men or postmenopausal women.

Treated Red Blood Cells PRBCs may be further treated for specific clinical applications: leukocyte-reduced PRBCs, irradiated PRBCs, washed PRBCs, and frozen PRBCs.[16] Leukocyte-reduced PRBCs have 70% to 85% of the white cells removed. Leukocyte-reduced PRBCs are used (1) to decrease the occurrence of nonhemolytic febrile reactions due to cytokines from transfused white cells, (2) to prevent sensitization to human leukocyte antigen antibodies found on white cells in patients who may be eligible for bone marrow transplantation, and (3) to minimize the risk of intracellular virus transmission, such as cytomegalovirus. Leukocytes can be reduced by filtration or other methods before storage of the PRBCs or during transfusion. Irradiation of PRBCs eliminates the capacity of T lymphocytes to proliferate, thereby preventing the donor's T lymphocytes from reacting to the recipient's cells and causing graft-versus-host disease. Irradiated cells are used in transplant patients, neonates, and immunocompromised patients, and with directed donations from relatives of the patient. Washed PRBCs are indicated in patients who have a hypersensitivity to plasma, such as immunoglobulin A deficiency or persistent febrile reactions. For rare blood types, red cells may be frozen and saved for up to 10 years for later use. Freezing red blood cells is more expensive than normal storage, and once thawed, the blood must be washed and transfused within 24 hours.

TABLE 238-2 Coagulation Factor Products

Type of Product*	Initial Dose	Comments and Approved Indications
Fibrinogen concentrate (human) RiaSTAP® (CSL Behring)	Dosed to increase fibrinogen level from baseline to over 150 milligrams/dL (1.5 grams/L) If baseline fibrinogen level unknown, administer 70 milligrams/kg	Each vial contains 900–1300 milligrams of fibrinogen Acute bleeding episodes in patients with congenital fibrinogen deficiency
Three-factor prothrombin complex concentrate (human) Profilnine SD® (Grifols Biologicals) Bebulin VH® (Baxter Healthcare Corporation)	Dosed according to desired factor IX increase	Contains factors II, IX, and X Treat hemophilia B (factor IX deficiency)
Four-factor prothrombin complex concentrate (human) Kcentra® or Beriplex® P/N (CSL Behring) Octaplex® (Octapharma)	Dosed in factor IX units according to pretreatment INR	Contains factors II, VII, IX, and X Urgent reversal of bleeding due to vitamin K antagonist (e.g., warfarin)–induced coagulation factor deficiency in adult patients
Anti-inhibitor coagulant complex FEIBA NF® (Baxter)	50–100 units/kg	Contains factors II, IX, and X, mainly nonactivated, and factor VII mainly in activated form Bleeding in patients with hemophilia A or B with inhibitors
Coagulation factor VIIa (recombinant) NovoSeven® RT (Novo Nordisk)	90 micrograms/kg	Bleeding episodes and perioperative management in adults and children with hemophilia A or B with inhibitors Congenital factor VII deficiency Glanzmann's thrombasthenia with refractoriness to platelet transfusions Bleeding episodes and perioperative management in adults with acquired hemophilia

*Commercial trade names provided for ease of specific identification.

MASSIVE TRANSFUSION

Massive transfusion is the replacement of one blood volume or approximately 10 units of PRBCs in an adult within a 24-hour period. If only PRBCs are used, platelets and coagulation factors lost or consumed will not be replaced, potentially producing increased bleeding. The military medical experience during the past decade finding good results with using fresh whole blood transfusion for trauma patients[17] has led to the concept of incorporating the platelets and plasma in addition to PRBCs to closer mimic whole blood during a massive transfusion.[18,19] Studies routinely using platelets and fresh frozen plasma (FFP) with PRBCs during massive transfusion have yielded mixed results on reducing mortality.[20,21]

Institution-specific massive transfusion protocol is recommended to guide the clinician in correct ordering of the individual products and facilitate release from the blood bank.[22] The best ratio of PRBCs to platelets to FFP during a massive transfusion is controversial.[23] **Some experts advocate a 1:1:1 ratio**, although lower ratios of platelets and FFP have been used without clear evidence of inferiority.[24] Including cryoprecipitate,[20] fibrinogen concentrate,[24] or coagulation factor VIIa (recombinant)[20,24] during a massive transfusion has produced mixed results, depending on the outcome measured.

If fixed ratios of platelets or FFP are not used, suggested indications for their administration during massive transfusion include the following: (1) when the platelet count is <50,000/mm^3(<50 × 10^9/L), a platelet transfusion is warranted; (2) if the INR is >1.5, FFP may be given; and (3) if the fibrinogen level is <100 milligrams/dL (<1 g/L), it may be replaced with cryoprecipitate or fibrinogen concentrate.

Draw sufficient specimens early in the course from massive transfusion patients because once the patient has received close to one blood volume of transfused products, new blood specimens will contain so much donor blood that it will confuse further cross-matching of subsequent units. Hypothermia is a risk during massive transfusion, so blood and crystalloid should be warmed, in addition to instituting warming measures for the patient. Hypocalcemia from the preservative citrate chelating calcium may occur with a massive transfusion.[22]

PLATELET TRANSFUSION

Platelet transfusions are used either prophylactically to prevent bleeding in thrombocytopenia or therapeutically when patients with thrombocytopenia are actively bleeding.[25,26] One apheresis-collected, single-donor platelet concentrate is the standard product in developed countries (Table 238-1). Platelets collected from six different donors (a "six pack") can be combined for transfusion but are not recommended because this increases the risk of disease transmission and transfusion reaction.

One apheresis single-donor platelet unit will increase the platelet count by up to 50,000/mm^3 (50 × 10^9/L), an amount sufficient to stop most spontaneous and minor traumatic bleeding. Check platelet levels at 1 and 24 hours after transfusion completion because the response is variable. Failure of platelets to rise appropriately may be due to increased consumption of platelets from an underlying process, active thrombosis due to ongoing hemorrhage, destruction due to platelet antibodies, or sequestration due to hypersplenism. Transfused platelets should survive 3 to 5 days unless there is a platelet-consumptive process.

The decision to transfuse platelets depends on the severity of thrombocytopenia and clinical circumstances (**Table 238-3**).[13,25-27] Patients with comorbid conditions, such as infection, fever, medications, and CNS involvement, may be more likely to bleed or be at higher risk if they bleed; therefore, the threshold for platelet transfusion is more liberal.[13,28]

There are no clear recommendations concerning platelet transfusions in patients with nonfunctioning platelets (antiplatelet medications, uremia, von Willebrand's disease, or hyperglobulinemia) and active bleeding. In von Willebrand's disease, normal platelets may help deliver von Willebrand factor to the bleeding site. Conversely, in uremic patients, the transfused platelets may not function any better than native platelets. In these complex cases, consult with a hematologist or transfusion medicine specialist for recommendations.

Relative contraindications to the transfusion of platelets are disorders associated with platelet activation, such as thrombotic thrombocytopenic purpura or heparin-induced thrombocytopenia, in which transfusion may worsen thrombosis. In these conditions, ongoing bleeding or the need to perform procedures may necessitate platelet transfusion in consultation with the appropriate specialist.

Platelet transfusions are usually ABO-type specific because the platelets are bathed in plasma, although a serologic cross-match is usually not done. As a result, patients receiving platelets are subject to many of the same complications described for plasma transfusion. Depending on availability, non–type-specific platelets may sometimes be transfused. This practice is usually avoided in children or patients receiving multiple transfusions because they are at higher risk for complications. Transfusing non–type-specific platelets may also shorten the half-life of the transfused platelets.

As with PRBCs, platelets can be leukocyte reduced or washed. Patients who have had repeated transfusions may become alloimmunized and refractory to platelet transfusion, noted by the lack of expected rise in platelet count after transfusion. Such patients need human leukocyte antigen–matched or cross-matched platelets. Other factors may affect the efficacy of platelet transfusion, including bacterial sepsis in the recipient, antibiotics forming an antigen complex epitope with the platelet, disseminated intravascular coagulation, and splenomegaly.

FRESH FROZEN PLASMA TRANSFUSION

FFP is plasma obtained after the separation of whole blood from erythrocytes and platelets and then frozen within 8 hours of collection.[29] FFP takes approximately 20 to 40 minutes to thaw, and this process cannot be sped up through artificial heating. Once thawed, FFP can be transfused up to 5 days later. Trauma centers and other specialty hospitals may keep prethawed units of FFP available.

Transfused FFP should be ABO-type compatible, and Rh compatibility is unnecessary. A common misconception is that type O plasma is the universal FFP donor, as it is for PRBCs. This is not the case, because type O plasma contains antibodies to A and B blood group antigens. **Type AB is the universal donor for FFP, and in emergencies, universal donor FFP can be given minutes after thawing.** Each unit of FFP has a volume of 200 to 250 mL and contains approximately 1 unit of each coagulation factor and 2 milligrams of fibrinogen per milliliter (Table 238-1). FFP is used for replacement of multiple coagulation deficiencies in cases such as liver failure, warfarin-induced overanticoagulation, disseminated intravascular coagulation, and massive transfusion in bleeding patients, although evidence of benefit is weak (**Table 238-4**).[30] FFP is also used with bleeding due to an individual coagulation factor deficiency when a specific replacement factor is not available. FFP is unlikely to reverse anticoagulation from oral anticoagulants such as dabigatran and rivaroxaban, which are specific inhibitors of thrombin and factor Xa, respectively (see chapter 239, "Thrombotics and Antithrombotics" and the "Prothrombin Complex Concentrate" section, below).[31]

TABLE 238-3 General Indications for Platelet Transfusion

Platelet count <5000/mm^3 (<5 × 10^9/L)
Platelet count <20,000/mm^3 (<20 × 10^9/L) with a coagulation disorder, low-risk procedure, or during outpatient treatment
Platelet count <50,000/mm^3 (<50 × 10^9/L) with active bleeding or invasive procedure within 4 h
Platelet count <100,000/mm^3 (<100 × 10^9/L) with neurologic or cardiac surgery
As part of a massive transfusion protocol

TABLE 238-4 General Indications for Fresh Frozen Plasma Transfusion

Reversal of warfarin overanticoagulation (not the primary agent)
Bleeding with multiple coagulation defects
Correction of coagulation defects for which no specific factor is available
As a component of a massive transfusion protocol
As part of plasma exchange when treating thrombotic microangiopathies or neurologic disorders

Response to FFP treatment is monitored by tests of the coagulation system: the prothrombin time, INR, and activated partial thromboplastin time. Using fresh frozen plasma to achieve complete normalization of coagulation studies is neither necessary nor realistic in most circumstances. Clinically adequate hemostasis is generally present with functional coagulation factor levels of 30% to 40% of normal, which corresponds to an INR of about 1.7. Although it is common to administer FFP before a procedure when the INR exceeds 1.5,[13,27] there is little evidence to support this practice,[32] and it will likely have little effect on patients with an INR less than 1.85.[33] If rapid reversal of a vitamin K antagonist coagulopathy is needed, prothrombin complex concentrate or coagulation factor VIIa (recombinant) is faster and more reliable.[34]

Administering FFP prophylactically to nonbleeding patients is not indicated, and prophylaxis is not needed before procedures in patients with a coagulopathy.[32] Procedures such as abdominal paracentesis[35] or endoscopy with variceal banding[36] can be performed safely with a coagulopathy. If correction is desired, the effect of FFP is transient, dose dependent, and may subject the patient to volume overload.

Other possible indications for FFP include hereditary angioedema if C1 esterase inhibitor is not available (see chapter 14, "Anaphylaxis, Allergies, and Angioedema").[37,38] FFP is used during plasma exchange for treatment of diseases such as thrombotic thrombocytopenic purpura and Guillain-Barré syndrome.[39,40]

For isolated factor deficiencies, specific factor replacement is preferred over FFP for major bleeding, with fresh frozen plasma sometimes used for minor bleeding episodes (**Table 238-5**).

The increase in individual coagulation factors seen after FFP infusion varies depending on the specific factor. In general, 1 unit of FFP will increase most coagulation factors by 3% to 5% in a 70-kg adult. Administering 2 units of FFP to an adult (approximately 7 to 8 mL/kg) will increase coagulation factors up to 10%, a clinically inconsequential benefit in most circumstances. For clinically relevant correction of coagulation factor deficiencies, a dose of 15 mL/kg (or 4 units in a 70-kg adult) is often required (Table 238-1). After transfusion, coagulation studies should be repeated and further FFP transfusion guided by the results.

TABLE 238-5 Replacement Therapy for Congenital Factor Deficiencies

Coagulation Factor	Approximate Incidence*	Replacement Therapy
Factor I (fibrinogen)	1 per million	Cryoprecipitate Fibrinogen concentrate
Factor II (prothrombin)	1 per 2 million	3- or 4-factor PCC for major bleeding
Factor V	1 per million	FFP
Factor VII	1 per 500,000	4-factor PCC for major bleeding Coagulation factor VIIa (recombinant)
Factor VIII†	1 per 5000–10,000 males	Recombinant factor VIII Desmopressin for mild hemophilia
Von Willebrand's disease‡	Up to 1 per 100 persons	Desmopressin or factor VIII concentrates (or cryoprecipitate if either unavailable)
Factor IX†	1 per 30,000 males	Recombinant factor IX 3- or 4-factor PCC
Factor X	1 per million	FFP for minor bleeding episodes 3- or 4-factor PCC for major bleeding
Factor XI‡	3 per 10,000 Ashkenazi Jews 1 per million in general population	FFP
Factor XII	25 per 1000	No bleeding manifestations, replacement not required
Factor XIII	1 per million	FFP or cryoprecipitate

Abbreviations: FFP = fresh frozen plasma; PCC = prothrombin complex concentrate.

†See chapter 235, "Hemophilias and von Willebrand's Disease."

‡Factor XI levels correlate poorly with bleeding complications; many patients have low levels but no bleeding complications.

TABLE 238-6 General Indications for Cryoprecipitate Transfusion

Bleeding with a fibrinogen level of <100 milligrams/dL (< 1 g/L)
Dysfibrinogenemia
Bleeding in some subtypes of von Willebrand's disease that are unresponsive to desmopressin, and factor VIII concentrates are unavailable

CRYOPRECIPITATE

Cryoprecipitate is the cold-insoluble protein fraction of fresh frozen plasma.[34] With the development of recombinant factor VIII products for use in hemophilia, the current role for cryoprecipitate is as replacement of fibrinogen.[41] Cryoprecipitate may be used in bleeding patients with fibrinogen levels <100 milligrams/dL (< 1 g/L) due to severe liver disease, uremia, disseminated intravascular coagulation, and dilutional coagulopathy, although there is controversy over dosing and efficacy (**Table 238-6**).[42,43] Five units of cryoprecipitate are typically pooled for use, with adults receiving one to three pooled infusions. Cryoprecipitate may also be included in some massive transfusion protocols.[20,24]

FIBRINOGEN CONCENTRATE

Fibrinogen concentrate is derived from pooled human plasma and used to treat bleeding episodes in patients with congenital fibrinogen deficiency.[44] Fibrinogen has been investigated for benefit in other hemorrhagic conditions with an observed ability to reduce bleeding and transfusion requirements, but without a measurable effect on mortality.[45] Four products are commercially available. The advantages over cryoprecipitate are minimal risk of disease transmission due to viral inactivation, accurate dosing because each vial is assayed for fibrinogen content, a lower volume for infusion, no need for thawing, no requirement of ABO testing and compatibility, and a rapid reconstitution for infusion.

Fibrinogen is dosed according the patient's baseline fibrinogen level, the target level (in most circumstances >150 milligrams/dL),[46] volume of distribution, and body weight. If the baseline fibrinogen level is unknown, the initial dose is 70 milligrams/kg. The most common adverse reactions include allergic reactions, fever, chills, nausea, and vomiting.

PROTHROMBIN COMPLEX CONCENTRATE

Prothrombin complex concentrates are blood-derived concentrations of three or four vitamin K–dependent clotting factors: prothrombin and factors VII, IX, and X.[47] Some prothrombin complex concentrate formulations may also contain the anticoagulant proteins C, S, and antithrombin, as well as heparin. Three-factor prothrombin complex concentrate is approved for treatment of hemophilia B (factor IX deficiency) (Table 238-2). Four-factor prothrombin complex concentrate is approved for urgent reversal of overanticoagulation from vitamin K antagonists (such as warfarin),[48,49] resulting in a more reliable reduction in the elevated INR than three-factor prothrombin complex concentrate.[50,51] The four-factor prothrombin complex concentrate dose in this circumstance is administered using factor IX units and adjusted according to the pretreatment INR value. Off-label use of three- or four-factor prothrombin complex concentrate includes bleeding in patients with congenital factor II, IX, or X deficiency.

Prothrombin complex concentrate does not require thawing, does not necessitate ABO-compatibility testing, and does not carry the risk of volume overload, all of which can hinder fresh frozen plasma use. Because prothrombin complex concentrate's effects are transient, vitamin K should usually be co-administered for sustained warfarin reversal. Prothrombin complex concentrate is part of some protocols for reversal of rivaroxaban and dabigatran in the setting of life-threatening bleeding, despite limited evidence for their effectiveness.[31,52,53] Thrombosis is the major complication of prothrombin complex concentrate,

observed in about 5% of treated patients, although this incidence is not much higher than in similar patients treated with fresh frozen plasma.

COAGULATION FACTOR VIIa (RECOMBINANT)

Coagulation factor VIIa (recombinant) is primarily used for treatment of hemophilia A and B in patients who have developed inhibitor antibodies to factors VIII or IX, respectively. Other uses for this agent have been investigated, such as coagulation support in liver failure, multisystem trauma, intracranial hemorrhage, and postpartum bleeding, but evidence for overall safety and efficacy in these expanded indications is lacking.[54-58] The major drawbacks to this product are risk of thrombosis (up to 4% in patients with acquired hemophilia) and the high cost.

COMPLICATIONS OF BLOOD TRANSFUSIONS

Up to 20% of all transfusions may result in some type of adverse reaction.[4,59] Most reactions are minor; serious reactions are uncommon, and life-threatening ones are rare (**Table 238-7**).[60] In critically ill patients, transfusion reactions may be difficult to identify; therefore, watch for unexpected changes in patient status during a transfusion. **Two important first steps in any confirmed or suspected transfusion reaction are to (1) immediately stop the transfusion, and (2) contact the blood bank that issued the transfusion product.**[12,16] The blood bank physician is an important resource for managing the suspected transfusion reaction.

Although stopping the transfusion at the first sign of complications is an important step, a common error in management of a confirmed or possible transfusion reaction is to abandon all transfusion. Typically, transfusion reactions, such as hemolytic reactions or transfusion-related acute lung injury, are due to the interaction between a particular unit and a particular patient. Even patients with severe reactions can still safely receive future blood products if they are appropriately matched to the patient. In fact, a patient who had clinical indications for transfusion may need that product even more if a transfusion reaction has caused deterioration. One of the first steps in management of a transfusion reaction is to draw a new specimen to retype and cross-match new units so that transfusion can resume as soon as possible.[12,16]

Premedication with diphenhydramine and acetaminophen is a widespread practice to prevent febrile and/or allergic transfusion reactions[61]; however, the effects are limited,[62,63] and routine prophylactic premedication is not recommended. Premedication may be used for patients with previous febrile or allergic transfusion reactions.

HEMOLYTIC TRANSFUSION REACTIONS

Hemolytic transfusion reactions occur when the recipient's antibodies recognize and induce hemolysis of the donor's RBCs.[1,12,16,64] The reaction is usually acute when antibodies already exist as anti-A or anti-B immunoglobulin M antibodies or immunoglobulin G antibodies in very high titer. Reactions can be delayed when there is an amnestic response to a transfused red blood cell antigen to which the recipient has been previously sensitized.[16,64,65] Immediate transfusion reactions are caused by ABO incompatibility and usually are the result of technical errors made during the collection of blood, in pretransfusion testing, or in patient identification. The majority of transfusion fatalities are acute hemolytic reactions due to human error of incorrect cross-matching or inadvertent administration of the wrong blood to the wrong patient. The risk of acute hemolytic transfusion reaction due to incompatible blood is 1 to 4 per million units transfused.

With acute hemolytic reaction, most of the transfused cells are destroyed, which may result in activation of the coagulation system, disseminated intravascular coagulation, and release of anaphylatoxins and other vasoactive amines. Clinical features of an acute hemolytic reaction include back pain, pain at the site of the transfusion, headache, alteration of vital signs (fever, hypotension, dyspnea, tachycardia), chills, bronchospasm, pulmonary edema, bleeding due to developing coagulopathy, and evidence of new or worsening renal failure.

Ongoing transfusion should be stopped immediately on first indication of potential problems. While laboratory confirmation is being performed, the sequelae of hemolysis are treated supportively. Check renal function, electrolytes, and coagulation status. Maintain renal blood flow and urine output with fluids, mannitol, and furosemide, as needed. Treat circulatory shock with intravenous infusions and vasopressors to support blood pressure.

The remaining donor blood should be sent, along with a posttransfusion blood specimen from the recipient, to the blood bank. Diagnosis is

TABLE 238-7 Transfusion Reactions

Reaction Type	Signs and Symptoms	Management	Evaluation
Acute intravascular hemolytic reaction	Fever, chills, low back pain, flushing, dyspnea, tachycardia, shock, hemoglobinuria	Immediately stop transfusion. IV hydration to maintain diuresis; diuretics may be necessary. Cardiorespiratory support as indicated.	Retype and repeat cross-match. Direct and indirect Coombs test. CBC, creatinine, prothrombin time, activated partial thromboplastin time. Haptoglobin, indirect bilirubin, lactate dehydrogenase, plasma free hemoglobin. Urine for hemoglobin.
Delayed extravascular hemolytic reaction	Often have low-grade fever but may be entirely asymptomatic	Usually presents days to weeks after transfusion. Rarely causes clinical instability.	Hemolytic workup as above to investigate the possibility of intravascular hemolysis.
Febrile nonhemolytic transfusion reaction	Fever, chills	Stop transfusion. Initially manage as in intravascular hemolytic reaction (above) because one cannot initially distinguish between the two. Can treat fever and chills with acetaminophen. Usually mild but can be life threatening in patients with tenuous cardiopulmonary status. Consider infectious workup. Premedication with acetaminophen can mask this reaction.	Hemolytic workup as above because may not be able to initially distinguish febrile from hemolytic transfusion reactions.
Allergic reaction	Mild: urticaria, pruritus Severe: dyspnea, bronchospasm, hypotension, tachycardia, shock	Stop transfusion. If mild, reaction can be treated with diphenhydramine; if symptoms resolve, can restart transfusion. If severe, may require cardiopulmonary support; do not restart transfusion.	For mild symptoms that resolve with diphenhydramine, no further workup is necessary, although blood bank should be notified. For severe reaction, do hemolytic workup as above because initially may be indistinguishable from a hemolytic reaction.

confirmed by evidence of hemolysis (hemoglobinuria or hemoglobinemia) and by blood incompatibility. In rechecking the blood type and cross-match, the patient's serum is tested for blood group alloantibodies, and the donor's plasma is tested for the presence of antibodies that react with the patient's blood. In intravascular hemolytic transfusion reactions, serum haptoglobin will be decreased, serum lactate dehydrogenase will be elevated, and a direct antigen (Coombs) test usually will be positive. The blood bank will be able to test the blood, review records, confirm blood types, and determine if the patient's syndrome is from a transfusion reaction.

Extravascular delayed hemolytic reactions occur in approximately 1 per 1000 to 6000 PRBC units transfused.[16] Hemolysis most commonly occurs in the spleen and occasionally in liver and bone marrow. This type of reaction is less serious and rarely fatal. It may be identified by a positive Coombs test, elevated unconjugated (indirect) bilirubin level, and less than expected increase in hemoglobin from the transfusion.

FEBRILE TRANSFUSION REACTIONS

Febrile transfusion reactions are characterized by fever during or within a few hours of a blood transfusion.[1,12,16] A febrile reaction occurs in approximately 1 per 300 units of PRBCs infused. Febrile transfusion reactions are more common in patients who have been exposed to foreign blood antigens, such as multiparous women or multiply transfused patients. Febrile transfusion reactions result from a combination of recipient antibody against donor leukocytes and the release of cytokines that are produced during storage. Clinical presentation can range from a mild elevation in temperature to a high fever along with rigors, headache, myalgias, tachycardia, dyspnea, and chest pain. A febrile reaction may be difficult to initially differentiate from the more serious hemolytic transfusion reaction or sepsis.

For a febrile reaction during a patient's first-time transfusion, or in any severe reaction, the transfusion should be stopped and the product returned to the blood bank for testing. Laboratory investigation similar to that done for possible hemolytic transfusion is done and blood cultures should be obtained. The febrile transfusion reaction is usually self-limited and will respond to antipyretics. A mild fever in a patient who has been transfused before is usually not serious. In most cases, the transfusion can be restarted after consultation with the blood bank physician. For patients with recurrent febrile reactions, the use of leukocyte-reduced blood products may be helpful, as well as pretreatment with antipyretics.

ALLERGIC TRANSFUSION REACTIONS

Allergic transfusion reactions typically manifest with urticaria and pruritus during the infusion.[1,12,16] A small percentage of patients will have more severe reactions, such as bronchospasm, wheezing, and anaphylaxis. These reactions are caused by an immune response to transfused plasma proteins. The incidence of allergic transfusion reactions varies widely.[66]

Antihistamine therapy usually will control the symptoms. The transfusion should be stopped but can usually be restarted after evaluation. For severe symptoms, the transfusion should be stopped and treatment with epinephrine or bronchodilators initiated. Patients with immunoglobulin A deficiency may experience severe anaphylactic reactions in response to exposure from immunoglobulin A in donor products. Washing the plasma from the red blood cells minimizes this type of reaction.

INFECTIOUS COMPLICATIONS OF BLOOD TRANSFUSION

Improved blood donor screening, serologic testing, safer handling of blood products, and viral inactivation of blood products have reduced the risk of infection from transfusion.[67-70] Despite screening donor blood for antibodies to most concerning viral agents, there is still a small risk of viral transmission (**Table 238-8**). Most cases of transmission are thought to occur during the window period between infection and antibody production in the donor. This window can be reduced by antigen testing of donated blood for known viral antigens.

Prevalence for cytomegalovirus antibodies in the general population is between 50% and 80%; therefore, a transfusable unit is not tested routinely for cytomegalovirus unless the recipient is seronegative and either pregnant, a potential or present transplant candidate, immunocompromised, or a premature infant. Leukocyte-reduced blood components further decrease the risk of cytomegalovirus transmission to susceptible populations because most of the virus resides in the leukocytes.[68]

TABLE 238-8 Risk of Infections from Transfusion of Blood Products

Etiology	Estimated Frequency: One Infection per Number of Units Transfused
HIV-1	1 per 6 million
HIV-2	Unknown, but extremely low
Human T-cell lymphotropic virus types 1 and 2	1 per 640,000
Hepatitis B	1 per million
Hepatitis C	1 per 100 million
Parvovirus B19	1 per 10,000

Abbreviation: HIV = human immunodeficiency virus.

Other infections transmitted by blood transfusion include West Nile virus, variant Creutzfeldt-Jakob, babesiosis, and dengue.[66,67,69] Additionally, blood can become contaminated with bacteria during storage or processing. Transfusion-associated bacterial infection was more commonly reported with platelet concentrates than PRBC or fresh frozen plasma. Bacterial screening and inactivation procedures have dramatically reduced the incidence of transfusion-associated bacterial sepsis.[60] Response to a possible septic reaction involves immediate discontinuation of the transfusion, blood cultures from the patient, therapy with broad-spectrum antimicrobials, and examination of material from the blood container by Gram stain with cultures of specimens from the container and the administration set.[12,16]

TRANSFUSION-RELATED ACUTE LUNG INJURY

Transfusion-related acute lung injury is an uncommon but complex process that is thought to be due to granulocyte recruitment and degranulation within the lung.[65,71,72] Transfusion-related acute lung injury is usually a complication of fresh frozen plasma or platelet transfusion and is rare after PRBC transfusion alone. This syndrome presents with respiratory distress and the appearance of bilateral pulmonary infiltrates due to noncardiogenic pulmonary edema, during or within 6 hours of transfusion. By itself, transfusion-related acute lung injury is self-limiting and generally resolves spontaneously with only supportive care, although severe, fatal reactions can occur. Because the pulmonary edema is noncardiogenic, use care to distinguish this situation from volume overload and avoid aggressive diuresis, which can cause rapid deterioration.

OTHER COMPLICATIONS

Hypervolemia Transfusion of blood products can cause rapid volume expansion when compared to similar volumes of crystalloid fluids, leading to transfusion-associated cardiovascular overload.[65] Patients with limited cardiovascular reserve, such as infants, those with severe chronic compensated anemia, and the elderly, are at the highest risk. Clinical features include dyspnea, hypoxia, and pulmonary edema. Recognize the potential for volume overload so that blood can be transfused slowly, the patient can be monitored carefully, and treatment with diuretics can be initiated when necessary. The usual rate of PRBC or fresh frozen plasma transfusion is 2 to 4 mL/kg per h, but it can be slowed to 1 mL/kg per h in more delicate patients. Blood product units may also be split, as described earlier.

Electrolyte Imbalance Electrolyte imbalances of hypocalcemia, hypokalemia, or hyperkalemia due to large-volume transfusions or altered elimination are uncommon. The anticoagulant citrate is a component of many blood preservatives and chelates calcium. The effect of infused citrate is clinically insignificant because patients with normal hepatic function metabolize the citrate to bicarbonate. Rarely with massive transfusions, hepatic metabolism is overwhelmed, and hypocalcemia can develop and/or the excess bicarbonate generated causes alkalemia, driving potassium into the cells and causing hypokalemia.[22] The potassium

content in stored blood products increases during storage, and uncommonly, patients with renal insufficiency or neonates can develop hyperkalemia from transfusion.

CHAPTER 239

Thrombotics and Antithrombotics

David E. Slattery
Charles V. Pollack, Jr.

INTRODUCTION

Antithrombotic therapy (i.e., **anticoagulants, antiplatelet agents, and fibrinolytics**) is used to treat arterial and venous thromboembolic conditions, including acute coronary syndrome, deep venous thrombosis, pulmonary embolism, transient ischemic attack, and ischemic stroke. Moreover, antithrombotic agents help prevent occlusive vascular events in patients at risk for thrombosis due to atherosclerotic arterial disease, atrial fibrillation, medical illness with immobility, or surgical insult. These agents, however, can cause life-threatening complications, primarily serious hemorrhage. Detailed management strategies for thromboembolic disorders are discussed in their respective chapters (see chapter 49, "Acute Coronary Syndromes"; chapter 56, "Venous Thromboembolism"; and chapter 167, "Stroke Syndromes").

Hemostasis—whether physiologic after accidental injury or pathologic after rupture of an atherosclerotic plaque—is initiated by platelet interaction with the vascular subendothelium and continues with a series of reactions among plasma coagulation proteins that generate the final product of cross-linked fibrin incorporated into the initial platelet plug (see chapter 232, "Tests of Hemostasis"). Arterial thrombi, composed primarily of platelets bound by thin fibrin strands, develop under high-flow conditions, especially at sites of ruptured plaques. **Both anticoagulants and platelet-inhibiting drugs may effectively prevent and treat arterial thrombosis.** In contrast, venous thrombi form in areas of sluggish blood flow and are composed mainly of red blood cells and large fibrin strands. **Anticoagulant drugs are more effective than antiplatelet drugs in preventing venous thromboembolism.**

Antithrombotic agents are classified by their mechanism of action. **Anticoagulants** block the synthesis or activation of clotting factors, interfering with the coagulation cascade at one or more steps. **Antiplatelet agents** interfere with platelet activation or aggregation. **Fibrinolytic agents** (often but inaccurately referred to as thrombolytic agents) stimulate the enzymatic dissolution of the fibrin component.

Thrombotic agents are used to diminish bleeding due to either an anithrombotic agent or and acquired or genetic bleeding disorder (see chapters 233 and 235, "Acquired Bleeding Disorders" and "Hemophilias and von Willebrand's Disease", respectively).

ORAL ANTICOAGULANTS

Oral anticoagulants are used to (1) stop further thrombosis when the condition already exists (e.g., venous thrombosis), (2) reduce the risk of embolism in patients with thrombotic disease (e.g., venous thrombosis or left ventricular mural thrombus), and (3) prevent thrombi from forming in patients with risk factors for their development (e.g., atrial fibrillation, prolonged immobilization, or prosthetic heart valve) (**Table 239-1**).

WARFARIN

Warfarin, a hydroxy coumarin compound, is the most widely used oral anticoagulant.[1,2] Warfarin is readily absorbed after ingestion, reaching peak blood concentrations in 2 to 4 hours, and has a circulating half-life of 20 to 60 hours. Warfarin is bound to albumin, metabolized by the liver, and excreted in the urine. Warfarin blocks activation of vitamin K and thereby interferes with hepatic carboxylation of coagulation factors II, VII, IX, and X. The decrease in these vitamin K–dependent cofactors impairs the extrinsic and common coagulation pathway. Warfarin also blocks the synthesis of proteins C and S. Activated protein C (with protein S and phospholipid as cofactors) proteolyses factors Va and VIIIa, thereby inhibiting the coagulation cascade. Thus, warfarin has both an antithrombotic effect (by inhibiting the synthesis of factors II, VII, IX, and X) and a prothrombotic effect (through inhibition of proteins C and S production), but during maintenance therapy, the overwhelming effect is one of anticoagulation.

Warfarin dosing is guided by measurement of the International Normalized Ratio (INR), a standardized measurement of prothrombin time, with a desired therapeutic range of 2.0 to 3.0 in most cases.[2] Drugs and food that interfere with warfarin absorption, bind to albumin, or alter hepatic metabolism can have a profound effect on warfarin activity (**Table 239-2**). Warfarin is generally contraindicated in pregnancy because it is teratogenic (especially during the 6th to 12th week of gestation) and can cause fetal hemorrhage.

Protein C has a short half-life (8 hours), and plasma levels quickly fall after starting warfarin. The vitamin K–dependent coagulation factors have half-lives that range from approximately 7 hours for FVII to approximately 60 hours for prothrombin (FII). **The phase delay between the fall in levels of protein C (an antithrombotic protein) and the fall in levels of the four affected coagulation factors (prothrombotic proteins) results in a transient state of increased thrombogenesis at the start of warfarin therapy that persists for 24 to 36 hours.** This hypercoagulable state is mitigated by providing sufficient overlap with a parenteral anticoagulant (e.g., heparin) during the first 3 to 5 days of warfarin treatment[1,2] and during any interruption of warfarin therapy for surgery or an invasive procedure.[3-5] Because factors X and II have relatively long half-lives, the parenteral anticoagulant should not be discontinued until the INR is in the desired therapeutic range for 2 consecutive days. **Thus, a noncompliant patient with the risk for catastrophic complications from sudden intravascular thrombosis—such as a patient with a mechanical prosthetic heart valve who has stopped oral anticoagulants—should be treated with a parenteral anticoagulant in addition to restarting warfarin.**

There is also a prothrombotic rebound during the first 4 days after cessation of warfarin therapy. However, there is no increased incidence of clinical episodes of thrombosis with termination of warfarin therapy, and thromboembolic events that occur in patients after warfarin discontinuation are most-likely related to the underlying condition.

The two major complications of warfarin therapy are bleeding and skin necrosis. The most important factor influencing the risk of bleeding is the intensity of anticoagulant therapy. The risk of clinically significant bleeding is increased when the INR is >4.5 to 5.0.[1,2] Skin necrosis occurs primarily (but not exclusively) in patients with protein C deficiency. This complication usually develops 3 to 8 days after starting treatment and is caused by thrombosis of small cutaneous vessels. Treatment includes discontinuation of warfarin, administration of a parenteral anticoagulant to maintain desired anticoagulation, vitamin K_1 administration, and screening for protein C and S deficiencies.

Patient-specific risk factors for increased risk of bleeding during warfarin treatment include hypertension, anemia, prior cerebrovascular disease, GI lesions, and renal disease. The relationship between advanced age and warfarin-associated bleeding is controversial. Elderly individuals who are otherwise appropriate candidates for anticoagulant therapy should not have warfarin withheld solely because of their age, although elderly patients require more frequent and careful monitoring. Medications that increase warfarin activity and antiplatelet medications increase bleeding risk during warfarin therapy (**Table 239-2**).

TABLE 239-1 Options for Antithrombotic Therapy

Clinical Indication	Comments
Treatment of Deep Venous Thrombosis and Pulmonary Embolism	
Unfractionated heparin 80 units/kg IV bolus followed by 18 units/kg per h continuous IV infusion, with the aPTT checked after 6 h and the infusion adjusted to maintain the aPTT 1.5–2.5 times control *with* concurrent institution of warfarin	In most cases, heparin and warfarin are started simultaneously, with an overlap of 3–5 d. Warfarin is monitored and dose adjusted to a target INR of 2.0–3.0 in most patients.
Enoxaparin 1 milligram/kg SC every 12 h or 1.5 milligrams/kg SC once a day	Monitoring not routinely required
Dalteparin 200 units/kg SC once daily or 100 units/kg SC twice daily	Not FDA approved for this indication
Fondaparinux weight-tiered regimen <50 kg: 5 milligrams SC once a day 50–100 kg: 7.5 milligrams SC once a day >100 kg: 10 milligrams SC once a day	Monitoring not routinely required — — —
Rivaroxaban 15 milligrams PO twice daily for 21 d, followed by 20 milligrams PO once daily	Avoid use in patients with CrCl <30 mL/min
Dabigatran 150 milligrams PO twice daily (after 5 to 10 d of parenteral anticoagulation)	Avoid in patients with CrCl <30 mL/min or on hemodialysis
Apixaban 10 milligrams PO twice daily for 7 d, followed by 5 milligrams twice daily	Reduce dose by 50% if patient taking dual strong VYP3A4 and P-glycoprotein inhibitors
Streptokinase 250,000 units IV bolus, followed by 100,000 units/h continuous IV infusion for 1–3 d OR Alteplase 100 milligrams IV infused over 2 h OR Tenecteplase weight-tiered single IV bolus <60 kg: 30 milligrams 60–70 kg: 35 milligrams 70–80 kg: 40 milligrams 80–90 kg: 45 milligrams >90 kg: 50 milligrams	Fibrinolytic treatment of deep venous thrombosis and pulmonary embolism is recommended only in carefully selected patients.
Prophylaxis of Deep Venous Thrombosis and Pulmonary Embolism	
Unfractionated heparin 5000 units SC every 8–12 h	Highest-risk patients for venous thromboembolism should receive every 8 h dosing.
Dalteparin 2500 to 5000 IU SC once a day	—
Enoxaparin 40 milligrams SC once daily (normal renal function), 30 milligrams SC twice daily (trauma) or 40 milligrams twice daily (obese patients)	—
Fondaparinux 2.5 milligrams SC once a day	—
Rivaroxaban 10 milligrams PO once a day	—
Apixaban 2.5 milligrams PO twice daily	For prophylaxis after hip and knee replacement surgery, initial dose taken 12–24 h after surgery
ST-Segment Elevation Myocardial Infarction	
Aspirin (non–enteric coated) 162–325 milligrams PO once a day Clopidogrel 300 milligrams PO loading dose (consider 600 milligrams if PCI is planned) followed by 75 milligrams PO once a day OR Ticagrelor 180 milligrams PO loading dose, followed by 90 milligrams PO twice daily	All post–myocardial infarction patients should receive aspirin, 162–325 milligrams PO once a day, for an indefinite period (unless contraindicated or if on warfarin).
Unfractionated heparin 60 units/kg IV bolus (maximum, 4000 units according to the ACC/AHA guidelines or 5000 units according to the ESC guidelines) followed by 12 units/kg per h (maximum, 1000 units) continuous IV infusion adjusted to keep aPTT 1.5–2.5 times control OR Enoxaparin 30 milligrams IV bolus, followed by 1 milligram/kg SC every 12 h for patients <75 years of age or 0.75 milligrams/kg SC every 12 h of patients >75 years of age OR Bivalirudin 0.75 milligram/kg IV bolus followed by 1.75 milligrams/kg per h continuous IV infusion (FDA approved for use in cardiac catheterization laboratory only)	Optimal anticoagulation strategies are not completely defined.

(*Continued*)

TABLE 239-1 Options for Antithrombotic Therapy (*Continued*)

Clinical Indication	Comments
Streptokinase 1.5 million units IV over 60 min OR Alteplase 15 milligrams IV bolus over 1–2 min followed by 0.75 milligram/kg IV over 30 min (maximum, 50 milligrams) and 0.50 milligram/kg IV over 60 min (maximum, 35 milligrams) OR Reteplase 10 units IV bolus, then a second 10-unit dose at 30 min OR Tenecteplase weight-tiered single IV bolus <60 kg: 30 milligrams 60–70 kg: 35 milligrams 70–80 kg: 40 milligrams 80–90 kg: 45 milligrams >90 kg: 50 milligrams	Early administration is more important than choice of specific fibrinolytic agent.
Unstable Angina and Non-ST-Segment Myocardial Infarction	
Aspirin (non–enteric coated) 162–325 milligrams PO once a day	Optimal antiplatelet strategies are not completely defined.
Clopidogrel 300 milligrams PO loading dose (consider 600 milligrams if PCI is planned) followed by 75 milligrams PO once a day OR Prasugrel 60 milligrams loading dose followed by 10 milligrams PO once daily OR Ticagrelor 180 milligrams PO loading dose, followed by 90 milligrams PO twice daily	Dual therapy—aspirin plus another antiplatelet agent—is common.
Unfractionated heparin 60 units/kg IV bolus (maximum, 4000 units according to the ACC/AHA guidelines or 5000 units according to the ESC guidelines) followed by 12 units/kg per h (maximum, 1000 units/h) continuous IV infusion adjusted to keep aPTT 1.5–2.5 times control Enoxaparin 1 milligram/kg SC every 12 h Glycoprotein IIb/IIIa inhibitor, depending on risk and whether PCI is planned Bivalirudin 0.75 milligram/kg IV bolus followed by 1.75 milligrams/kg per hour continuous IV infusion (FDA approved for use in cardiac catheterization laboratory only)	Optimal anticoagulation strategies are not completely defined.
Peripheral Artery Disease	
Aspirin 162–325 milligrams PO once a day	—
Cilostazol 100 milligrams PO twice a day	—
Acute Ischemic Stroke	
Alteplase 0.9 milligram/kg (maximum, 90 milligrams) with 10% of total dose given as an IV bolus over 1 min followed by the remainder as an IV infusion over 60 min	Use of fibrinolytics in acute ischemic stroke requires *strict* adherence to recommended guidelines and should be done with informed consent. Adjunctive use of anticoagulants should be avoided for 48 h.
Postischemic Stroke	
Aspirin 81 milligrams PO once a day	—
Clopidogrel 75 milligrams PO once a day	Use clopidogrel if aspirin allergic.
Dipyridamole 200 milligrams extended-release PO twice a day	Usually combined with aspirin 25–50 milligrams PO twice a day.
Transient Ischemic Attack	
Aspirin 81 milligrams PO once a day	Use clopidogrel if "aspirin failure" or aspirin allergic.
Clopidogrel 75 milligrams PO per day	—
Stroke Prevention in Atrial Fibrillation	
Warfarin dose monitored and adjusted by INR	Target INR is 2.0–3.0 in most patients.
Dabigatran 75–150 milligrams PO twice daily	Dosing guided by renal function; not routinely monitored.
Rivaroxaban 15–20 milligrams PO once a day	Dosing guided by renal function; not routinely monitored.
Apixaban 2.5–5.0 milligrams PO twice daily	Dose adjustment in patients with any two of the following characteristics: Age >80 years Weight <60 kg Serum creatinine >1.5 mg/dL

Abbreviations: ACC = American College of Cardiology; AHA = American Heart Association; aPTT = activated partial thromboplastin time; ESC = European Society of Cardiology; FDA = U.S. Food and Drug Administration; PCI = percutaneous coronary intervention.

TABLE 239-2 Warfarin Interactions

Consideration	Effect on PT or INR*
Major	
Vitamin K malabsorption or dietary deficiency	↑
Excess vitamin K	↓
Reduced gut bacteria (antibiotics)†	↑
Decreased warfarin absorption	↓
Altered warfarin metabolism (cytochrome P-450)	Variable
Drug effects†	Variable
Other	
Decreased clotting factor production (liver disease)	↑
Increased metabolism of clotting factors (fever)	↓
Confounding technical or laboratory factors (e.g., phlebotomy, handling in transport, thromboplastin reagents)	Variable

*↑ = prothrombin time (PT) or INR prolonged; ↓ = PT or INR decreased.

†Consult drug-interaction reference for new medications.

Drug interactions with warfarin are numerous and complex. Emergency physicians should carefully review medications prescribed on ED discharge, and **it is recommended that drug–drug interaction references be utilized whenever adding a new medication to a patient on warfarin**. Drugs frequently prescribed upon ED discharge should generally be avoided in patients on warfarin because of the increased risk of bleeding, including nonsteroidal anti-inflammatory drugs, sulfa-containing drugs (e.g., sulfamethoxazole), macrolides (with the exception of azithromycin), and fluoroquinolones. Drugs that induce hepatic cytochrome P-450 activity may increase the metabolism and reduce the effect of warfarin. Because the effect may take several days to manifest, the following agents should only be prescribed upon ED discharge after careful review and with close follow-up: barbiturates, anticonvulsants (e.g., phenytoin, carbamazepine, primidone), antibiotics (e.g., dicloxacillin, nafcillin, rifampin), and antipsychotics or sedatives (e.g., haloperidol, trazodone).

The two important principles when warfarin-treated patients bleed with a prolonged INR are (1) attempt to identify and attenuate the cause of bleeding, and (2) lower the intensity of the anticoagulant effect. In patients with a modestly elevated INR without clinically evident bleeding, cessation of warfarin, careful observation, and periodic monitoring comprise the safest course (**Figure 239-1**).[2,6,7] Conversely, reversal is recommended when the INR is markedly elevated or there is clinically significant bleeding.[2,7] The speed and extent of reversal should be balanced against the risk of recurrent thromboembolism in patients who require therapeutic anticoagulation. For example, an over-anticoagulated patient with a prosthetic mitral valve may develop fatal thrombosis if supratherapeutic anticoagulation is rapidly and fully reversed.

Three approaches used to reverse warfarin-induced coagulopathy are as follows: (1) stop warfarin therapy; (2) administer **vitamin K_1** (PO or IV); and (3) replace deficient coagulation factors using either **fresh frozen plasma**, **3- for 4-factor prothrombin complex concentrate**, or **recombinant activated factor VII (Figure 239-1)**.[2,8-11] In asymptomatic patients with an elevated INR of 4.5 to 10 due to warfarin, oral vitamin K_1 1.0 to 2.0 milligrams will produce a measurable reduction in INR by 16 hours, with a therapeutic level by the second day.[6,7] In asymptomatic patients with an INR >10, oral vitamin K_1 2 milligrams is also effective, although the reduction in INR takes longer. Although low-dose oral vitamin K_1 carries a small risk for patients who require therapeutic anticoagulation, it is recommended that the emergency physician consult an appropriate specialist before using vitamin K_1 to reverse anticoagulation in stable patients.

IV vitamin K_1 carries a rare but serious, non–dose-dependent risk of anaphylaxis and should not be used for routine reversal of therapeutic

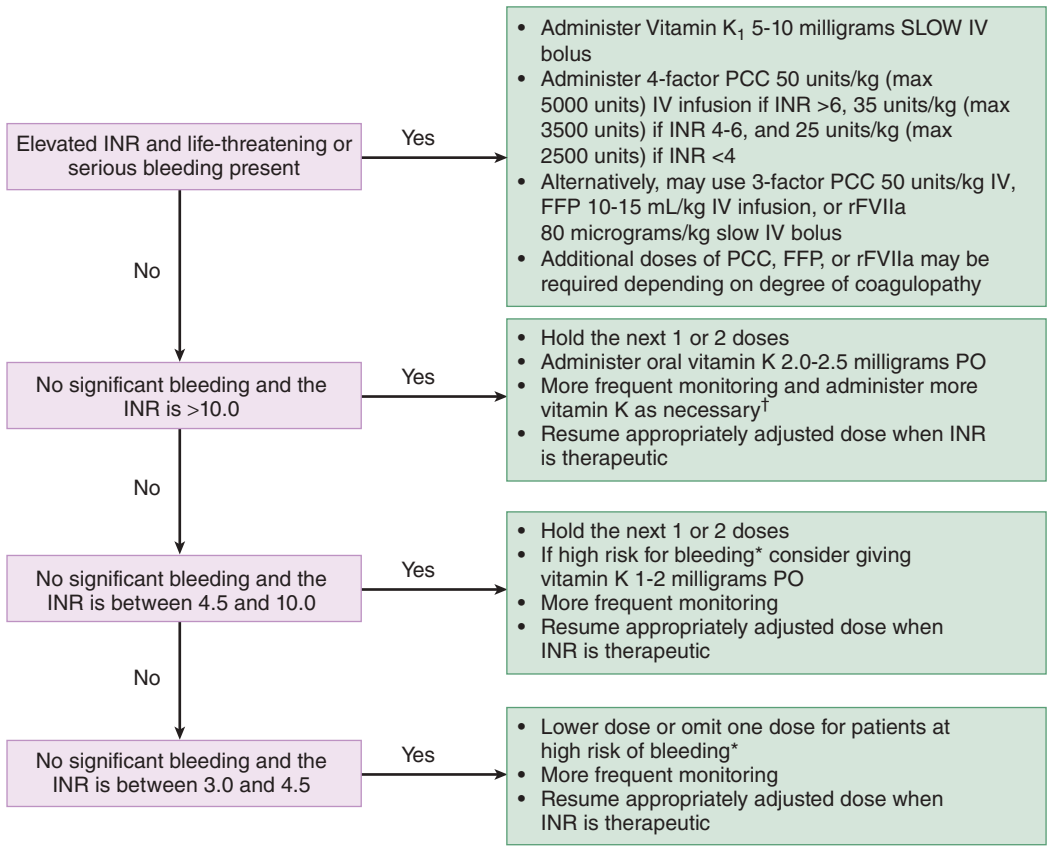

FIGURE 239-1. Management of prolonged INR (warfarin-induced coagulopathy). *High risk of bleeding: age >75 years, concurrent antiplatelet drug use, polypharmacy, liver or renal disease, alcoholism, recent surgery, or trauma. †There are no validated tools to predict risk of short-term major bleeding in patients with severe over-anticoagulation. The decision to admit for observation relies on physician judgement. FFP = fresh frozen plasma; 4-factor PCC = Prothrombin Complex Concentrate containing coagulation factors 2, 7, 9, and 10; 3-factor PCC = Prothrombin Complex Concentrate containing coagulation factors 2, 9, and 10; rFVIIa = recombinant activated factor VII.

over-anticoagulation. For patients who require continued anticoagulation, IV administration also carries the risk of overcorrection not associated with oral use. IV vitamin K_1 should be restricted to those patients with life-threatening bleeding[2] and to symptomatic patients poisoned by an excessive ingestion of warfarin (e.g., suicidal overdose). Generally, overdose patients do not require long-term therapeutic anticoagulation, and reversal does not carry the risk of recurrent thrombosis.

The fastest method of reversing therapeutic over-anticoagulation is with coagulation factor infusion, using either fresh frozen plasma, prothrombin complex concentrates, or recombinant activated factor VII.[8-11] For patients with intense anticoagulation (INR >10) who require only partial reversal, fresh frozen plasma 10 to 15 mL/kg would be expected to restore coagulation factors to about 30% of normal, corresponding to an INR of 1.7 to 1.8. Disadvantages of fresh frozen plasma include potential fluid overload, which can be difficult to reverse with furosemide. Some institutions provide **"universal donor" fresh frozen plasma**, which is derived from AB+ donors and thus contains no AB antibodies. If available and indicated, it can be given without a type and cross-match of blood of the recipient and as soon as it is defrosted (20 to 30 minutes).

For patients with life-threatening hemorrhage who require rapid, complete reversal, such as warfarin-associated intracranial hemorrhage, **prothrombin complex concentrates** or recombinant activated factor VII are preferred.[12-14] Four-factor prothrombin complex concentrate is preferred over the 3-factor product, and dosing is according to the patient's INR level; expert consultation is advised prior to administration. Additional doses of these products may be required depending on the degree of coagulopathy.

DIRECT THROMBIN INHIBITORS

Dabigatran etexilate, an oral direct thrombin inhibitor, is used to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation, and the risk of recurrent DVT or PE after treatment of the acute episode.[1,15-18] After ingestion, dabigatran etexilate is converted to the active agent dabigatran by esterase, achieving peak serum concentrations in 2 hours with a terminal elimination half-life of 12 to 17 hours. Dabigatran is a reversible inhibitor of both circulating and clot-bound thrombin. Dabigatran has more predictable pharmacologic activity than warfarin, a broad therapeutic window, low interpatient variability, and no significant drug–drug (except for rifampin) or drug–diet interactions. Monitoring with standard coagulation tests during therapeutic use is not required. In routine use in patients with atrial fibrillation, dabigatran is generally safer than warfarin, with the notable exception of a higher risk of major GI bleeding. As with warfarin, the concomitant use of nonsteroidal anti-inflammatory drugs and other antiplatelet medications greatly increases the risk of bleeding for patients taking dabigatran.

Prothrombin time and the aPTT are insensitive to the activity of dabigatran, whereas the thrombin clotting time is typically overly sensitive.[1,19] The ecarin clotting time has a linear dose response through the range of dabigatran concentrations seen during clinical use, but this test is not commonly available. **For practical purposes, a normal thrombin clotting time excludes a significant coagulopathy due to dabigatran.**[1]

Only about 15% to 20% of absorbed dabigatran is metabolized, and the remainder is excreted unchanged in the urine. It is therefore important to maintain urinary output in patients with active bleeding while taking dabigatran to enhance drug elimination. **If emergency measures are required to reverse the anticoagulant effect of dabigatran, hemodialysis can be effective with removal of 60% or more of the drug within 2 hours.**[1,11,20]

Idarucizumab, a monoclonal antibiotic fragment that binds dabigatran, is in development to reduce serious bleeding or reverse anticoagulation in patients who require an urgent procedure in patients taking dabigatran.[20] Until idarucizumab is available, observational experience suggests that both recombinant activated FVII (rFVIIa) or activated prothrombin complex concentrate (aPCC) can reverse the anticoagulative effect of dabigatran,[21,22] whereas fresh frozen plasma does not.[1]

FACTOR Xa (FXa) INHIBITORS

Rivaroxaban and apixaban, oral direct FXa inhibitors, are used for the prevention of venous thromboembolism in adult patients undergoing elective hip or knee replacement surgery and for the reduction of the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation.[1,23] Edoxaban, a third orally active direct FXa inhibitor is likely to become available soon for similar indications.[24] These FXa inhibitors have predictable pharmacologic properties and do not require routine laboratory monitoring.

The effect of rivaroxaban or apixaban on blood clotting is not easy to reliably measure. Although FXa inhibitors demonstrate a dose-dependent increase in prothrombin time, the sensitivity of this assay varies according to the thromboplastin reagent used. The activated partial thromboplastin time is less sensitive than the prothrombin time for measuring effects of FXa inhibitors. The currently available anti–FXa activity assays must be adjusted for the specific FXa inhibitor used.

Rivaroxaban and apixaban are metabolized by the liver, with about two thirds of the drug and metabolites excreted by the kidneys with an elimination half-life of 5 to 12 hours in healthy individuals. Discontinuation of the drug for at least 24 hours could be sufficient when there is no imminent need for reversal, as in elective or nonurgent procedures. However, in patients with renal impairment and the elderly, additional time for clearance would be required before any surgical procedures are undertaken. There is an increased risk of stroke or other thrombotic event when rivaroxaban is suddenly discontinued in patients with nonvalvular atrial fibrillation.[25] When possible, another anticoagulant should be substituted.

Andexanet alfa, a recombinant modified FXa, is in development for treatment of major bleeding due to FXa inhibitors, but is currently not available for clinical use. Due to high plasma protein binding, rivaroxaban or apixaban are not readily removed by dialysis. Current options for the emergency reversal include transfusion of blood products such as fresh frozen plasma, prothrombin concentrate complex, or recombinant activated factor VII.[1,23,26]

Administration of **activated charcoal** within 2 hours of taking an oral anticoagulant may adsorb the drug from the intestines before it reaches the plasma. It would be reasonable to administer activated charcoal to a patient who has deliberately or accidentally ingested an inappropriate amount of dabigatran, rivaroxaban, or apixaban, and likewise in a patient with significant bleeding who has recently ingested even a therapeutic dose.

HEPARINS AND POLYSACCHARIDES

UNFRACTIONATED HEPARIN (UFH)

Unfractionated heparin (UFH) is a heterogeneous mixture of polysaccharides ranging in molecular weight from 3 to 30 kD, with most commercial preparations possessing a mean molecular weight of about 15 kD, corresponding to about 45 saccharide units.[27,28] The anticoagulant effect of UFH requires binding to antithrombin (previously named antithrombin III), and heparins are therefore "indirect" anticoagulants.[27,28] Although the UFH–antithrombin complex interferes with several activated factors in both the extrinsic and common coagulation pathways (Xa, IXa, XIa, and XIIa, and thrombin), the primary anticoagulant effect of heparin is due to thrombin and FXa inhibition. The majority of heparin's anticoagulant effect is dependent on a unique pentasaccharide sequence found in only about one third of heparin molecules. Variations in polysaccharide chain lengths found in UFH likely contribute to the unpredictable nature of heparin's dose-response relationship.

UFH is given parenterally with a half-life (30 to 150 minutes) that depends on the dose and route. Weight-based IV UFH dosing protocols are the most reliable approach for achieving a therapeutic effect and preventing further thrombosis during acute thromboembolic events.[28] Subcutaneous UFH heparin is not recommended for the treatment of acute thromboembolic disease because the bioavailability via this route of administration ranges from 10% to 90%, depending on the dose. However, subcutaneous UFH can be used to prevent thromboembolism (**Table 239-1**). **Because UFH interferes with most laboratory investigations for hypercoagulable states, these tests should ideally be ordered before the patient is anticoagulated.** Neither UFH nor low-molecular-weight heparin crosses the placenta; consequently, both are safe to use in pregnancy.

UFH has an unpredictable anticoagulation effect, requires frequent monitoring, binds nonproductively to vascular endothelium and ubiquitous plasma proteins, and actually activates platelets by interacting with platelet factor 4. The unpredictable inhibition of thrombin by heparin is attributable to a low bioavailability from extensive nonspecific binding to serum proteins, macrophages, and endothelial cells. The anticoagulant effect of UFH is generally monitored with the activated partial thromboplastin time (**Table 239-1**).[28] For most purposes, a therapeutic range for UFH can be either an activated partial thromboplastin time of 1.5 to 2.5 times the "normal" value, a heparin level of 0.2 to 0.4 units/mL when assayed by protamine titration, or a level of 0.3 to 0.7 units/mL when measured for anti–FXa activity. UFH can increase the prothrombin time by a variable amount, typically 1 to 5 seconds depending on the heparin concentration and the thromboplastin reagent used in the assay.

LOW-MOLECULAR-WEIGHT HEPARIN (LMWH)

Low-molecular-weight heparins (LMWH) are polysaccharide chains ranging in molecular weight from 2 to 9 kD, with commercial preparations (enoxaparin, dalteparin, and tinzaparin) possessing a mean molecular weight of approximately 4 to 5 kD, corresponding to about 15 saccharide units. LMWH possesses many clinical advantages compared to the parent compound (**Table 239-3**).[27] Both UFH and LMWH exert their anticoagulant effect by binding to and enhancing the activity of antithrombin. This interaction is mediated by a unique pentasaccharide sequence that induces a conformational change in antithrombin, enhancing binding to and inaction of thrombin and factors Xa, IXa, XIa, and XIIa. Inhibition of thrombin is facilitated by an additional 13-saccharide group that brings the key binding regions of antithrombin and thrombin into contact. However, only the specific pentasaccharide sequence is necessary to bind to antithrombin for effective inhibition of FXa. UFH inhibits FXa and thrombin in roughly equal proportions (anti–FXa to anti-thrombin activity ratio about 1) because chains of at least 18 saccharide units predominate. In contrast, more than half of LMWH molecules are smaller than 18 saccharide units, resulting in a reduced ability to inactivate thrombin and an enhanced affinity for inactivating FXa (anti–FXa to anti-thrombin activity ratio between 2:1 and 4:1).[28]

LMWH is cleared by the kidneys, and bleeding complications due to accumulation of the agent can occur in patients with significant renal impairment. Appropriate dosing of LMWH in patients with severe renal insufficiency (creatinine clearance <30 mL/min) is unclear. In patients with severe renal insufficiency, it is suggested that either a reduced dose of enoxaparin (50% of the usual amount) be used or UFH be administered instead.[28] Obese patients (body mass index >30) should receive weight-based LMWH dosing.[28]

The plasma half-life of LMWH is two to four times longer than UFH, allowing for once- or twice-daily dosing. LMWH has a decreased binding affinity for plasma proteins, endothelial cells, and macrophages, thus yielding a more predictable anticoagulant and dose-response relationship, allowing for SC administration at fixed dosages. There are greatly reduced interactions with the platelet factor 4 receptor, resulting in a much lower incidence of heparin-induced thrombocytopenia than that seen with UFH. Laboratory monitoring of the activity of LMWH is unnecessary in most patients. If required, anti–FXa activity obtained 4 hours after drug administration is recommended, with a therapeutic range of 0.6 to 1.0 units/mL for enoxaparin.

TABLE 239-3 Advantages of Low-Molecular-Weight Heparin over Unfractionated Heparin

Pharmacologic Effects	Clinical Benefit
Quick and predictable SC absorption	More reliable level of anticoagulation
More stable dose response	Eliminates need for monitoring
Resistance to inhibition by platelet factor 4	Decreased incidence of thrombocytopenia
Decreased antiheparin antibody production	Greater antithrombotic effects
Greater anti–FXa activity	Potential for reduced bleeding
Less anti-thrombin activity	Absence of "rebound"
Ease of administration	Outpatient therapy

FONDAPARINUX

Fondaparinux is a synthetic pentasaccharide that binds to antithrombin and enhances its affinity for FXa, but not thrombin.[15,28] Fondaparinux is administered by SC injection using fixed doses stratified according to the indication and body weight (**Table 239-1**). The drug has a terminal half-life of about 17 hours, which allows for once-daily dosing. Laboratory monitoring of the activity of fondaparinux is unnecessary in most patients. If required, a fondaparinux-specific anti–FXa activity assay measured 3 hours after drug administration is recommended, but a therapeutic range has not been established.

COMPLICATIONS AND MANAGEMENT

The two major complications of heparin are bleeding and heparin-induced thrombocytopenia.[28-30] Up to one third of patients receiving UFH develop some form of bleeding complication, with a 2% to 6% incidence of major bleeding.[28] An increased risk of up to 20% for major bleeding is associated with concomitant conditions, such as recent surgery or trauma, renal failure, alcoholism, malignancy, liver failure, and GI bleeding, as well as the concurrent use of warfarin, fibrinolytics, steroids, or antiplatelet drugs.

Bleeding in patients being treated with UFH is managed according to the clinical severity and less by activated partial thromboplastin time level **(Table 239-4)**.[2,28] Heparin-associated bleeding is not always reflected by a supratherapeutic activated partial thromboplastin time, so if bleeding develops during UFH therapy, heparin administration should be stopped immediately. **Although UFH half-life is dose dependent (30 to 150 minutes), its anticoagulation effect can last up to 3 hours.** Observation may be appropriate in less severe cases, with serial activated partial thromboplastin time used to determine when therapy may be resumed. Although **protamine** can reverse the anticoagulant effect of UFH, the adverse effects of protamine are significant. Protamine should be given slowly IV over 1 to 3 minutes and should not exceed 50 milligrams in any 10-minute period. However, because the half-life of protamine is shorter (7 minutes) than heparin, an anticoagulant rebound may occur, requiring a second treatment. Reversal of subcutaneously administered heparin may require repeated or prolonged protamine administration. Allergic reactions are possible, and approximately 0.2% of patients receiving protamine develop anaphylaxis. Thus, protamine should be reserved for major bleeding complications.

Platelet count may fall in 10% to 20% of patients 2 to 3 days following initiation of UFH treatment due to nonimmunologic direct platelet aggregation. This process is sometimes termed "heparin-associated thrombocytopenia" and was previously termed "type I heparin-induced thrombocytopenia." The platelet nadir is typically no lower than 100,000/mm^3 (100×10^9/L), there is no risk for associated thrombosis, and platelet count recovers within 4 days despite continued heparin treatment.

Heparin-induced thrombocytopenia (previously termed type II heparin-induced thrombocytopenia or HIT) is a syndrome due to the formation of immunoglobulin G or immunoglobulin M autoantibodies directed against both heparin and platelet factor 4 that activates platelets, producing both thrombocytopenia and a tendency for thrombosis.[30] Thrombosis may involve the skin (similar to warfarin-induced cutaneous necrosis), major arteries (e.g., ischemic limbs), or the veins (e.g., recurrent venous thrombosis or pulmonary embolism). The onset of HIT is usually 5 to 10 days after heparin treatment is started but may be sooner for patients who developed an antibody from a previous heparin exposure. Although rare, one of the earliest clues is an anaphylactoid reaction within 30 minutes of receiving an IV bolus of heparin, often while the patient is in the ED. Patients who exhibit acute systemic reactions such as fevers, chills, hypertension, tachycardia, dyspnea, or chest pain should be evaluated for HIT by obtaining an immediate platelet count. Because a decrease in platelet count may be transient and under these circumstances heparin is often stopped, the diagnosis can be missed if there is a delay in obtaining the platelet count.[30]

The incidence of HIT is variable and influenced by the specific heparin preparation used, dose, duration, and patient characteristics. In

TABLE 239-4 Emergency Treatment of Bleeding Complications of Antithrombotic Therapy

Agent	Management
Heparins	
Minor bleeding	Immediate cessation of heparin administration. Supratherapeutic aPTT not always present. Anticoagulation effect lasts up to 3 h from last IV dose. Observation with serial aPTT may be sufficient.
Major bleeding	Protamine 1 milligram IV per 100 units of total amount of IV UFH administered within the past 3 h. Protamine is given slowly IV over 1–3 min with a maximum of 50 milligrams over any 10-min period. Protamine has an anaphylaxis risk. Protamine does not completely reverse low-molecular-weight heparin. Enoxaparin: Protamine 1 milligram IV (maximum dose, 50 milligrams) for every 1 milligram of enoxaparin given in the previous 8 h. If 8–12 h since last enoxaparin dose, give protamine 0.5 milligram IV for every 1 milligram of enoxaparin given. Dalteparin and tinzaparin: Protamine 1 milligram IV per every 100 units of dalteparin or tinzaparin given. If aPTT (measured 2–4 h after the protamine infusion) remains prolonged, give a second dose of protamine 0.5 milligram IV per 100 units of dalteparin or tinzaparin.
Pentasaccharides	
Fondaparinux	Antithrombotic effect of fondaparinux is 24–30 h. For life-threatening bleeding, anecdotal evidence suggests rFVIIa 90 micrograms/kg IV is effective.
Oral Direct Thrombin Inhibitors	
Dabigatran	Oral activated charcoal if recent or excessive ingestion. Maintain urine output. Consider hemodialysis or charcoal hemoperfusion For life threatening bleeding, consider in descending order: aPCC, rFVIIa, or PCC. For severe bleeding or urgent reversal, Idarucizumab (when available), dose not established.
Oral Factor Xa Inhibitors	
Rivaroxaban Apixaban	For major bleeding, experimental evidence suggests PCC can reverse the antithrombotic effect of rivaroxaban. For major bleeding, andexanet alfa (when available), dose not established.
Oral Antiplatelet Agents	
Aspirin	Desmopressin 0.3–0.4 microgram/kg IV over 30 min. Platelet transfusion to increase count by 50,000/mm^3 (typically requires one single donor apheresis-collected platelet concentrate or 6 units of random donor platelets). Aspirin-induced platelet inhibition may last for 7 d, so repeat platelet transfusions are sometimes required.
Other antiplatelet agents: clopidogrel, prasugrel, ticagrelor	Platelet transfusion to increase count by 50,000/mm^3 (typically requires one single donor apheresis-collected platelet concentrate or 6 units of random donor platelets). Desmopressin 0.3–0.4 microgram/kg IV over 30 min. NSAID-induced platelet inhibition typically lasts <1 d. Clopidogrel-, prasugrel-, or ticagrelor-induced platelet inhibition may last up to 5–7 d.
Fibrinolytics	
Minor external bleeding	Manual pressure
Significant internal bleeding	Immediate cessation of fibrinolytic agent, antiplatelet agent, and/or heparin. Reversal of heparin with protamine as above. Typed and cross-matched blood ordered with verification of aPTT, CBC, thrombin clotting time, and fibrinogen level. Volume replacement with crystalloid and packed red blood cells as needed.
Major bleeding or hemodynamic compromise	All measures listed for significant internal bleeding. Fibrinogen concentrate 70 milligrams/kg IV, and recheck fibrinogen level; if fibrinogen level <100 milligrams/dL, repeat fibrinogen concentrate dose. If bleeding persists after fibrinogen concentrate or despite fibrinogen level >100 milligrams/dL, administer FFP 2 units IV. If bleeding continues after FFP, administer an antifibrinolytic such as aminocaproic acid 5 grams IV over 60 min followed by 1 gram/h continuous IV infusion for 8 h or until bleeding stops, or tranexamic acid 10 milligrams/kg IV every 6–8 h. Consider platelet transfusion.
Intracranial hemorrhage	All measures listed for significant internal and major bleeding with hemodynamic compromise. Immediate neurosurgery consultation.

Abbreviations: aPCC = activated prothrombin complex concentrate (not available in the United States); aPTT = activated partial thromboplastin time; FFP = fresh frozen plasma; NSAID = nonsteroidal anti-inflammatory drug; PCC = prothrombin complex concentrate; rFVIIa = recombinant activated factor VII; UFH = unfractionated heparin.

general, between 1% and 3% of postoperative patients treated with UFH for 4 to 14 days will develop HIT, compared with only 0.1% to 1.0% of medical or obstetric patients who receive UFH for a similar duration. In general, HIT is approximately 10 times less frequent in patients treated with LMWH products. With HIT, the platelet count nadir is variable, typically 20,000 to 150,000/mm^3 (20 to 150 × 10^9/L). During treatment with UFH, it is recommended that a baseline platelet count be obtained and the count be repeated at 24 hours and every 2 to 3 days thereafter during the duration of therapy. A drop of 50% or more from baseline is considered evidence of HIT, even if the platelet count is within a normal range. It is recommended to assess for recent use of UFH or LMWH before instituting heparin therapy for a new venous thrombosis that may, in fact, be a thrombotic complication of HIT.

With HIT, all heparin therapy (including "heparin lock" IVs and heparin-coated catheters) should be stopped. Protamine is not effective against the immune-mediated response. Platelet transfusion is not indicated because bleeding is not usually a manifestation of HIT and may precipitate thrombosis. The platelet count generally returns to normal in 4 to 6 days after heparin discontinuation. During the recovery phase, the risk of arterial or venous thrombosis is substantially elevated, and the potential complications include gangrene, stroke, and myocardial infarction. LMWH is not recommended to prevent thrombosis during this recovery period because of cross-reactivity between LMWH and the antiplatelet antibody. Additionally, warfarin should not be started until the platelet count has normalized and the patient is sufficiently anticoagulated by an alternative measure to avoid precipitating arterial or venous thrombosis or producing skin necrosis. Anticoagulation with a non-heparin anticoagulant, such as danaparoid, lepirudin, fondaparinux, or bivalirudin, is recommended for strongly suspected or confirmed cases of HIT, even in the absence of symptomatic thrombosis.[30,31]

In general, LMWH preparations cause less bleeding than UFH. Other reported side effects of LMWH include local skin reaction, pruritus, and rarely skin necrosis. Protamine will neutralize the inhibitory effect of LMWH on thrombin but not the inhibitory effect on FXa. Thus, protamine will not completely reverse the anticoagulant effect of LMWH (**Table 239-4**).

For fondaparinux-associated bleeding, limited data suggest that activated recombinant factor VII and activated prothrombin complex concentrates can reverse the coagulopathy.[22,32,33]

HIRUDINS

Hirudins (hirudin and lepirudin) and hirudin analogues (bivalirudin and argatroban) are parenteral direct thrombin inhibitors, possessing several potential advantages over heparin.[17,28] Unlike heparin, direct thrombin inhibitors are capable of inhibiting both circulating and clot-bound thrombin, do not inhibit other coagulation pathway or fibrinolytic enzymes, do not require antithrombin as a cofactor for activity, and do not interact with platelet factor 4 or plasma proteins. Therefore, direct thrombin inhibitors have a more predictable anticoagulant effect than UFH. Hirudin, lepirudin, and argatroban are used for anticoagulation in patients with heparin-induced thrombocytopenia.[30,31] Bivalirudin and argatroban are potential alternatives to UFH and LMWH for the treatment of acute coronary syndrome with percutaneous coronary intervention.[34,35]

The primary adverse effect of direct thrombin inhibitors is bleeding, and the majority of bleeding events occur at invasive sites. Because the half-life of hirudin and its analogues is relatively short (<2 hours), and an antidote is not currently available, management of hemorrhage may require only stopping the IV infusion and waiting. Coagulation factor replacement with fresh frozen plasma or prothrombin complex concentrates can be used if bleeding persists.

ANTIPLATELET AGENTS

ASPIRIN

Aspirin irreversibly blocks cyclooxygenase, an enzyme that in platelets catalyzes the conversion of arachidonic acid to thromboxane A_2, and in the blood vessel wall promotes prostacyclin synthesis (**Table 239-5**).[36,37] The net effect of aspirin in ischemic arterial beds depends on the balance between reduction in thromboxane A_2 (a vasoconstrictor and platelet-aggregation inducer) and reduction in prostacyclin (a vasodilator and platelet-aggregation inhibitor). Aspirin's antithrombotic effect can be seen with doses as low as 30 milligrams, but for reliable antiplatelet effect, an initial dose of 162 to 325 milligrams is recommended (**Table 239-1**).

Aspirin is quickly absorbed in the upper GI tract (unless consumed in an enteric-coated formulation), reaches peak blood concentrations in 20 to 40 minutes, and circulates with a half-life of 3 to 4 hours. However, cyclooxygenase inactivation is irreversible and lasts for the life span of the platelet. Only non–enteric-coated aspirin should be administered when prompt onset of action is necessary, as in patients with acute coronary syndrome.[38,39]

Side effects of aspirin use are mainly GI and are dose-related. The side effects may be reduced in the maintenance therapy setting with concomitant use of antacids, enteric coating, and buffering agents. Aspirin should be avoided in patients with known hypersensitivity and used cautiously in those with bleeding disorders or severe hepatic disease. Active GI hemorrhage (e.g., bleeding peptic ulcer) is a contraindication to aspirin use. However, in acute coronary syndrome with occult GI bleeding (e.g., guaiac-positive stool), most experts favor aspirin use with careful monitoring. Daily aspirin therapy is advocated in the prevention of cardiovascular events in patients with known cardiovascular disease.

TABLE 239-5 Oral Antiplatelet Agents

	Class/Mechanism of Action	Type of Inhibition	Time to Peak Effect	Half-Life	Duration of Antiplatelet Effect	Typical Dose
Aspirin	Nonselective cyclooxygenase inhibitor	Irreversible	20–40 min	3–4 h	Up to 7 d	162–325 milligrams PO once per day
Clopidogrel	ADP receptor inhibitor Prodrug, requires production of active metabolite	Irreversible	2–4 h	7–8 h	Up to 7 d	300 milligrams PO loading dose (consider 600 milligrams if PCI is planned) followed by 75 milligrams PO once per day
Prasugrel	ADP receptor inhibitor Prodrug, requires production of active metabolite	Irreversible	1–2 h	7–8 h	5–7 d	60 milligrams PO loading dose, followed by 10 milligrams (5 milligrams if <60 kg) PO once per day
Ticagrelor	ADP receptor inhibitor	Reversible	2–3 h	7–9 h	3–5 d	180 milligrams PO loading dose, 90 milligrams PO twice per day
Dipyridamole	Multiple: reduces platelet aggregation, vasodilator, weak phosphodiesterase inhibitor	Reversible	N/A	Biphasic: 40 min and 10 h	1–2 d	200 milligrams extended-release PO twice per day (usually combined with low-dose aspirin)
Cilostazol	Phosphodiesterase inhibitor: reduces platelet aggregation, vasodilator	Reversible	N/A	11–13 h	3–4 d	100 milligrams PO twice per day

Abbreviations: ADP = adenosine diphosphate; N/A = not applicable; PCI = percutaneous coronary intervention.

The benefits of patients without cardiovascular disease are modest and almost offset by the risk of hemorrhagic stroke and major bleeding.[40,41] In general, daily aspirin therapy does reduce the incidence of myocardial infarction, ischemic stroke, and sudden cardiovascular death, with an increased risk of major bleeding events, primarily GI, and cerebral hemorrhage. The overall effect tends to be beneficial, although the magnitude of change with individual outcomes does vary with indication and between genders.

Nonsteroidal anti-inflammatory drugs reversibly inhibit platelet cyclooxygenase and have the potential to reduce the antiplatelet efficacy of aspirin. Myocardial infarction patients have an increased risk of mortality, reinfarction, heart failure, and shock if taking nonsteroidal anti-inflammatory drugs within 7 days of presentation[42] and up to 90 days after the acute event.[43] Current acute coronary syndrome guidelines contain admonitions against the use of nonsteroidal anti-inflammatory drugs.[44-47]

Upper GI irritation is the most common side effect of aspirin therapy.[37] Some patients are markedly sensitive to aspirin, such that even low doses lead to markedly prolonged bleeding times and risk of severe clinical hemorrhage, particularly related to surgery or trauma. Uremia or the combination of ethanol and aspirin are two circumstances where patients are especially sensitive to bleeding induced by aspirin.

Management of acute aspirin-induced or nonsteroidal anti-inflammatory drug–induced hemorrhage involves the transfusion of enough normal platelets to increase the platelet count by 50,000/mm^3 (50×10^9/L), a level that will halt most bleeding. Alternatively, desmopressin alone or combined with platelet transfusion can reverse the effect of aspirin on platelet function.[22] Because of the irreversible effect of aspirin on platelets, the hemostatic compromise might last for up to 7 days after aspirin has been discontinued, and platelet transfusions may have to be repeated daily.

ADENOSINE DIPHOSPHATE RECEPTOR AGENTS

Clopidogrel, prasugrel, ticagrelor, and ticlopidine inhibit platelet activation by blocking the adenosine diphosphate receptor.[37,47] These agents are also termed "membrane-deforming" agents because by inhibiting the adenosine diphosphate receptor, the adjacent region of the platelet membrane containing the fibrinogen receptor is deformed and the fibrinogen receptor is rendered ineffective.

Clopidogrel is a prodrug that is metabolized into an irreversible adenosine diphosphate receptor inhibitor. Rapidly absorbed from the GI tract, oral doses of 600 milligrams result in a full antiplatelet effect by 2 hours that is sustained for up to 48 hours. Platelet function typically returns to normal 7 days after the last clopidogrel dose. Clopidogrel is used for the treatment of acute coronary syndrome[46,47] and established peripheral artery disease,[48] as well as for secondary prevention of myocardial infarction[49] and ischemic stroke.[50] Although clopidogrel is generally well tolerated, adverse effects include dyspepsia, rash, and diarrhea. Clopidogrel can also be used in patients who have a history of aspirin hypersensitivity or major GI intolerance.

The active metabolite is produced by the cytochrome P-450 system, principally isoenzyme 2C19 (CYP2C19). Patients with a diminished CYP2C19 metabolizer status have a lessened antiplatelet response to clopidogrel. The reported frequency for poor CYP2C19 metabolizer status varies by ethnic background: approximately 2% for whites, 4% for blacks, and 14% for Chinese. A patient's CYP2C19 metabolizer status can be determined with genotype testing, and a higher dose regimen (600-milligram loading dose followed by 150 milligrams once daily) is suggested in poor metabolizers, although this dose regimen has not been validated in clinical outcome trials.[51] Omeprazole is an inhibitor of CYP2C19 and reduces the antiplatelet activity of clopidogrel if both drugs are given within 12 hours of each other. While the effect on clinical outcome from this interaction is variable according to the patient's risk for cardiovascular events, it is prudent to not give omeprazole in the ED to patients receiving clopidogrel for acute coronary syndrome.[52]

Prasugrel, like clopidogrel, is a prodrug that is converted to the active metabolite that is an irreversible inhibitor of the adenosine diphosphate receptor on platelets.[47] Prasugrel is used in the treatment of acute coronary syndrome.[49] Compared to clopidogrel, prasugrel has an increased risk of bleeding and is less effective in patients with a history of a stroke or transient ischemic attack, patients >75 years of age, and patients with a body weight of <60 kg.

Ticagrelor is a reversible adenosine diphosphate receptor antagonist that does not need to be converted by the liver into an active metabolite.[47] Ticagrelor is used in a broad range of acute coronary syndrome patients.[47,53] Compared with clopidogrel, ticagrelor reduces the subsequent deaths from all cardiovascular causes or myocardial infarction.[54] There is a modest increase in the risk of major bleeding not related to coronary artery bypass graft surgery with ticagrelor and a trend toward more intracranial bleeding.

Ticlopidine is associated with significant risk for hematologic problems, such as neutropenia and thrombotic thrombocytopenic purpura. Therefore, ticlopidine is now rarely used in the United States.

Antiplatelet therapy is a risk factor for increased intracranial bleeding and worse outcome in closed head injury.[55] The observed risk is highest with clopidogrel.[55] Uncontrolled bleeding in patients on adenosine diphosphate receptor antagonist therapy should be treated with supportive therapy, platelet transfusion, and possibly desmopressin.[22]

PHOSPHODIESTERASE INHIBITORS

Dipyridamole is both a vasodilator and antiplatelet agent.[37,56] The specific antiplatelet effects are multiple and include reversible phosphodiesterase inhibition. Clinical efficacy of dipyridamole appears to be enhanced by formation into an extended-release preparation.[56] Current recommendations highlight the use of dipyridamole when combined with aspirin for the secondary prevention of stroke or transient ischemic attacks.[50,57] A fixed combination of aspirin, 25 milligrams, and extended-release dipyridamole, 200 milligrams PO twice a day, is commonly used for this indication. Dipyridamole is occasionally used in the standard formulation (not extended release) for angina prophylaxis and the prevention of prosthetic cardiac valve thrombosis when combined with warfarin or aspirin where doses of 50 to 100 milligrams PO three or four times a day are typical. Common adverse side effects include headache, dizziness, flushing, and abdominal pain.

Cilostazol is a strong reversible phosphodiesterase inhibitor in addition to having other effects on platelet metabolism.[56] Cilostazol is used to increase walking distance in patients with peripheral arterial disease[58] and reduce the incidence of stroke in patients with cerebrovascular disease.[50]

GLYCOPROTEIN IIB/IIIA ANTAGONISTS

During platelet aggregation, fibrinogen binds to the glycoprotein platelet-surface IIb/IIIa receptor. Thus, fibrinogen attached to glycoprotein IIb/IIIa receptors connecting adjacent platelets represents the final common pathway for platelet aggregation. Three parenteral glycoprotein IIb/IIIa receptor inhibitors are currently available (**Table 239-6**).[28,59] These agents are all administered as an initial IV loading dose (bolus for abciximab and eptifibatide, and 30-minute infusion for tirofiban) followed by a continuous IV infusion. Abciximab is a noncompetitive glycoprotein IIb/IIIa inhibitor with a much longer platelet effect than its plasma half-life of 10 minutes; platelet function will take up to 48 hours to return to normal after discontinuing the infusion. Conversely, eptifibatide and tirofiban are competitive glycoprotein IIb/IIIa inhibitors, with a plasma half-life of approximately 2.5 and 2.0 hours, respectively, and functional platelet recovery is usually seen 3 to 5 hours after stopping either eptifibatide or tirofiban infusion.

Glycoprotein IIb/IIIa inhibitors produce the greatest benefit in acute coronary syndrome patients undergoing percutaneous coronary intervention.[60,61] Delaying initiation of eptifibatide to the time of percutaneous coronary intervention results in less bleeding with otherwise similar outcomes, suggesting that the preferred time for administration of glycoprotein IIb/IIIa inhibitors is in the cardiac catheterization laboratory, not in the ED.[62]

Patients receiving glycoprotein IIb/IIIa inhibitors have an increased risk for bleeding complications (often related to catheterization or coronary artery bypass surgery) but have no increased risk of intracranial hemorrhage. Treatment of major hemorrhage in patients on glycoprotein IIb/IIIa inhibitors requires red cell and platelet transfusions and replacement of coagulation factors as needed.

TABLE 239-6 Glycoprotein IIb/IIIa IV Antagonists

	Type	Mechanism of Action	Half-Life	Duration of Antiplatelet Effect	Loading Dose	Continuous Infusion
Abciximab	Monoclonal antibody fragment	Noncompetitive inhibition	10 min	24–48 h	0.25 milligram/kg IV bolus	0.125 micrograms/kg per min (maximum 10 micrograms/min) IV
Eptifibatide	Cyclic heptapeptide	Competitive inhibition	2.5 h	3–5 h	180 micrograms/kg IV bolus over 1–2 min (maximum 22.6 milligrams)	2 micrograms/kg per min (maximum 250 micrograms/min) IV
Tirofiban	Nonpeptide	Competitive inhibition	2 h	3–5 h	25 microgram/kg per min IV for 30 min	0.15 micrograms/kg per min

FIBRINOLYTICS

Although mechanisms vary, each fibrinolytic agent enhances the conversion of plasminogen to plasmin, which then enzymatically breaks apart the fibrin component of thrombi. Currently approved fibrinolytic agents include streptokinase, anistreplase, alteplase, reteplase, and tenecteplase.[63,64]

STREPTOKINASE AND ANISTREPLASE (FIRST GENERATION)

Streptokinase, derived from β-hemolytic streptococci, binds to and activates circulating plasminogen, converting it to plasmin, which in turn attacks fibrin. Circulating fibrinogen also undergoes plasmin-induced lysis, producing a state of "systemic fibrinolysis." Streptokinase is administered as a slow infusion (usually 1.0 to 1.5 million units IV over 60 minutes) and has a serum half-life of approximately 23 minutes, but in most patients, the fibrinolytic effect persists for up to 24 hours. Because of the prolonged systemic fibrinolytic state and increased risk of hemorrhage, anticoagulation with heparin is usually delayed following treatment with streptokinase.

Anistreplase, a modified active plasminogen-streptokinase complex, has an effect similar to that of streptokinase, but its chief advantage is that it can be administered as a slow bolus (usually 30 units IV over 5 minutes) and has a serum half-life of approximately 90 minutes. Anistreplase has similar benefits and adverse effects compared to streptokinase.

Both streptokinase and anistreplase are antigenic, with allergic reactions occurring in approximately 6% of patients treated with streptokinase. Antibodies to streptokinase develop approximately 5 days after treatment and persist for 6 months, so retreatment with streptokinase or anistreplase is not advised during this interval. In addition, streptokinase or anistreplase should not be administered within 12 months of a streptococcal infection.

ALTEPLASE, OR TISSUE PLASMINOGEN ACTIVATOR (SECOND GENERATION)

Alteplase, or tissue plasminogen activator, is a naturally occurring enzyme in vascular endothelial cells that directly cleaves a specific peptide bond in plasminogen, converting it to active plasmin. Alteplase has binding sites for fibrin, which would suggest specificity for activity in the thrombus and less systemic fibrinolysis.[65] Despite the in vitro clot specificity of alteplase, its clinical side effect profile is comparable to that of other fibrinolytics. The serum half-life of alteplase is 4 to 8 minutes, and it produces a shorter fibrinolytic state than streptokinase. Heparin is commonly administered shortly after the completion of alteplase infusion.[46,64] Unlike streptokinase and anistreplase, alteplase is not antigenic; allergic reactions occur in <2% of patients treated with alteplase and IV heparin. Depending on the indication, alteplase is given as a weight-based dose via an IV infusion over 60 to 90 minutes.

RETEPLASE AND TENECTEPLASE (THIRD GENERATION)

Both reteplase and tenecteplase are derived from modifications of the parent alteplase molecule, with the intent of improving both efficacy and safety.[65] Reteplase is a deletion mutant in which the fibronectin finger (high-affinity fibrin binding), epidermal growth factor, and kringle-1 (receptor binding) regions of the wild-type alteplase molecule have been deleted. These modifications prolong the half-life of reteplase to 15 minutes, nearly fourfold longer than alteplase, allowing for bolus administration of reteplase as opposed to infusion administration of alteplase.[46,64,65]

Tenecteplase is created using amino acid substitutions in four different regions of the alteplase molecule, with the intention of producing a product with a longer half-life, higher level of fibrin specificity, and extended duration.[65] The long half-life of tenecteplase (approximately 20 minutes) allows for weight-tiered bolus dosing. The specific amino acid substitutions produce a 14-fold greater fibrin specificity than alteplase and reduced systemic plasmin generation. Tenecteplase has a plasminogen activator inhibitor 1 resistance 80 times greater than alteplase, thus allowing for a longer association of tenecteplase with the fibrin-rich clot. In addition, tenecteplase does not stimulate an increase in thrombin-antithrombin complexes, in contrast to a fourfold increase following administration of streptokinase and a twofold increase after administration of alteplase, with the potential for reduced bleeding complications.

Despite theoretical advantages associated with genetic modification, neither reteplase nor tenecteplase demonstrates an absolute mortality or safety benefit in the treatment of ST-segment elevation myocardial infarction. Although bolus-dose fibrinolytics result in fewer medication errors, when compared with more complicated regimens, this has not translated into improved patient outcome.[66,67]

CONTRAINDICATIONS TO FIBRINOLYTIC THERAPY

All available fibrinolytic agents have systemic antithrombotic effects and possess the potential for serious hemorrhage. Fibrinolytic-induced bleeding can be minor (such as oozing at IV sites), major (defined as hemodynamic compromise or significant drop in hemoglobin), or catastrophic (intracranial hemorrhage). The prevalence with which bleeding occurs varies according to the condition being treated. For example, intracranial hemorrhage typically occurs in <1% of patients treated with fibrinolytics for acute myocardial infarction[46] but is seen in approximately 6% of patients treated with alteplase for acute ischemic stroke.[68] Also, the risk of hemorrhage is increased according to patient characteristics and the use of concomitant drugs that also vary according to the condition under treatment.[68] General contraindications to fibrinolytic therapy are designed to reduce the risk of major and catastrophic bleeding (**Table 239-7**).

COMPLICATIONS AND MANAGEMENT

The most significant complications of fibrinolytic therapy are hemorrhagic, and the most catastrophic complication is intracranial hemorrhage. Allergic reactions and anaphylaxis from streptokinase and anistreplase should be treated with diphenhydramine 50 milligrams IV and methylprednisolone 125 milligrams IV. Hypotension occurs in up to 10% of patients treated with either streptokinase or alteplase and is treated by slowing the fibrinolytic infusion rate and administering IV crystalloid, paying close attention to the patient's volume status.

To minimize the bleeding risks associated with fibrinolytic therapy, the following precautions should be observed: (1) avoid all unnecessary needle sticks; (2) avoid any arterial punctures; (3) limit venous access to easily compressible sites (e.g., avoid central venous lines, especially the jugular or subclavian veins); and (4) avoid both nasogastric tubes and nasotracheal intubation.

TABLE 239-7 General Contraindications to Fibrinolytic Therapy

Absolute
Active or recent (<14 d) internal bleeding
Ischemic stroke within the past 2–6 months
Any prior hemorrhagic stroke
Intracranial or intraspinal surgery or trauma within the past 2 months
Intracranial or intraspinal neoplasm, aneurysm, or arteriovenous malformation
Known severe bleeding diathesis
Current anticoagulant treatment (e.g., warfarin with INR >1.7 or heparin with increased aPTT)
Current use of a direct thrombin inhibitor or direct factor Xa inhibitor with evidence of anticoagulant effect by laboratory tests
Platelet count <100,000/mm^3 (<100 × 10^9/L)
Uncontrolled hypertension (i.e., blood pressure >185/110 mm Hg)
Suspected aortic dissection or pericarditis
Pregnancy
Relative*
Active peptic ulcer disease
Cardiopulmonary resuscitation for longer than 10 min
Hemorrhagic ophthalmic conditions
Puncture of noncompressible vessel within the past 10 d
Significant trauma or major surgery within the past 2 wk to 2 months
Advanced renal or hepatic disease

Abbreviation: aPTT = activated partial thromboplastin time.

*Concurrent menses is not a contraindication.

Careful monitoring of the patient is crucial. The hemoglobin level should be checked every 4 to 6 hours after fibrinolytic therapy is initiated. A fall in hemoglobin >1 to 2 grams/dL (0.6–1.2 mmol/L) should prompt a search for the source of blood loss. Most bleeding episodes (>70%) occur at vascular puncture sites, but intracranial, intrathoracic, retroperitoneal, GI, urologic, or soft tissue extremity hemorrhage may occur.

External bleeding at any site should be controlled with prolonged manual pressure (**Table 239-4**). Significant bleeding, especially from an internal site, mandates discontinuation of the fibrinolytic agent along with any antiplatelet agents and heparin. Volume replacement should be provided as necessary and supplemented with red blood cell transfusions if clinically indicated. The thrombin clotting time, activated partial thromboplastin time, platelet count, and fibrinogen level should be checked. Heparin administered within 4 hours of the onset of bleeding can be reversed with protamine.

Massive bleeding with hemodynamic compromise necessitates empiric coagulation factor replacement with cryoprecipitate (rich in fibrinogen) and/or fresh frozen plasma. If bleeding persists after appropriate cryoprecipitate and fresh frozen plasma replacement, an antifibrinolytic agent (e.g., aminocaproic acid or tranexamic acid) with or without platelets should still be administered. Fibrinolytic-associated intracranial hemorrhage requires an aggressive response with protamine (if the patient received heparin), cryoprecipitate, fresh frozen plasma, platelet transfusion, and an antifibrinolytic agent.

ANTIFIBRINOLTYIC AGENTS

Two agents are used clinically to inhibit the enzymatic degradation of fibrin by plasmin; tranexamic acid and aminocaproic acid (**Table 239-8**). Both agents are derivatives of the amino acid lysine, have low-molecular weight, can be administered both orally and IV, attach to several sites on plasminogen, prevent plasminogen from binding to fibrin, are minimally metabolized, and are primarily excreted by the kidney, but tranexamic acid has roughly 8 times the antifibrinolytic activity of aminocaproic acid.

These agents are used in hemorrhagic disorders to stop excessive bleeding and reduce perioperative blood transfusion requirements (**Table 239-9**).[69-72] Both agents had minimal use in emergency practice until a randomized clinical trial of the effect of TXA on mortality and vascular thrombotic events in 20,211 adult trauma victims was published

TABLE 239-8 Antifibrinolytic Agents

Agent	Suggested Initial Adult IV Dose for Emergent Indications*	Excretion	Elimination half-life
Tranexamic acid (TXA)	10 milligrams/kg IV over 10 min (max 1 g), repeat doses every 6–8 h	95% by kidney	3 h
Aminocaproic acid (ACA)	4–5 g IV over 1 h, then 1 g/h for 8 h or until bleeding stops (max 30 g/d)	65% by kidney	2 h

*Doses vary between indications and route, consult prescribing information for specifics.

TABLE 239-9 Emergent Conditions Where Antifibrinolytic Agents Have Been Used

Condition	Comment*
Adult trauma with significant hemorrhage (BP <90 mm Hg or HR >110 bpm) or considered at risk for significant hemorrhage	TXA IV reduces death from bleeding and all-cause mortality if administered within 3 h[74,76]
Postpartum hemorrhage	TXA IV may prevent and treat excessive postpartum hemorrhage[78]
Hemoptysis	TXA IV or PO may reduce the duration and volume of bleeding[79,80]
UGI bleeding	TXA IV may reduce mortality and rebleeding rate, no effect on transfusion requirement[81]
Aneurysmal subarachnoid hemorrhage	No proven benefit[82]
GI and nasal bleeding due to hereditary hemorrhagic telangiectasia	ACA PO may reduce bleeding and transfusion requirements[83,84]
Dental bleeding in hemophilia	FDA approved indication for TXA PO
Prevent bleeding in hemophilia patients during surgery	TXA and ACA reduces bleeding and transfusion requirements[71]
Traumatic hyphema	FDA approved indication for TXA PO; both TXA and ACA prevent secondary hemorrhage[85]
Heavy menstrual bleeding	FDA approved indication for TXA PO; TXA available without prescription in Europe for menstrual bleeding
When fibrinolysis contributes to bleeding	FDA approved indication for ACA IV

Abbreviation: bpm = beats per minute.

*Not a U.S. Food and Drug Administration (FDA) approved indication unless otherwise noted.

in 2010.[73] This study found that TXA (1 gram IV over 10 minutes followed by 1 gram infused over 8 hours) reduced death due to bleeding and all-cause mortality, assessed at 4 weeks, with no observed increase in vascular thrombotic complications.[73] Mortality reduction was dependent on timing; efficacy was seen if administered within 3 hours, but not afterwards.[74,75] Based on this study and additional analysis,[76] the World Health Organization added TXA to its List of Essential Medications in 2011. There is ongoing debate about the role of TXA in trauma care with questioning about its value in the modern trauma care systems found in heavily-resourced counties as opposed to the resource-limited hospitals that provided the bulk of patients in the CRASH-2 study.[77]

Both drugs have potential to cause vascular thrombosis, with reported rates that vary according to the condition being treated.[86] The observed incidence of limb ischemic and myocardial infarction is low, less than 1%.[86] The incidence of DVT and PE is highest with patients with subarachnoid hemorrhage, 2% and 3%, respectively.[86] In adult trauma, the observed incidence of DVT or PE after treatment with IV TXA was not significantly increased in the control group, about 1% for each thrombotic event.[73]

CHAPTER 240

Emergency Complications of Malignancy

J. Stephan Stapczynski

INTRODUCTION

The incidence of cancer is increasing as the general population ages and individual longevity grows. More patients with active malignancy are likely to come to the ED for care because of this increase, coupled with more intensive and varied treatments being applied in the outpatient setting.[1] Many conditions that prompt these patients to come to the ED will not be due to cancer.[2,3] Conversely, there are disorders often or uniquely related to malignancy that collectively are termed *oncologic emergencies*.[4-7] These malignancy-related emergencies are broadly categorized as: (1) those due to local physical effects, (2) those secondary to biochemical derangement, (3) those that are the result of hematologic derangement, and (4) those related to therapy (**Table 240-1**).

EMERGENCIES RELATED TO LOCAL TUMOR EFFECTS

MALIGNANT AIRWAY OBSTRUCTION

Malignancy-related airway compromise is usually an insidious process that results from a mass originating in the oropharynx, neck, or superior mediastinum progressively obstructing air flow.[6,8] Acute compromise may occur with supervening infection, hemorrhage, or loss of protective mechanisms, such as muscle tone. Iatrogenic factors, such as radiation therapy, may create additional difficulties by producing local inflammation with tissue breakdown. It is helpful to classify airway impairment due to malignant tumor obstruction in two manners, as to location—from the lips and nares to the vocal cords (**upper airway**) versus those from the vocal cords to the carina (**central airway**)—and, as to nature of the obstruction—**endoluminal**, **extraluminal**, or **mixed**. Almost regardless of the cause, airway obstruction usually presents with symptoms of shortness of breath and signs of tachypnea and stridor. The physical examination may show evidence of a mass in the pharynx, neck, or supraclavicular area.

Patients with airway obstruction due to a malignant tumor are evaluated with a combination of plain radiographs, CT, and endoscopic visualization.[6,8] Direct laryngoscopy is discouraged because injudicious manipulation of the upper airway may convert a partial obstruction into a complete one by provoking bleeding or edema.[9]

Emergency management includes the administration of supplemental humidified oxygen and maintenance of the best airway possible through patient positioning. Heliox—typically a 50:50 mixture of helium and oxygen—may provide symptomatic improvement in upper airway obstruction due to cancer when combined with other therapy.[10]

Mechanical intervention for critical airway obstruction from a tumor is rarely required in the ED. For patients with critical upper airway obstruction, emergency transtracheal jet ventilation or cricothyroidotomy could be lifesaving if the obstruction is above the vocal cords (see chapter 30, "Surgical Airways"). However, the presence of an overlying tumor or swelling may render such procedures technically difficult. Alternatively, passage of the endotracheal tube beyond the area of obstruction is a consideration when the patient is progressing to complete airway occlusion.[6,9] This is best done using awake fiberoptic intubation with a 5-0 or 6-0 endotracheal tube, wire reinforced, if possible. Placement of such a tube can provide symptomatic relief and time until procedures with more sustained benefit can be performed.

The two procedures that provide sustained relief of airway obstruction are neodymium-yttrium-aluminum-garnet laser photoradiation for vaporization of obstructing tissue and placement of a self-expanding stent at the stenotic site; these two modalities are often combined.[11,12] Alternatively, variations of radiotherapy—endobronchial brachytherapy, photodynamic therapy, and external-beam radiation therapy—can be directed to the obstructing tumor, but the time for symptomatic response is longer than the mechanical approaches of laser photoradiation and stenting.

TABLE 240-1 Emergency Complications of Malignancy

Related to local tumor effects	Malignant airway obstruction
	Bone metastases and pathologic fractures
	Malignant spinal cord compression
	Malignant pericardial effusion with tamponade
	Superior vena cava syndrome
Related to biochemical derangement	Hypercalcemia
	Hyponatremia due to inappropriate antidiuretic hormone secretion
	Adrenal insufficiency
	Tumor lysis syndrome
Related to hematologic derangement	Febrile neutropenia and infection
	Hyperviscosity syndrome
	Thromboembolism
Related to therapy	Chemotherapy-induced nausea and vomiting
	Chemotherapeutic drug extravasation

BONE METASTASES AND PATHOLOGIC FRACTURES

Anatomic disruption of bone weakened by preexisting conditions is termed a *pathologic fracture*. Pathologic fractures due to malignancy most commonly affect the axial skeleton (calvarium included) and the proximal aspect of the limbs. Most pathologic fractures are due to metastases from solid tumors (e.g., breast, lung, prostate) that localize in areas of bones with high blood flow, identified as containing red marrow.[13] Most patients with pathologic fractures have a known malignancy. Patients with bone metastases usually present with localized pain and a benign outward appearance of the involved area.

Malignancy alters the normal radiographic appearance of bone, including loss of trabeculae with indistinct margins (osteolytic, or "moth eaten"), poorly demarcated areas of increased density (osteoblastic), and/or a periosteal reaction. Plain radiographs may identify only about half of metastatic bone lesions.[14] Advanced imaging is often required; CT with IV contrast, particularly when using reconstruction software, can visualize three-dimensional bone integrity and soft tissue extension, whereas MRI best delineates soft tissue and bone marrow involvement. A total-body radionuclide bone scan can be used as a screening tool to identify areas of increased bone activity that could represent additional metastatic spread.[14] However, areas of radionuclide localization on the bone scan are not specific for cancer, and additional imaging studies of these areas are necessary for confirmation.

Treatment priorities are pain relief and restoration or salvage of function. For acute pain or fracture, parenteral analgesics are recommended for rapid treatment. Patients with bone metastases often require long-acting oral opioids and other adjunctive medications for pain relief (see chapter 38, "Chronic Pain"). Approximately 80% of painful bone metastases can be helped with palliative radiotherapy, although it may take several weeks after completion of a typical 5-day course of treatment to experience maximal benefit. The majority of pathologic fractures require open surgical repair.

MALIGNANT SPINAL CORD COMPRESSION

Up to 20% of cancer patients will develop neoplastic involvement of the vertebral column, and 3% to 6% will develop spinal cord compression.[4-6,15] Most cases of malignant spinal cord compression are due to metastases to vertebral bodies from solid organ tumors. with the thoracic vertebrae being the most common location for such metastases. Spinal cord compression occurs when these metastases enlarge, erode through the vertebral cortex into the spinal canal, and compress on the spinal cord. Less common causes of malignant spinal cord compression include local spread from paraspinal tumors through the intervertebral foramen or tumors (primary or metastatic) directly involving the spinal cord or meninges.

TABLE 240-2	Malignant Spinal Cord Compression
Suspect	Patient with known cancer: especially lung, breast, prostate
	Thoracic location: 70%
	Progressive pain and worse when supine
	Motor weakness: proximal legs
	Sensory changes: initially radicular, later distal anesthesia
	Bladder or bowel dysfunction: late findings
Imaging	Plain radiographs: may detect vertebral body metastases but less sensitive and specific for malignant spinal cord compression
	MRI: modality of choice, image entire vertebral column
	CT myelography: used when MRI not available or accessible
Corticosteroids	Dexamethasone, 10 milligrams IV followed by 4 milligrams PO or IV every 6 h
	Consider starting in ED if imaging is delayed
Radiotherapy	Standard approach, beneficial in approximately 70%
	No specific radiotherapy regimen proven superior
	Prognosis highly dependent on pretreatment neurologic function
Surgery	Consider in highly selected cases, such as
	Patient in good general condition and able to undergo extensive surgery
	Appropriate prognostic life expectancy
	Rapidly progressive symptoms
	Clinical worsening during radiotherapy
	Unstable vertebral column

Approximately 90% of patients with malignant spinal cord compression will have back pain (**Table 240-2**). Such pain is often described as unrelenting, progressive, worse when supine, and located in the thoracic vertebral area. Approximately 80% of patients with malignant spinal cord compression have a prior diagnosis of cancer, so individuals with known cancer and back pain should undergo radiographic imaging. Other symptoms of malignant spinal cord compression may include muscular weakness, radicular pain, and bladder or bowel dysfunction. Weakness is most apparent in the proximal extremity musculature and may progress to complete paralysis. Sensory changes initially may be confined to a band of hyperesthesia around the trunk at the involved spinal level and that eventually becomes anesthetic distal to the level. Urinary retention (with overflow incontinence), fecal incontinence, and impotence are late manifestations.

MRI is the imaging modality of choice to define the site and degree of cord compression and to identify the presence of additional vertebral lesions. The entire spinal column is usually imaged due to the potential for multiple level involvement, although because cervical metastases are unusual, it may be reasonable to not image the cervical spine if there are no symptoms referable to that region. CT with or without myelography is used when MRI is contraindicated or inaccessible. Plain radiography may identify an abnormality in approximately 80% of patients with painful vertebral metastases. However, plain radiographs are less useful in patients with suspected malignant spinal cord compression, because radiographic findings do not always correlate with the level of spinal cord compression, and causes of malignant spinal cord compression other than vertebral body metastases will not produce visible changes in vertebral body radiographic appearance.

Use opioid analgesics for initial pain control. Consider administration of corticosteroids in the ED, especially if there will be a delay in MRI or CT myelography.[4-6,15] Typically dexamethasone, 10 milligrams IV bolus, followed by 4 milligrams PO or IV every 6 hours, is used. Further treatment, with continued corticosteroids, radiation therapy, surgery, or a combination of modalities, will depend on the life expectancy of the patient, extent of disease, and degree of motor impairment. Radiation therapy has been the typical treatment for patients with malignant spinal cord compression, and a beneficial response is seen in approximately 70% of those treated.[16] The overall prognosis for those treated with radiotherapy is highly dependent on pretreatment functional ability; approximately 90% of those who can walk at the time of diagnosis remain ambulatory after radiation treatment, about half of those who have motor function but cannot walk will recover ambulatory ability with radiotherapy, but few patients with complete paraplegia at the time of diagnosis will recover lower extremity motor function. Therefore, **malignant spinal cord compression is considered a radiotherapy emergency.** Select patients with malignant spinal cord compression may benefit from surgical tumor resection, including those with neurologic impairment (Table 240-2).[15] Because of the complex decision making from among the therapeutic options, specialists in oncology, radiotherapy, and spinal surgery should be consulted early.

MALIGNANT PERICARDIAL EFFUSION WITH TAMPONADE

Pericardial involvement, often with effusion, occurs in up to 35% of patients with all types of cancer, although the effusions are often small and remain undiagnosed.[4-6] Symptomatic pericardial effusions occur less frequently and usually result from lung or breast cancer. Other etiologies for pericardial effusions in patients with malignant disease include other tumor types (such as melanoma, leukemia, or lymphoma) and a complication of treatment (radiotherapy or chemotherapy).

Symptoms and physical examination findings are a function of pericardial fluid accumulation rate and volume (see chapter 55, "Cardiomyopathies and Pericardial Disease"). Large effusions can develop gradually and are surprisingly well tolerated. Symptoms of a pericardial effusion include dyspnea, orthopnea, chest pain, dysphagia, hoarseness, and hiccups. Physical findings include distant cardiac sounds, jugular venous distention, and a pulsus paradoxus.

A sudden increase in fluid between the nondistensible pericardium and compressible heart creates a cardiac tamponade: the low-pressure right heart is unable to accept vena caval return or pump forward to the pulmonary arteries, and the left ventricle cannot fill or produce a sustainable ejection fraction. Signs and symptoms include accentuation of those noted with pericardial effusion with additional manifestations of circulatory shock. There is usually tachycardia, hypotension, and a narrowed pulse pressure.

The ECG may demonstrate reduced voltage in the QRS complex throughout all leads, a reflection of the insulating characteristics of the effusion. Electrical alternans is a classic, although infrequent, finding with a large pericardial effusion. The cardiac silhouette on chest radiography may appear large, reflecting the gradually accumulated effusion in the stretched pericardial sac. **Echocardiography is the diagnostic tool of choice, being noninvasive, portable, and highly accurate in trained hands.** Echocardiography can not only detect the presence of a significant pericardial effusion but also assess cardiac function and identify physiologic changes associated with cardiac tamponade.

Asymptomatic pericardial effusions do not require specific treatment. Patients with symptomatic effusions should undergo pericardiocentesis, ideally with echocardiographic guidance. See chapter 34, "Pericardiocentesis." Most often, this procedure can await the arrival of the specialist and transport of the patient to the appropriate procedural area. If patients with cardiac tamponade require emergent pericardiocentesis in the ED, use a portable US device to guide needle direction during the procedure.

Malignant pericardial effusions are treated depending on the tumor type and overall patient condition. Reduction in fluid production can be done by treating the tumor with appropriate systemic chemotherapy or radiotherapy. Intrapericardial chemotherapy may be useful in tumors sensitive to these agents. A pericardial window or partial pericardial resection can be done to prevent accumulation of fluid within the pericardial space. A percutaneous indwelling intrapericardial catheter can also prevent accumulation of fluid, but with the risks associated with percutaneous devices. Malignant pericardial effusion typically indicates the presence of advanced disease, and most patients die within 1 year after diagnosis.

SUPERIOR VENA CAVA SYNDROME

The term *superior vena cava (SVC) syndrome* describes the clinical effects of elevated venous pressure in the upper body that result from

obstruction of venous blood flow through the SVC.[4-6,17,18] This syndrome is most commonly caused by external compression of the SVC by an extrinsic malignant mass. The most common tumors associated with malignant SVC syndrome are lung cancer in 70% and lymphoma in approximately 20%. Benign conditions and intravascular thrombosis (precipitated by indwelling vascular catheters or pacemaker leads) currently account for about one third of all SVC syndrome cases. SVC syndrome rarely constitutes an emergency; the vast majority of patients do not materially deteriorate during the initial 1 to 2 weeks after diagnosis. The exception is when neurologic abnormalities are present due to increased intracranial pressure.

Symptom development correlates roughly with the severity of obstruction and the rate of narrowing. If compression occurs over weeks, collateral vessels dilate to compensate for impaired flow through the SVC. Most patients will describe symptoms developing a few weeks before seeking medical attention. Clinical manifestations correlate with a jugular venous pressure of 20 to 40 mm Hg (2.7 to 5.4 kPa), as compared with a normal range of 2 to 8 mm Hg (0.3 to 1.0 kPa). The most common symptoms are facial swelling, dyspnea, cough, and arm swelling.[18] Less common symptoms include hoarse voice, syncope, headache, and dizziness. In rare but extreme cases, venous obstruction can lead to increased intracranial pressure that produces visual changes, dizziness, confusion, seizures, and obtundation. Physical examination findings may show swelling of the face and arm, sometimes with a violaceous hue or plethora, and distended neck and chest wall veins.

The plain chest radiograph will usually show a mediastinal mass in cases of malignant SVC syndrome. CT of the chest with intravascular contract is the recommended imaging modality to assess the patency of the SVC.[17,18] MRI is useful for patients who cannot receive IV contrast. Contrast venography is rarely needed, except in uncertain cases or as part of an intravascular interventional procedure. In patients with a known diagnosis of lung cancer, biopsy for pathologic confirmation of a malignancy is usually not required. For patients without a known intrathoracic cancer, tissue confirmation of a malignant cause is highly desirable before initiation of radiotherapy and required before initiation of chemotherapy.[17,18]

Initial management is with head elevation to decrease venous pressure in the upper body and supplemental oxygen to reduce the work of breathing. Corticosteroids and loop diuretics are commonly used, but there is no evidence that they contribute to clinical improvement, with the exception that corticosteroids would be expected to be helpful when the cause of the obstruction is lymphoma.

Radiation therapy is effective in reducing symptoms in approximately 75% of patients with SVC syndrome, reflecting the approximate incidence of radiosensitive tumors producing this disorder.[18] Many patients will experience a reduction in symptoms within 3 days after the start of radiation treatment. The mechanism by which radiotherapy reduces symptoms in SVC syndrome is unclear, because the majority of patients receiving such treatment do not achieve complete relief of the obstruction. It is likely that continued development of collaterals contributes to the reported benefit seen during radiotherapy.

Intravascular stents, with or without angioplasty, can be used to reduce obstruction to SVC flow.[17,18] These stents appear to produce a more rapid improvement in symptoms and signs compared with radiotherapy or chemotherapy, suggesting a preferential benefit in patients with severe manifestations who require urgent treatment.[18] Stent placement should also be considered for malignant causes that do not respond well to radiotherapy or chemotherapy (like mesothelioma), for benign causes (like fibrosing mediastinitis), or for intravascular thrombosis associated with an indwelling catheter.[17,18]

Chemotherapy is effective in producing symptomatic relief from SVC syndrome in approximately 80% of patients with lymphoma, 80% of patients with small-cell lung cancer, and 40% of patients with non–small-cell lung cancer. For these chemotherapy-sensitive cancers, there is no evidence of benefit from additive radiotherapy, again indicating that dilation of venous collaterals may play a role in clinical improvement.

Patients with SVC syndrome due to intravascular thrombosis can be treated with catheter-directed fibrinolytics.[18] Removal of an inciting intravascular object, such as a central venous catheter, should be considered. Postfibrinolytic anticoagulation is generally recommended to prevent recurrence, although there is no firm supporting evidence.[18] For cancer patients with an indwelling central venous catheter, there is no proven role for prophylactic anticoagulation to reduce the risk of venous thromboembolism.[19]

Recurrence of SVC syndrome is seen in approximately 20% of lung cancer patients treated with radiotherapy and/or chemotherapy and 10% treated with intravascular stents.[18] For patients with malignant SVC syndrome, survival is dependent in the causative cancer; with lung cancer, median survival is approximately 6 to 12 months.

EMERGENCIES RELATED TO BIOCHEMICAL DERANGEMENT

HYPERCALCEMIA

Hypercalcemia is seen in 5% to 30% of patients with advanced cancer at some time during their disease course.[20] Breast cancer, lung cancer, and multiple myeloma are the malignancies most commonly associated with hypercalcemia. The three key mechanisms whereby malignancy produces hypercalcemia are: (1) by production of a parathyroid hormone–related protein that is structurally similar to parathyroid hormone, (2) by extensive local bone destruction associated with osteoclast-activating factors, and (3) by production of vitamin D analogues. The most common mechanism with solid tumor–associated hypercalcemia is the production of the parathyroid hormone–related protein that binds to parathyroid hormone receptors, thereby mobilizing calcium from bones and increasing renal reabsorption of calcium.[20] Hypercalcemia from enhanced osteoclastic activity is associated with bone metastases from lung and breast cancer, and multiple myeloma. Production of vitamin D analogues is generally seen in lymphomas, usually Hodgkin's disease.

Classic symptoms of hypercalcemia include lethargy, confusion, anorexia, and nausea (see chapter 17, "Fluids and Electrolytes"). Because most patients with hypercalcemia due to malignancy have advanced cancer, symptoms of general debility due to tumor may be difficult to distinguish from those caused by hypercalcemia. Hypercalcemia reduces intestinal motility, so constipation is common, although that symptom can be produced by concomitant opioid therapy for pain. Hypercalcemia produces an osmotic diuresis, so some of the nonspecific symptoms can be due to relative hypovolemia. **Clinical symptoms of hypercalcemia are most correlated with the rate of rise in the serum calcium level, as opposed to the actual calcium level. Therefore, slow increases in serum calcium may be relatively asymptomatic until reaching high levels.**

Hypercalcemia does not always require treatment, especially if the patient is asymptomatic and well hydrated and the total serum calcium is less than 14 milligrams/dL (3.5 mmol/L). The initial treatment of symptomatic hypercalcemia is with IV isotonic saline at a rate adjusted to the ability of the patient's cardiovascular system to tolerate a volume load.[7] A typical dose would be normal saline, 1 to 2 L bolus, to restore intravascular volume, followed by an infusion at a rate of 200 to 250 mL/h.[7] Such treatment will result in clinical improvement and a modest decrease in the plasma calcium over 24 to 48 hours but rarely normalizes the level. Furosemide is useful in patients with heart failure or renal insufficiency to prevent volume overload from normal saline infusion but has little additive effect to the use of IV saline alone in the treatment of hypercalcemia in patients with normal cardiac and renal function. **Therefore, furosemide is not routinely recommended in the treatment of hypercalcemia due to malignancy.**

Because the initial priority is restoration of intravascular volume with IV saline, pharmacologic treatment of hypercalcemia is usually not initiated in the ED.[7] **Bisphosphonates** are the recommended agents to treat malignancy-associated hypercalcemia.[7,20] Bisphosphonates are potent inhibitors of bone resorption and produce a sustained decrease in calcium 12 to 48 hours after administration, with the effect lasting for approximately 2 to 4 weeks. Bisphosphonates, such as pamidronate, etidronate, or zoledronic acid, are given by slow IV infusion to prevent precipitation of bisphosphonate-calcium complexes in the kidney and subsequent renal failure.

Other agents have a limited role in the treatment of malignancy-induced hypercalcemia. Calcitonin, 4 units/kg SC or IV every 12 hours,

lowers plasma calcium within 2 to 4 hours, but it may cause a hypersensitivity response, and tachyphylaxis develops within 3 days, so the beneficial effect is short lived. Glucocorticoids, such as prednisone 60 milligrams PO per day, may be helpful with steroid-sensitive tumors, such as lymphomas and multiple myeloma.[7] Gallium nitrate, mithramycin, and plicamycin are used infrequently due to their toxicity. Hemodialysis can be used to treat hypercalcemia and is indicated for those with profound mental status changes or renal failure or for those unable to tolerate a saline load.

HYPONATREMIA DUE TO INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Inappropriate secretion of antidiuretic hormone is most commonly associated with bronchogenic cancer but may be seen in other malignancies and can also occur from chemotherapy, opioids, carbamazepine, and selective serotonin reuptake inhibitors.[21] Regardless of the etiology, the syndrome of inappropriate antidiuretic hormone consists of hyponatremia, decreased serum osmolality, and less than maximally dilute urine, all in the presence of euvolemia, absence of diuretic therapy, and normal renal, adrenal, and thyroid function (see chapter 17). **Syndrome of inappropriate antidiuretic hormone secretion should be suspected if a patient with cancer presents with normovolemic hyponatremia.**

Signs and symptoms of hyponatremia are primarily neurologic and correlate with severity and with rapidity of development. Anorexia, nausea, and malaise are the earliest findings, followed by headache, confusion, obtundation, seizures, and coma. Seizures are usually generalized tonic-clonic in nature; focal seizures are uncommon from hyponatremia, and their occurrence suggests focal CNS lesions. Life-threatening symptoms are almost invariably associated with sodium concentrations <110 mEq/L (<110 mmol/L).

Water restriction is the mainstay of treatment in euvolemic asymptomatic patients. Patients with sodium levels >125 mEq/L (>125 mmol/L) are generally asymptomatic and can be managed with water restriction of 500 mL/d and close follow-up. More severe hyponatremia—serum sodium between 110 and 125 mEq/L with mild to moderate symptoms—may require furosemide 0.5 to 1.0 milligram/kg PO with concomitant IV normal saline to maintain euvolemia and affect a net free water clearance. **For severe hyponatremia—serum sodium <110 mEq/L, usually with coma or repetitive or sustained seizures—use 3% hypertonic saline (510 mEq/L). Infuse carefully, usually at a rate of 25 to 100 mL/h, to avoid volume overload or too rapid correction in sodium level,** with subsequent osmotic demyelination syndrome (central pontine myelinolysis). The rate of correction of hyponatremia is controversial, but serum sodium increasing at a rate of 0.5 to 1.0 mEq/L per hour, with not more than a total increase of 12 to 15 mEq/L in the first 24 hours, is recommended (see chapter 17).

ADRENAL INSUFFICIENCY

Adrenal insufficiency associated with malignancy may be secondary to adrenal tissue replacement by metastases but is more commonly due to abrupt physiologic stress in the face of chronic glucocorticoid therapy with pharmacologic adrenal suppression (see chapter 230, "Adrenal Insufficiency"). The subsequent vasomotor collapse may be sudden and severe.[22] Clues for acute adrenal insufficiency include mild hypoglycemia, hyponatremia, and hypotension refractory to volume loading and vasoconstrictor therapy.

Along with rapid IV rehydration, the stressed and steroid-dependent patient should be given hydrocortisone, 100 to 150 milligrams IV, followed by an infusion of an additional 100 to 200 milligrams IV over 6 hours.[22] If possible, obtain a serum cortisol level before steroid treatment. While results will generally not be available to the ED, values can help future management.

TUMOR LYSIS SYNDROME

Tumor lysis syndrome is a metabolic crisis resulting from massive cytolysis and release of intracellular contents into the systemic circulation.[7,23] Of particular concern are the individual ions (potassium, phosphate, calcium), nucleic acids (which metabolize to uric acid), and intracellular proteins. Tumor lysis syndrome most commonly occurs with treatment of hematologic malignancies because of rapid cell turnover and growth rates, bulky tumor mass, and high sensitivity to antineoplastic agents. Tumor lysis syndrome is uncommon with solid tumors or without prior therapy ("spontaneous tumor lysis syndrome").

The manifestations of tumor lysis syndrome can be categorized by clinical effects (acute kidney injury, seizure, cardiac dysrhythmia or arrest) and laboratory abnormalities (hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia). Renal failure is the strongest predictor of morbidity in tumor lysis syndrome and usually results from uric acid precipitation within the renal tubules. Phosphorus released from tumor cells may combine with calcium and precipitate in renal tubules and parenchyma as well. Hypovolemia may contribute to the renal impairment seen with tumor lysis syndrome. The release of intracellular potassium can produce acute hyperkalemia and provoke or contribute to cardiac dysrhythmias or cardiac arrest. Because malignant cells can contain fourfold the amount of phosphorus as normal cells, the abrupt release of extensive phosphate into the circulation may produce a drop in serum calcium. The resultant hypocalcemia may induce tetany and seizures and contribute to dysrhythmias.

Recognize the potential for tumor lysis syndrome with treatment of hematologic malignancies. Prophylactic allopurinol and maintaining good hydration can reduce the risk of tumor lysis syndrome developing. Patients with established tumor lysis syndrome may experience sudden electrolyte changes and life-threatening complications, so admission to an intensive care unit with cardiac rhythm monitoring is indicated. Aggressive IV fluid administration to increase urinary excretion of the released intracellular solutes is the cornerstone for treatment of tumor lysis syndrome. Increased urine flow will counteract the precipitation of urate and calcium phosphate crystals in the renal tubules.

Hyperkalemia is the most immediate life-threatening element with tumor lysis syndrome because of induced cardiac dysrhythmias and cardiac arrest.[7,23] Treatment is identical to other causes of hyperkalemia: β-adrenergic agonists, sodium bicarbonate, and dextrose-insulin therapy (see chapter 17). Avoid calcium administration unless there is cardiovascular instability (ventricular dysrhythmias or wide QRS complexes) or neuromuscular irritability (seizures) because supplemental calcium may cause metastatic precipitation of calcium phosphate. Hyperphosphatemia is managed with phosphate binders (limited effect) or by the administration of dextrose and insulin. Hemodialysis can correct all biochemical abnormalities of tumor lysis syndrome, although a large phosphate burden may require repeat frequent and prolonged dialysis sessions or continuous renal replacement therapy.[7,23]

EMERGENCIES RELATED TO HEMATOLOGIC DERANGEMENT

FEBRILE NEUTROPENIA AND INFECTION

Infections are a common source of morbidity and mortality in patients with malignancies.[24] A common feature associated with the increased risk of infection in these patients is the presence of impaired immunity, especially neutropenia.[24,25] The absolute neutrophil count normal range is 1500 to 8000/mm^3 (1.5 to 8.0 × 10^9/L). For clinical decision making, neutropenia is defined as an absolute neutrophil count <1000/mm^3 (<1.0 × 10^9/L), severe neutropenia is defined as an absolute neutrophil count <500/mm^3 (<0.5 × 10^9/L), and profound neutropenia is defined as an absolute neutrophil count <100/mm^3 (<0.1 × 10^9/L).[25,26] Fever, the most consistent finding in bacterial infection, is defined for the purposes of clinical decision making as a temperature of 38.3°C (100.9°F) on one occasion or 38.0°C (100.4°F) persisting >1 hour.[25,26]

Neutropenia in cancer patients is most commonly caused by chemotherapy, with the lowest neutrophil count typically seen 5 to 10 days after the last chemotherapeutic dose and recovery usually seen within 5 days afterward.[25-27] The risk of developing an infection primarily depends on the severity and duration of neutropenia. Comorbid conditions and other circumstances, like indwelling devices, also contribute to the risk.[4,5,7,25,26]

Fever is the most common finding seen with bacterial infections in the neutropenic patient. Common symptoms and signs that usually localize the infectious source are often absent or muted in the neutropenic patient because the lack of neutrophils impairs the inflammatory response and diminishes the occurrence of expected findings.[25] Thus, a pulmonary infection may have minimal cough, have no productive phlegm, and lack radiographic infiltrates. A kidney infection may not produce pyuria.

Perform a careful physical examination, with attention to three areas typically overlooked in routine examination: the oral cavity, the perianal area, and entry sites of intravascular catheters. **Digital rectal examination is relatively contraindicated in neutropenic patients—withhold until after initial antibiotic administration. Evaluate the entry sites of IV and tunneled catheters for evidence of infection.** Clotted catheters represent a high risk of infection due to bacterial colonization, and central venous catheters may cause endocarditis.

Localizing signs and symptoms of a specific infection are often lacking, and an evaluation for an occult infection is indicated.[25-28] Obtain two blood culture samples, one from a peripheral vein and the other from a central catheter, if present. A urinalysis, urine culture, and chest radiograph should be performed. Sputum, stool, and wound drainage Gram stain and culture should be obtained if productive cough, diarrhea, or wound drainage, respectively, are present. Assess serum electrolyte levels, renal function, and hepatic function.

Risk Factors If an infectious source is found, therapy and disposition are guided by the presumed pathogens and the expected clinical course. If, after assessment, no localized infection can be found, the two major clinical decisions are: (1) Does this patient require hospitalization, and (2) should empiric antibiotics be started? To assist in addressing both these questions, consult with the patient's oncologist.

Although hospitalization enhances the ability to reassess the patient and intervene early if a severe infection or clinical deterioration develops, hospitalization exposes the immunocompromised patient to hospital flora that is often drug resistant. Patients who appear well, have no abdominal pain, have no physical signs of infection, have a normal chest radiograph, and are expected to resolve their neutropenia within 7 days have a low risk of severe infection and can be considered for outpatient care.[25,26] Scoring systems, such as the Multinational Association for Supportive Care in Cancer Risk Index[29,30] or the Clinical Index of Stable Febrile Neutropenia[31] can be used to determine if the febrile neutropenic patient is at low risk for serious complications and eligible for outpatient care. High-risk febrile neutropenic patients for whom hospitalization is recommended are defined by one or more of the following features: profound neutropenia expected to last >7 days, comorbid medical conditions, acute liver or renal injury, or non–low-risk scores by the Multinational Association for Supportive Care in Cancer Risk Index or Clinical Index of Stable Febrile Neutropenia tool.[25,26,29-31]

Treatment Empiric broad-spectrum antibiotics are used in febrile neutropenic patients when the benefits of early treatment are greater than the adverse side effects associated with such drugs.[25-28] **Clinical evidence consistently supports the benefits of empiric antibiotics when the absolute neutrophil count is ≤500/mm³** (<0.5 × 10⁹/L) . There is little convincing evidence for empiric antibiotics when the absolute neutrophil count is >1000/mm³. For neutrophil counts between 500 and 1000/mm³ (0.5 and 1.0 × 10⁹/L), other risk factors for bacterial infection are used to make a decision regarding empiric antibiotics.[25-27]

Gram-positive bacteria currently account for 60% of microbiologically confirmed infections in febrile neutropenic patients, although gram-negative bacteria are undergoing resurgence in some institutions.[25] Bacteremia is most frequently due to aerobic gram-positive cocci (*Staphylococcus aureus*, coagulase-negative staphylococci, *Viridans* streptococci, or *Enterococcus faecalis/faecium*) or aerobic gram-negative bacilli (*Escherichia coli*, *Klebsiella* species, or *Pseudomonas aeruginosa*).

Administer the initial empiric antimicrobial therapy to cover the range of potential bacterial pathogens (**Table 240-3**).[25-28,32,33] No specific antibiotic regimen has proven consistently superior in clinical trials, and monotherapy with an appropriate broad-spectrum agent is as effective as dual-agent treatment in most circumstances. Add vancomycin in the following situations: hemodynamic instability, radiographic pneumonia, catheter-related infection, skin or soft tissue infection, known colonization with resistant gram-positive organism, or severe mucositis when fluoroquinolone prophylaxis was recently used.[26]

TABLE 240-3 Empiric Antibiotic Therapy in Febrile Neutropenia

Circumstance	Drug and Adult Dose	Comments
Outpatient	Ciprofloxacin 500 milligrams PO every 8 h or 1000 milligrams twice daily *or* Levofloxacin 750 milligrams PO daily *plus* Amoxicillin/clavulanate 500/125 milligrams PO every 8 h or 1000/62.5 milligrams PO twice daily *or* Moxifloxacin 400 milligrams PO daily	For low-risk patients with daily assessments by a medical provider for the initial 3 d
Monotherapy	Cefepime 2 grams IV every 8 h *or* Ceftazidime 2 grams IV every 8 h *or* Imipenem/cilastatin 1 gram IV every 8 h *or* Meropenem 1 gram IV every 8 h *or* Piperacillin/tazobactam 4.5 grams IV every 6 h	Monotherapy with these broad-spectrum agents is as good as dual-drug therapy in most circumstances
Dual therapy	One of the monotherapy agents *plus* Vancomycin 1 gram IV every 12 hours *or* Metronidazole 1 gram IV, followed by 500 milligrams IV every 6 h	Increased risk of adverse effects If hemodynamic instability, catheter-related infection, cellulitis, pneumonia, or known colonization with resistant organism If abdominal symptoms are present

The median duration of fever after initiation of empiric antibiotics is 2 days in low-risk patients and 5 to 7 days in high-risk patients. Therefore continue initial empiric antibiotic therapy for 2 to 4 days before assessing clinical response and making therapeutic adjustments. Adjustments may be made earlier if clinical deterioration occurs or culture results become available. Continue empiric antibiotics until either a documented infection has clinically resolved and/or the absolute neutrophil count is >500/mm³ (>0.5 × 10⁹/L).[25,26]

HYPERVISCOSITY SYNDROME

Hyperviscosity syndrome is a pathologic condition in which blood is "thicker" than normal and its flow is impaired.[34,35] Blood viscosity depends on its plasma and cellular contents. Abnormal plasma contents that most commonly produce hyperviscosity are Waldenström's macroglobulinemia and immunoglobulin A–producing myeloma.[34] Hyperproduction of any cell line can lead to hyperviscosity. Polycythemia (with a hematocrit >60%) and leukemia (with a WBC count >100,000/mm³ (>100 × 10⁹/L) or a leukocrit >10%) are often are associated with clinically significant hyperviscosity.[35] Dehydration exacerbates hyperviscosity.

Initial symptoms are vague and may include fatigue, abdominal pain, headache, blurry vision, or, most commonly, altered mental status.[32-36] Cutaneous or mucosal bleeding is common. Intravascular thrombosis may occur, with the creation of focal or unusual findings. Patients with hyperleukocytosis often report dyspnea and fever. Funduscopic findings include retinal venous engorgement appearing as linked sausages, along with exudates, hemorrhages, and papilledema.

Laboratory findings suggesting hyperviscosity include rouleaux formation (red cells stacked like coins) on a peripheral blood smear and being unable to perform chemical testing due to serum stasis in the laboratory analyzers. Laboratory testing of blood viscosity is usually done on plasma or serum, and specific analytic methodology varies.[36] A common approach is to report the viscosity of the sample as a ratio to that of water; normal plasma viscosity is 1.7 to 2.1 and normal serum viscosity is 1.4 to 1.8, compared with water. Symptomatic patients usually have a serum viscosity >4.[36] **Laboratory measurement of plasma or serum viscosity will not identify hyperviscosity from polycythemia or leukemia.**

Initial therapy is intravascular volume repletion, early involvement of a hematologist, and emergency plasmapheresis or leukapheresis.[34-36] If coma is present and the diagnosis established, a temporizing measure can be a 2-unit (1000-mL) phlebotomy with concomitant volume replacement using 2 to 3 L of normal saline.[35] Transfusion of red blood cells should be done with caution because such treatment may increase blood viscosity. Long-term management is appropriate chemotherapy.

THROMBOEMBOLISM

Thromboembolism occurs with all tumor types and is the second leading proximate cause of death in cancer patients.[37-39] Symptomatic deep venous thrombosis occurs in approximately 15% of all patients with cancer and up to 50% of those with advanced malignancies.[37-39] Multiple factors contribute to an increased risk for thromboembolism. The tumor may release procoagulant factors or inflammatory cytokines that directly activate the coagulation system. Large tumors may cause venous obstruction and promote thrombosis. Impaired production of proteins C and S and antithrombin can produce a hypercoagulable state. Surgery with attendant postoperative immobilization or long-term central venous catheterization can incite thrombosis. Chemotherapy or hormonal therapy for breast cancer increases the risk for thromboembolism. The angiogenesis inhibitors thalidomide, sunitinib, and bevacizumab are associated with significant thrombotic risks.[37-39]

Low-molecular-weight heparin (LMWH) is recommended as the initial treatment for 5 to 10 days in cancer patients with venous thromboembolism, both deep venous thrombosis and pulmonary embolism.[40,41] Continued treatment with low-molecular-weight heparin for at least 6 months is also recommended because of better efficacy in preventing recurrent thromboembolic events compared to vitamin K antagonists.[41,42] There is little experience with the novel oral anticoagulants, so their use is not recommended.[41]

EMERGENCIES RELATED TO THERAPY

CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

Nausea and vomiting can be debilitating to an already compromised patient. Because most IV chemotherapeutic agents are emetogenic, antiemetics are commonly administered on the day of therapy and for 2 to 4 days afterward.[43] Guidelines recommend specific antiemetic regimens based on the emetogenic potential of the chemotherapeutic agent.[43,44] Recommended antiemetics include neurokinin-1 receptor antagonists, serotonin receptor antagonists, and corticosteroids (**Table 240-4**).[45] For refractory nausea and vomiting, benzodiazepines, dopamine receptor antagonists, or antipsychotic agents are added.[43]

Chemotherapy-induced vomiting can be anticipatory, acute, or delayed.[45] Anticipatory vomiting is a conditioned reflex where vomiting occurs prior to administration of the chemotherapeutic agent. Acute vomiting occurs during the first 24 hours with maximal intensity at 5 to 6 hours after administration. Delayed vomiting has maximal intensity 48 to 72 hours after administration and can last up to 7 days.

TABLE 240-4 Antiemetic Agents for Chemotherapy-Induced Vomiting

Class and Agent	Initial Adult Dose	Comments
Neurokinin-1 (NK1) Receptor Antagonists		
Aprepitant	125 milligrams PO	Expensive, use restricted to highly emetogenic chemotherapy agents, half-life 9–14 h
Fosaprepitant	150 milligrams IV	
Serotonin Receptor Antagonists		
Granisetron	1 milligram (10 micrograms/kg) IV	Common reactions: headache, abdominal pain Serious reactions: serotonin syndrome, QT interval prolongation Half-lives vary from 5 h for ondansetron, 9 h for granisetron, and 40 h for palonosetron
Ondansetron	8 milligrams (0.15 milligrams/kg) IV	
Palonosetron	0.25 milligram IV	
Tropisetron*	5 milligrams IV	
Ramosetron*	0.3 milligram IV	
Corticosteroids		
Dexamethasone	8–12 milligrams IV	Mechanism unknown
Benzodiazepines		
Lorazepam	1–2 milligrams IV	Sedation, half-life 14 h
Midazolam	1 milligram IV or 5 milligrams IM	Sedation, half-life 2–3 h
Dopamine Receptor Antagonists		
Metoclopramide	10 milligrams IV or IM	Dose-related extrapyramidal side effects, half-life 5–6 h
Prochlorperazine	5–10 milligrams IV or IM	Extrapyramidal side effects, half-life 7 h
Antipsychotics		
Olanzapine	10 milligrams PO or IM	Not FDA approved for this indication, half-life 21–54 h

Abbreviation: FDA = U.S. Food and Drug Administration.

*Not available in the United States.

EXTRAVASATION OF CHEMOTHERAPEUTIC AGENTS

Most chemotherapeutic agents cause local tissue reaction when extravasated, but the agents associated with significant tissue damage are the vesicants primarily in the anthracycline, taxane, platin salt, and vinca alkaloid classes.[46-48] Clinical manifestations of chemotherapeutic drug extravasation include pain, erythema, and swelling, usually within hours of the infusion. Occasionally, clinical signs may be delayed if only a small amount of highly cytotoxic drug is extravasated. Serious injury produces blistering, induration, ulceration, and necrosis over a few days to weeks.

If extravasation happens to occur through an active peripheral line, the infusion is stopped and aspiration through the line is attempted and continued while the catheter is removed.[48] Aspirate palpable cutaneous blebs containing the extravasated chemotherapeutic agent. Elevate and

TABLE 240-5 Antidotes for Selected Extravasated Chemotherapeutic Drugs

Drug	Antidotes	Comments
Anthracyclines (daunorubicin, doxorubicin, epirubicin, and idarubicin)	Dry cooling	Initially 1 h, then 15 min several times per day Hold during dexrazoxane therapy
	Dexrazoxane	IV infusion within 6 h, repeat doses at 48 and 72 h
	Dimethyl sulfoxide	Apply over involved area, repeat 4–6 times per day for 7 or more days
Vinca alkaloids (vincristine and vinblastine)	Dry warming	Do not press or rub area
	Hyaluronidase	Inject in and around extravasated area
Mitomycin, cisplatin, mechlorethamine	Dry cooling	Initially 1 h, then 15 min several times per day
	Dimethyl sulfoxide	Apply over involved area, repeat 4–6 times per day for 7 or more days
Paclitaxel	Hyaluronidase	Inject in and around extravasated area

immobilize the affected limb. Cooling or warming is beneficial for some agents **(Table 240-5)**. Consult with the oncologist for treatment recommendations. Early referral to a plastic surgeon is suggested for anthracycline and vinca alkaloids.

Antidotes vary according to the specific agent (Table 240-5).[48] Dexrazoxane is used for anthracycline extravasation at dose of 1000 milligrams/m^2 IV infused over 1 to 2 hours within 6 hours of the extravasation event, with additional doses of 1000 milligrams/m^2 at 48 hours and 500 milligrams/m^2 at 72 hours.[49] Dimethyl sulfoxide and hyaluronidase are used to enhance absorption of the extravasated agent.[48] Dimethyl sulfoxide is applied as a generous trickle of the 99% solution over the involved area without pressing or rubbing and then covered with dry pads.[48] Hyaluronidase is reconstituted with normal saline to a concentration of 150 units/mL and then injected in and around the extravasation area via multiple punctures.[48] Inject about 0.2 mL per puncture site with a typical total dose of 1 mL, but up to 10 mL may be required. There is limited data supporting the use of sodium thiosulfate for reversal of alkylating agent toxicity.[48] Intralesional injections of corticosteroids or bicarbonate are not effective.

Eye, Ear, Nose, Throat, and Oral Disorders

CHAPTER 241

Eye Emergencies

Richard A. Walker
Srikar Adhikari

INTRODUCTION AND EPIDEMIOLOGY

The breadth of ocular emergencies seen in the ED requires solid examination skills and an understanding of basic differential diagnosis. A recent review[1] of 1400 ED ocular emergencies identified the following conditions: ocular trauma in 27%, of which 73% involved corneal abrasions, 6% involved blunt eye trauma, and 5% involved a corneal foreign body; the second most common condition was conjunctivitis (15%), and retinal problems and glaucoma involved 6%.

This chapter reviews eye anatomy, the essential skills needed for the ED eye examination, and common ophthalmic medications. Common causes of the red eye, ocular infections and inflammation, trauma to the eye, acute visual reduction or loss, and acute cranial nerve palsies are discussed. The principles and advantages of ocular US are summarized.

EYE ANATOMY

The **orbit** is a pyramid of bony walls that converge to an apex posteriorly. The orbit is bordered superiorly by the frontal sinus, medially by the ethmoid sinus, inferiorly by the maxillary sinus, and laterally by the zygomatic bone. The ethmoid bone (lamina papyracea) is paper thin and is the most likely sinus wall to break in blunt eye trauma or to be perforated due to sinusitis with subsequent spread of infection to the orbit. The orbital contents include the ocular muscles, retroseptal fat, and the optic nerve, whereas the globe is considered a separate entity.

The anterior limit of the orbital cavity is the **orbital septum**, which is a layer of fascia extending from the periosteum along the orbital rim to the levator aponeurosis of the upper eyelid and to the edge of the tarsal plate of the lower eyelid. Abnormalities, such as the accumulation of blood or infection, are referred to as "preseptal" or "postseptal." Postseptal conditions are extremely serious. **The septum is generally impervious to bacteria, which serves to limit spread of infection from the facial skin into the orbit (Figure 241-1).** All nerves and vessels of the eye enter through the apex of the orbit, which is also the site of origin for the extraocular muscles. The optic nerve is subject to compression from mass effect due to tumors, abscesses, or hematomas.

The arterial blood supply of the eye and orbit is the ophthalmic artery, the first major branch of the intracranial portion of the internal carotid artery, which enters the orbit beneath the optic nerve. The **central retinal artery** is the first intraorbital branch of the ophthalmic artery and courses through the optic nerve. The venous drainage of the eye and orbit is through the ophthalmic veins, which drain into the central retinal vein. The ophthalmic veins communicate directly to the cavernous sinus. This venous system has no valves, and this fact is the basis for the spread of facial and periorbital infections to the cavernous sinus.

The eye itself is composed of several different layers (**Figure 241-2**). The outermost layer is a thin, transparent mucous membrane (the **bulbar conjunctiva**) that continues onto the posterior surface of the eyelids (the **palpebral conjunctiva**). Deep to the conjunctiva is the **episclera**, a layer of thin, elastic tissue containing blood vessels that nourish the next deepest layer, the sclera. The **sclera** is the collagenous protective coating of the eye, which is the thinnest (and prone to rupture) at the insertion of the rectus muscles.

The **cornea** forms the anterior surface of the eyeball and is attached to the sclera at the limbus. From anterior to posterior, the cornea has five separate layers: epithelium, Bowman layer, stroma, Descemet membrane, and endothelium. The epithelium is five or six cell layers thick and is subject to damage from minor mechanical forces, resulting in corneal abrasion (**Figure 241-3**).

The iris, ciliary body, and choroid (the vascular pigmented layer of the eye between the sclera and retina) make up the **uveal tract**. The uveal tract supplies nutrition to the eye and assists in accommodation and pupillary constriction. The lens separates the aqueous humor in the anterior chamber from the vitreous humor in the remainder of the globe. (See the section **Acute and Painful Vision Reduction or Loss, Acute Angle-Closure Glaucoma** in this chapter for discussion of the production and flow of aqueous humor.) The retina is the sheet of neural tissue containing the rods and cones that lines the posterior two thirds of the inner surface of the globe, extending anteriorly as far as the ciliary body.

EYE EXAMINATION

HISTORY

A detailed history is as important in the patient with an eye complaint as it is for a complaint related to any other organ system. History should first categorize the symptom as vision loss, change in appearance of the eye, eye pain/discomfort, or trauma. The onset (gradual or sudden) of symptoms, duration of the symptoms, and circumstances surrounding the onset are important. For example, a history of sudden, painless monocular vision loss associated with a history of atrial fibrillation or carotid stenosis would suggest a central retinal artery occlusion, but a history of eye pain occurring while hammering metal on metal would suggest a projectile causing corneal abrasion or intraocular foreign body. Eye discomfort should be characterized as pain (aching, burning, throbbing, etc.), pruritus (associated with allergy), or a foreign body sensation as seen with corneal foreign bodies, abrasions, or ulcers. "Flashing lights" and a "curtain or veil" obstructing a portion of the visual field suggest a retinal detachment. In the case of trauma, ask about onset (traumatic iritis occurs 1 to several days after blunt trauma to the eye) and mechanism (globe penetration may occur in association with hammering, grinding, or use of other high-speed machinery). Document tetanus status and give tetanus toxoid as appropriate.

Past medical history is always important and can focus the physical examination and narrow the differential diagnosis. Previous surgery may be the cause of an irregular pupil. Absence of corrective lenses may account for decreased visual acuity and will require modification of the method for testing visual acuity. Use of contact lenses, especially the extended wear type, may be associated with bacterial corneal ulcers. Chronic use of certain ophthalmic medications may cause chemical conjunctivitis and inflammatory changes of the cornea. A history of diabetes or chronic hypertension and acute isolated sixth-nerve palsy suggests an ischemic cranial neuropathy. Monocular diplopia following trauma in a patient with an intraocular lens implant suggests dislocation of the intraocular lens. Always ask about previous instances of similar **symptoms** and the associated diagnosis.

EXAMINATION

The eye examination typically proceeds in a sequential fashion unless the circumstances require otherwise (e.g., **chemical ocular injuries**

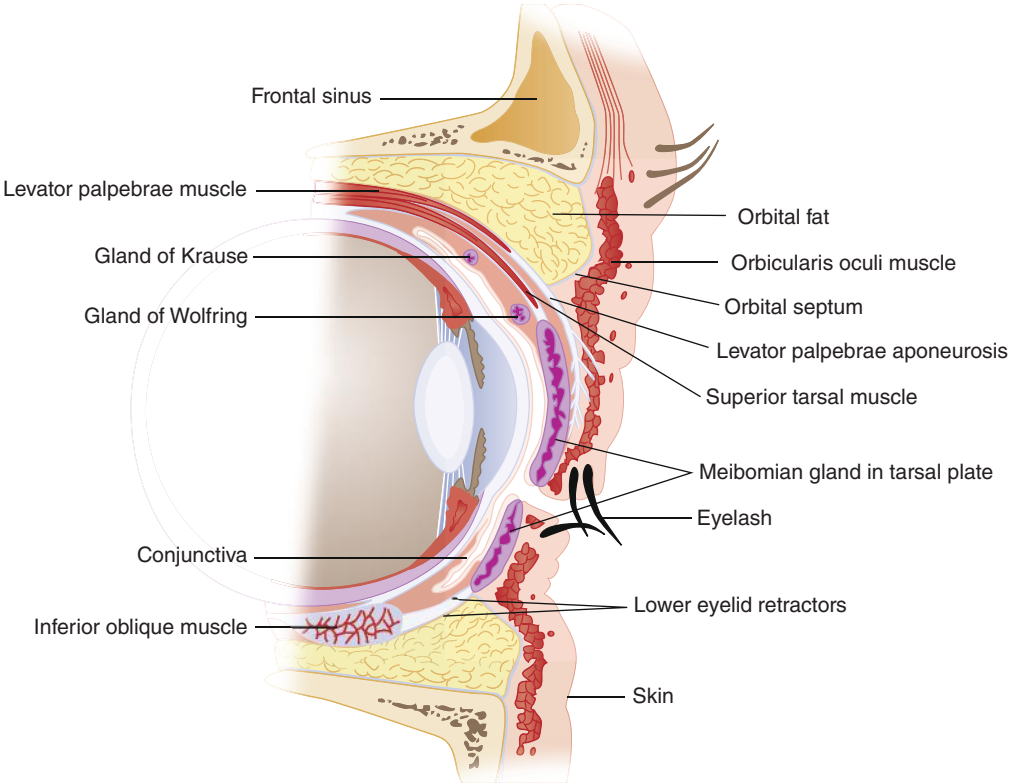

FIGURE 241-1. Cross-section of the eyelids. [Reproduced with permission from Riordan-Eva P, Whitcher J: *Vaughn & Asbury's General Ophthalmology,* 17th ed. New York: Lange Medical Books/McGraw-Hill, 2008.]

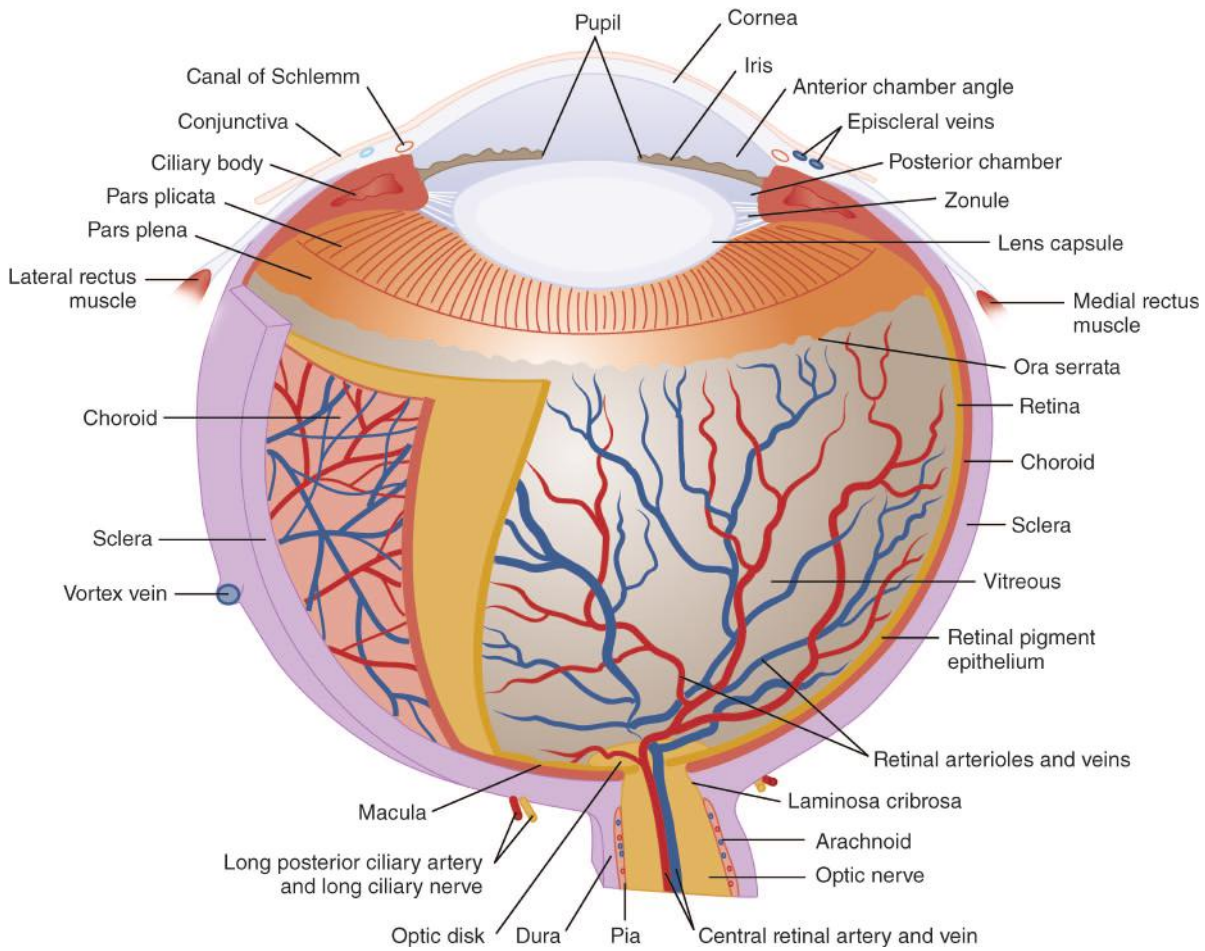

FIGURE 241-2. Internal structures of the human eye. [Reproduced with permission from Riordan-Eva P, Whitcher J: *Vaughn & Asbury's General Ophthalmology,* 17th ed. New York: Lange Medical Books/McGraw-Hill, 2008.]

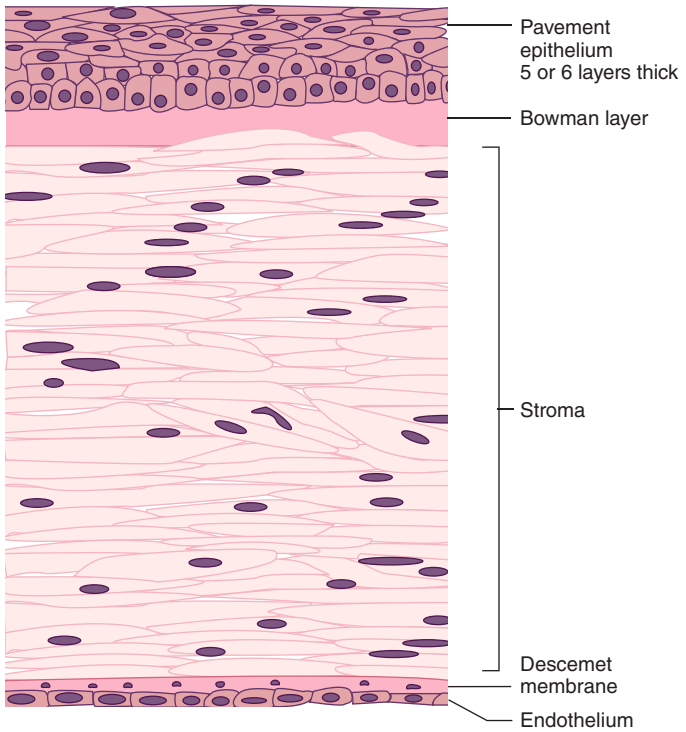

FIGURE 241-3. Transverse section of cornea. [Reproduced with permission from Riordan-Eva P, Whitcher J: *Vaughn & Asbury's General Ophthalmology,* 17th ed. New York: Lange Medical Books/McGraw-Hill, 2008.]

require irrigation *before* assessment of visual acuity). The glossary of terms and abbreviations in **Table 241-1** is helpful when communicating with the ophthalmologist.

Full examination should include the following, generally in the order listed: visual acuity, confrontational visual fields, extraocular movements, pupillary reactions, lids and adnexa, conjunctiva and sclerae, cornea, anterior chamber, iris, lenses, vitreous, intraocular pressure, and funduscopic examination. Measurement of intraocular pressure is done toward the end of the examination because physical touching of the cornea is more irritating and invasive than the rest of the examination. Performance of a thorough funduscopic examination requires dilatation of the pupil, so this part of the examination is performed last. Not all parts of the examination need to be done on every patient. For example, testing visual fields adds little to the evaluation of a corneal foreign body but is essential to the evaluation of acute vision loss.

Visual Acuity Most vision-threatening disorders present with decreased visual acuity. **Visual acuity testing is the vital sign of the eye** and is the first step in any eye examination, even before shining a light in the eye; bright light can temporarily decrease visual acuity. The only exception to this rule is for chemical burns to the eye, where irrigation takes precedence above all else. Test visual acuity with contact lenses or glasses in place if possible. If the patient's glasses or contacts are unavailable, use **pinhole testing** of visual acuity. A commercial pinhole occluder may be used, although a perforated metal eye shield or a note card perforated with an 18-gauge needle are acceptable substitutes. The pinhole allows only parallel light rays to fall on the macula, thereby reducing the refractive error and allowing an estimate of the person's corrected visual acuity. Visual acuity testing is ideally done with a standard wall-mounted visual acuity chart (**Snellen chart**) with the patient standing 20 ft (6 m) from the chart. Record the visual acuity as 20/x, where the numerator is the distance from which the patient can read the line (always 20) and the denominator is the distance from which a person with normal vision can read the same line. **The visual acuity is determined by the smallest line a patient can read with one half of the letters correct.** The number of incorrect letters is listed after the visual acuity as follows: 20/x-y (e.g., 20/40-2). Document best acuity in each eye and whether prosthetic devices were used in testing (glasses, pinhole).

Visual acuity can also be tested with a near card (**Rosenbaum chart**) held 14 in. (36 cm) from the patient. Patients in their mid-40s or older may require reading glasses or bifocals to read a near card because of presbyopia. If the bifocals are not available, use a pinhole occluder.

For patients with visual acuity <20/200, figure counting at a distance (e.g., figure counting at 3 ft or 1 m), perception of hand motion

TABLE 241-1 Glossary of Terms, Abbreviations, and Notations

AC	Anterior chamber, the first portion of the anterior segment.	IOP	Intraocular pressure (mm Hg).
Anisocoria	Unequal pupil size under equal lighting conditions.	Limbus	Circumferential border where clear cornea ends and white sclera begins.
Anterior segment	Consists of the anterior chamber and posterior chamber. Aqueous humor is produced in the posterior chamber of the anterior segment and circulates through the pupil into the anterior chamber of the anterior segment.	NLP	No light perception (blind).
		OD	Oculus dexter (right eye).*
		OS	Oculus sinister (left eye).
APD	Afferent pupillary defect (see **Figure 241-8**).	OU	Oculus uterque (each eye).*
CF	Counting fingers (visual acuity assessment).	PH	Pinhole visual acuity.
CVF	Confrontation visual fields.	RD	Retinal detachment.
EOM	Extraocular muscle. Extraocular movements.	Tono-Pen® (Reichert, Inc., Depew, NY)	A hand-held, pen-shaped device for measuring IOP.
HM	Hand motion (visual acuity assessment).		
Hyphema	RBCs in the anterior chamber.	T_{tono}	Tension (IOP) with subscript representing method used: (tono = Tono-Pen®; S = Schiötz; A = applanation).†
Hypopyon	WBCs in the anterior chamber.		
INO	Internuclear ophthalmoplegia.	V_{Ac}	Visual acuity with correction (glasses or contact lenses).†
IOFB	Intraocular foreign body.	V_{As}	Visual acuity without correction.

*By convention, in documenting the visual acuity (V_A) or IOP, the right eye is listed above the left, as follows:

$T_{tono} < \begin{matrix}14\\15\end{matrix}$ †This represents an IOP of 14 mm Hg in the right eye and 15 mm Hg in the left eye measured by Tono-Pen®.

$V_{Ac} < \begin{matrix}20/20\\20/30\end{matrix}$ †This represents a visual acuity *with* glasses/contacts of 20/20 right eye and 20/30 left eye.

$V_{As} < \begin{matrix}20/400 \rightarrow 20/30\\CF \text{ at } 8 \text{ ft} \rightarrow 20/40\end{matrix}$ This represents a visual acuity *without* glasses/contacts of 20/400 in the right eye, improving to 20/30 with pinhole testing; counting fingers at 8 ft (2.4 m) in the left eye, improving to 20/40 with pinhole testing.

at 1 to 2 ft (0.3 to 0.6 m), and ultimately light perception can be used to document visual acuity. If the patient is unable to detect hand motion, turn off all the lights in the room, fully occlude the contralateral eye, and test for light perception. Illiterate patients can be tested using the direction of the letter **E** on the chart, and a verbal child may be tested with an **Allen chart** (pictures). Corneal abrasions or foreign bodies can cause severe photophobia, pain, and tearing, so a topical anesthetic can reduce discomfort sufficiently to allow a more accurate assessment of visual acuity. In recording the results of visual acuity testing, refer to **Table 241-1.**

When alternating black-and-white lines are passed from one side to another in front of a patient's eyes, **involuntary horizontal nystagmus (optokinetic nystagmus)** will occur. The presence of optokinetic nystagmus excludes blindness in a patient with an otherwise normal examination who claims he or she cannot see (hysterical blindness). The test can be performed by placing thick black lines approximately 1 in. apart on a 2-ft strip of cardiac monitor paper, which is passed back and forth at eye level a distance of 1 ft from the patient.

Confrontation Visual Fields Test all four quadrants of the visual fields by having the patient cover one eye and look at the physician's nose. The examiner closes the opposite eye and holds a finger halfway between the patient and himself or herself. The finger is wiggled as it is moved medially toward the patient. The normal patient should see movement at approximately the same time as the physician does. A visual field defect may represent pathology anywhere from the occipital cortex to the optic nerve (**Figure 241-4**). Bitemporal hemianopia can occur in pituitary adenoma; homonymous hemianopia is associated with some cerebrovascular accidents; and monocular field cuts are sometimes seen with large retinal detachments.

Ocular Motility The normal patient can move the eye through the six cardinal positions of gaze, and the eye movements are controlled by the six extraocular muscles attached to each eye (**Figures 241-5** and **241-6**). Extraocular muscles are innervated by cranial nerves III, IV, and VI. **Cranial nerve IV controls the superior oblique muscle, cranial nerve**

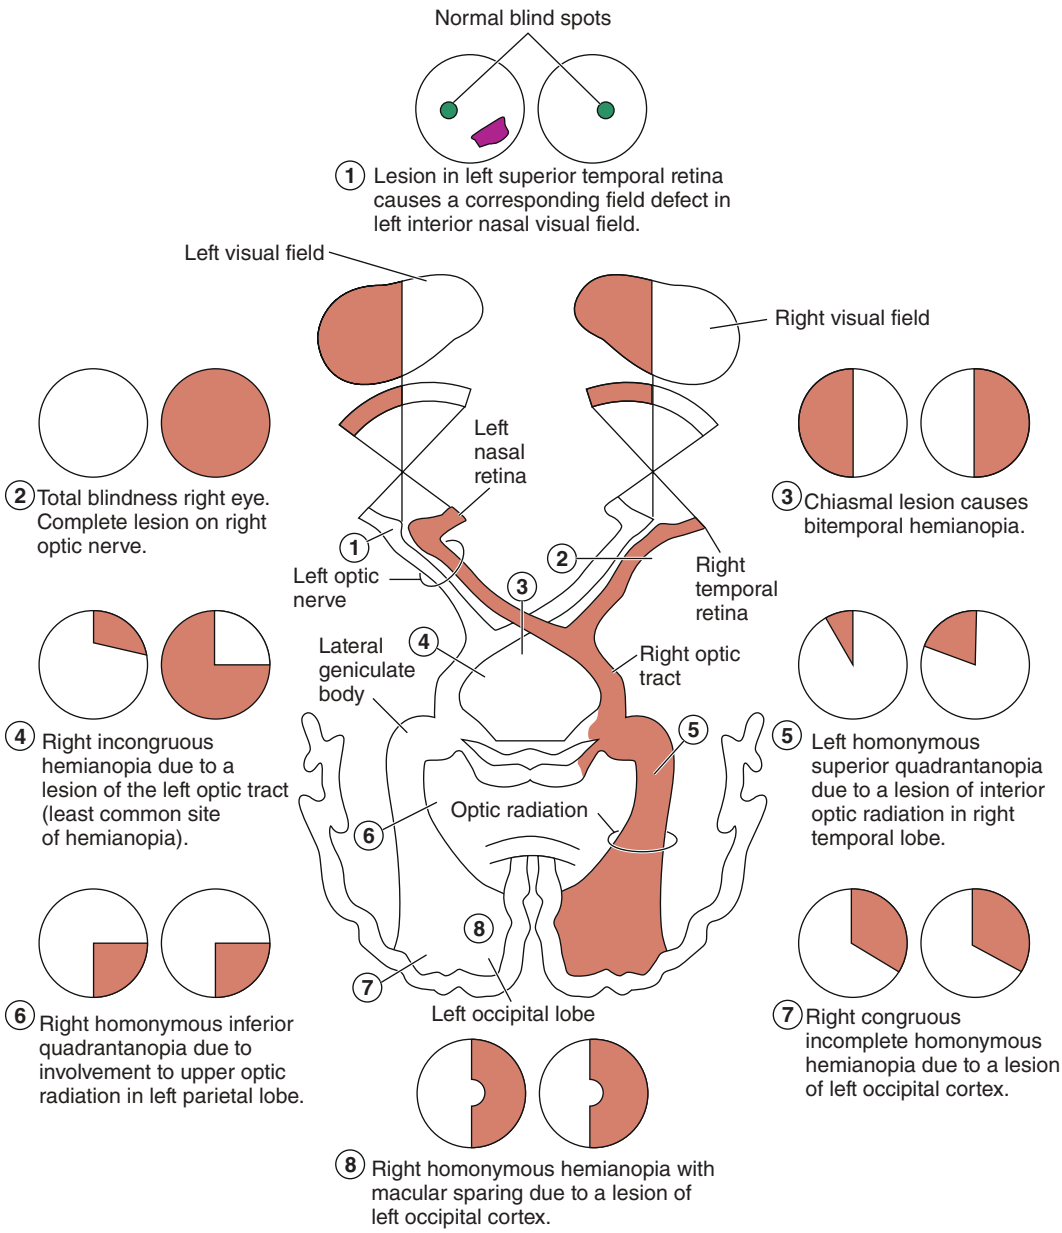

FIGURE 241-4. Visual field defects produced by lesions at various points along the optic pathways: (*1*) field defect caused by retinal lesion, (*2*) total blindness right eye, (*3*) bitemporal hemianopia, (*4*) right incongruous hemianopia, (*5*) left homonymous superior quadrantanopia, (*6*) right homonymous inferior quadrantanopia, (*7*) right congruous incomplete homonymous hemianopia, and (*8*) right homonymous hemianopia with macular sparing. [Reproduced with permission from Riordan-Eva P, Whitcher J: *Vaughn & Asbury's General Ophthalmology*, 17th ed. New York: Lange Medical Books/McGraw-Hill, 2008.]

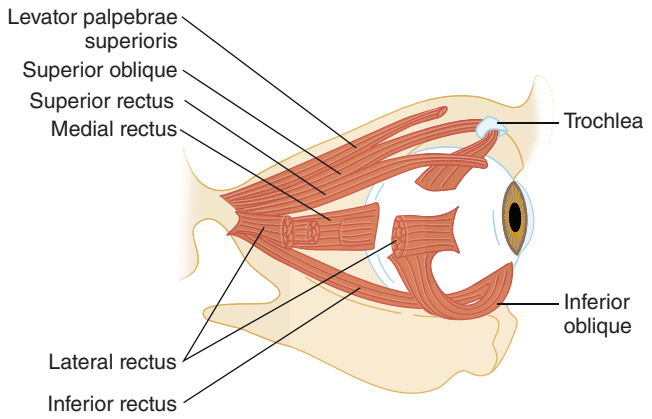

FIGURE 241-5. Extraocular muscles of the eye.

VI controls the lateral rectus muscle, and all other extraocular muscles are controlled by cranial nerve III. Extraocular movement can be impaired by restriction, interrupted or decreased innervation, or trauma. Examples of restriction include thyroid orbitopathy, myositis, and mechanical entrapment of a muscle secondary to an orbital blow-out fracture. Cranial nerve palsies or paresis may be caused by stroke, myasthenia gravis, diabetes, hypertension, tumors, aneurysms, infections, and trauma. Penetrating or blunt traumatic injury to an extraocular muscle also can result in motility disturbance.

Evaluate ocular alignment initially in *primary gaze* (looking straight ahead), and then test eye movements in all fields of gaze. Always ask the patient about diplopia, which may be a subtle sign of problems with extraocular muscles. Diplopia is usually worse when the patient is attempting to look in the direction of the malfunctioning muscle. Ask patients if diplopia persists when one eye is covered (monocular diplopia). **Monocular diplopia** can be caused by corneal irregularity, lens problems, or intraocular lens dislocation, or can be a sign of malingering. Resolution of diplopia when one eye is covered represents pathology of an extraocular muscle or its innervation. Patients with lesions of the superior oblique muscle or the fourth cranial nerve may tilt their head to compensate for the diplopia.

Pupils Note the pupil size in millimeters and test shape and reaction to light. An irregular pupil may occur from prior surgery or remote trauma. The patient will usually be able to relate a previous history of irregular pupil. The classic irregular teardrop-shaped pupil may also be seen in acute blunt or penetrating trauma with rupture of the iris (**Figure 241-7**).

Assess pupils under slightly dim light to test for an afferent pupillary defect (**Figure 241-8**). **A positive afferent pupillary defect indicates an optic nerve disorder.** Any pathology that prevents light from getting to the CNS, such as opacification of the vitreous with blood, retinal pathology, or optic nerve pathology, will cause an afferent pupillary defect, also known as a ***Marcus-Gunn pupil***. The pupils will be equal in size *before* testing because of the consensual light response. Therefore, an afferent pupillary defect does *not* cause a baseline anisocoria and will be discovered only if specifically tested for. Perform the "swinging flashlight test" to detect an afferent pupillary defect. Shine a light in the pupil. The light causes constriction of the ipsilateral pupil and consensual constriction of the opposite pupil. The light is then shined/swung to the opposite pupil. The opposite pupil will dilate if an afferent pupillary defect is present, because the effect of light is not getting through to the CNS.

FIGURE 241-7. Prolapse of the iris with the classic teardrop-shaped pupil after penetrating trauma. [Courtesy of Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

Causes of unequal pupils (**anisocoria**) can range from an acute emergency (posterior communicating artery aneurysm) to chronic baseline conditions such as previous intraocular trauma or surgery, or they can be idiopathic. **Physiologic anisocoria (difference in pupil size) is the most common cause of asymmetric pupils.** The difference in size is usually <1 mm, and both pupils react normally by constricting to light and dilating in darkness. A single dilated pupil may represent impending **uncal herniation** (from pressure on the third nerve), but uncal herniation is accompanied by an altered level of consciousness and other focal neurologic signs. A single nonreactive dilated pupil may result from a topical cycloplegic agent (scopolamine, cyclopentolate, or atropine) for uveitis or if an anticholinergic medication (such as ipratropium from a nebulization treatment for bronchospasm) is splashed into the eye. A careful history is important to determine whether anisocoria is preexisting. **It is not worthwhile to attempt to "reverse" a suspected chemically altered pupil in the ED as a diagnostic test because the results are not reliable.**

External Eye: Periorbital Skin, Lids, and Adnexa The ocular adnexa include the eyebrows, eyelids, and lacrimal apparatus. Examine the periorbital skin and lids for trauma, infection, dysfunction, deformity, crepitus, or proptosis. Subcutaneous emphysema can be found with blow-out fractures of the medial orbital wall (ethmoid). Palpate the orbital rims for step-off deformities in trauma. Evert the upper eyelid to check for foreign bodies. Use of a cotton applicator is often recommended; however, this technique will only visualize the lower half of the inner upper eyelid (**Figure 241-9**). The edge of an eyelid retractor may be used to tent the upper lid while a second examiner looks under the lid from a caudal direction, so-called *double eversion of the eyelid*. This will allow visualization of the upper half of the inner eyelid. A large

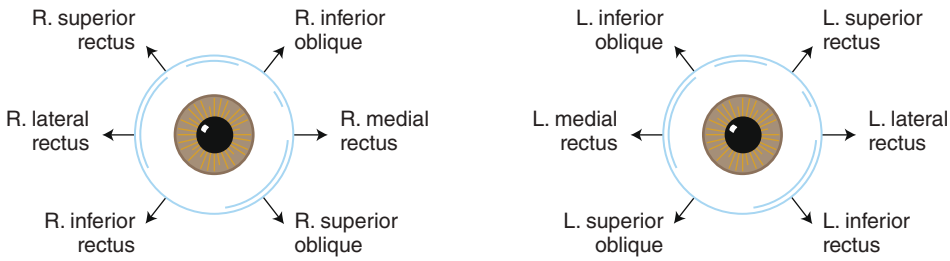

FIGURE 241-6. Arrows indicate direction of ocular movement by each muscle. Cranial nerve IV, superior oblique muscle; cranial nerve VI, lateral rectus muscle; cranial nerve III, superior rectus, inferior rectus, inferior oblique, and medial rectus muscles.

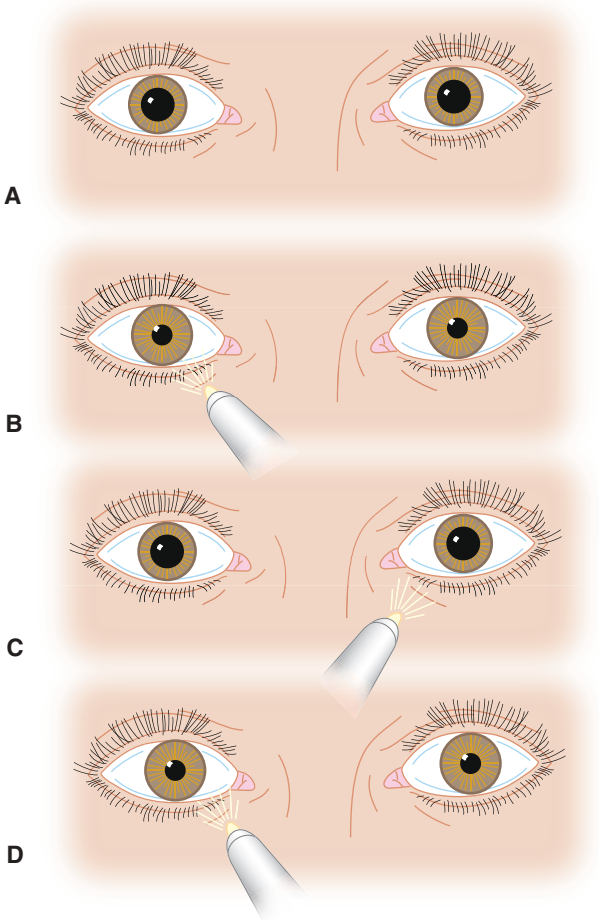

FIGURE 241-8. **A** and **B.** "Swinging flashlight test" revealing an afferent pupillary defect (Marcus-Gunn pupil) of the left eye. **A.** Pupils are normal and equal before light testing. **B.** Both pupils constrict when light is shined into the normal (right) eye. **C** and **D.** The test is positive when the affected pupil (left pupil) dilates in response to light. Conditions with an afferent pupillary defect include optic neuritis and central retinal artery occlusion.

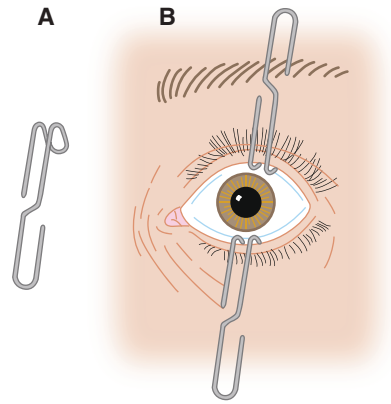

FIGURE 241-10. An alternative to an eyelid retractor. **A.** Unfold a paper clip and bend it into shape with a hemostat. **B.** Paper clips used to retract the eyelids. paperclip may be bent into the shape of an eyelid retractor for this purpose (**Figure 241-10** and see **Figure 241-38**).

Anterior Segment and the Slit Lamp Examination The palpebral and bulbar conjunctiva, sclerae, cornea, anterior chamber, and iris and ciliary body make up the anterior chamber, and all except the ciliary body may be examined with the slit lamp (**Figure 241-11A**).

The slit lamp is a binocular microscope that affords a highly magnified three-dimensional view of ocular structures. Use the slit lamp to assess eye complaints whenever possible. The patient and examiner should both be seated on adjustable stools so that the examiner's and patient's eyes are at the same level. Cover the chin rest with tissue paper or a washcloth. Adjust the slit lamp height so the patient can lean forward and comfortably place the forehead against the upper plastic bar and the chin on the chin rest. Adjust the height of the chin rest so the patient's lateral canthus is even with the black line on the vertical bar. The oculars and light source are generally straight ahead for the general eye evaluation. Focus is adjusted by the anterior-posterior movement of the ocular and light source in relation to the patient. The joystick generally controls focus by moving the slit lamp closer to or farther away from the patient's eyes. Rotation of the joystick usually controls vertical movement of the light source and oculars. When one looks through the oculars, the focus should be close to correct if a narrow slit of light falls on

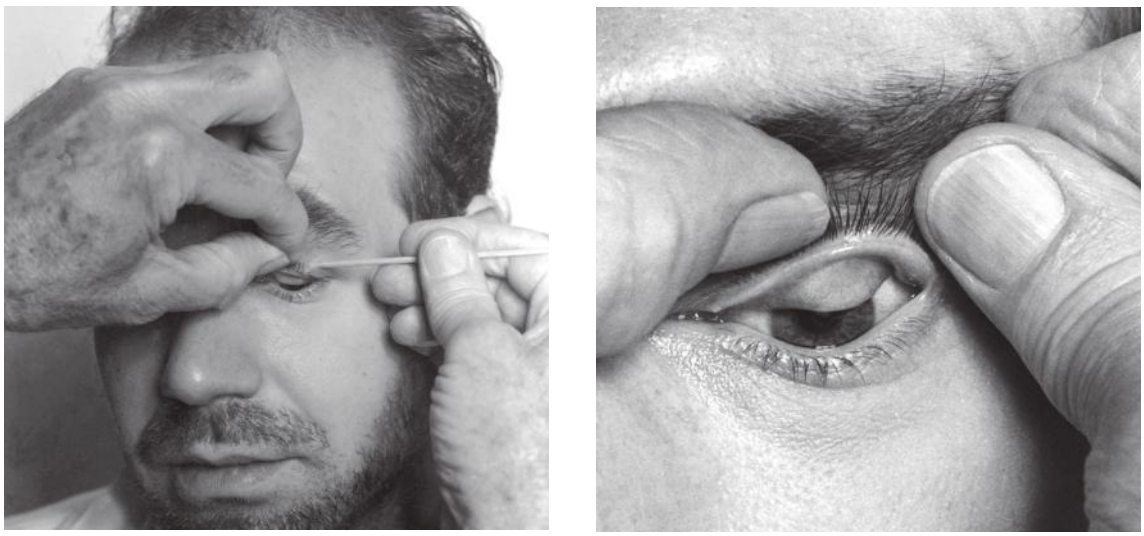

FIGURE 241-9. Single eversion of eyelid when a cotton applicator is used. [Reproduced with permission from Riordan-Eva P, Whitcher J: *Vaughn & Asbury's General Ophthalmology*, 17th ed. New York: Lange Medical Books/McGraw-Hill, 2008.]

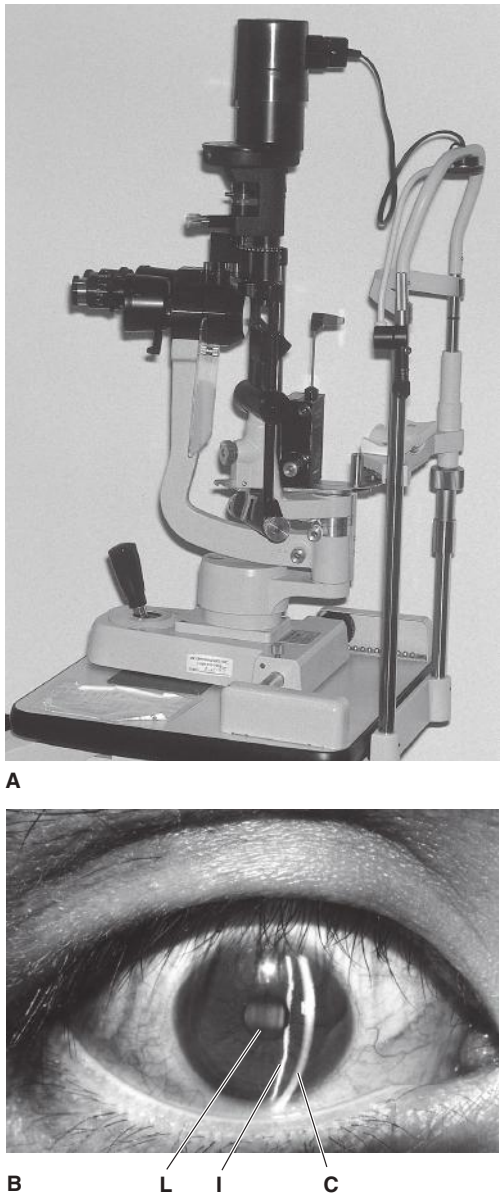

FIGURE 241-11. **A.** The slit lamp provides a magnified view of the eye. **B.** A thin slit can demonstrate the cornea (*C*), iris (*I*), and lens (*L*).

the structures to be examined. Fine adjustments in focus are then made with the joystick. Adjust the vertical light beam to the full height of the cornea with a width of approximately 1 mm (**Figure 241-11B**).

Examine the palpebral and bulbar conjunctivae for follicles (seen with allergic and viral conjunctivitis), chemosis (subconjunctival edema fluid), injection/inflammation, discharge, trauma, and foreign bodies.

To examine the cornea, rotate the light source to a 45-degree angle. The slit lamp can be brought close to the proper focus by looking at the slit of light on the cornea with the naked eye and moving the slit lamp in an anterior-posterior direction to obtain the thinnest and sharpest slit possible. The cornea is assessed by narrowing the light source to produce a slit beam that optically sections the cornea (**Figure 241-12**). Inspect the corneal epithelium for abrasions, ulcers, edema, and foreign bodies. Examine the corneal stroma for edema, scars, and lacerations, and examine the endothelium for precipitates (WBCs on the endothelium characteristic of iritis) and lacerations.

Assess the depth of the anterior chamber by adjusting the angle of the light source on the slit lamp or by shining a penlight onto the iris from a lateral direction. If the iris is bowed forward, as with a shallow anterior chamber, a shadow will be cast on the medial (nasal) iris (**Figure 241-13**).

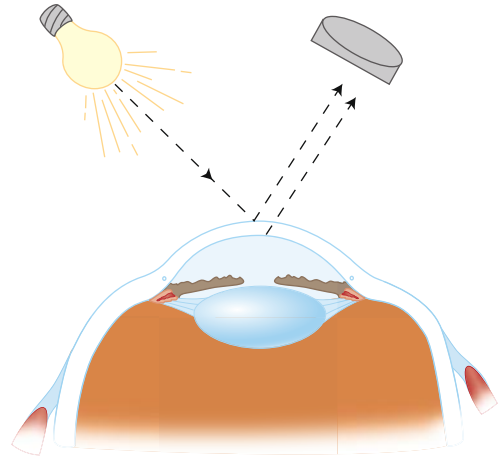

FIGURE 241-12. Optical sectioning. By creating an angle of 45 to 60 degrees between the slit-beam light source and the observer's biomicroscope objective, the cornea can be optically "sectioned" obliquely. This allows a cross-sectional view of the cornea and is helpful in ascertaining the depth of penetration of corneal foreign bodies and injuries.

Assess the anterior chamber for flare and cells as follows: shorten the slit beam to approximately 1 mm, and shut off the room lights. Select the high-magnification position of the oculars. The incident light source should create an angle of 45 to 60 degrees with the objective (similar to optical sectioning). Focus the light beam on the pupillary margin and pull the joystick back to focus on the cornea. One may see keratitic precipitates that are white spots on the undersurface of the corneal epithelium, representing deposits of inflammatory cells in iritis.

Now move the focus inward halfway between the iris and cornea, with the pupillary aperture as a dark backdrop. This will place your focus in the center of the aqueous humor, and the light beam will illuminate WBCs and red blood cells (if present) slowly drifting up and down in the aqueous convection currents, sometimes likened to snowflakes floating through the beam from a car's headlight at night. Iritis may result in WBC layers in the anterior chamber (hypopyon) (**Figure 241-14**). Trauma to the eye may cause red blood cells in the anterior chamber (hyphema or microhyphema). **Hyphema** is layering of the red cells in the anterior chamber visible to the naked eye (**Figure 241-15**). A hyphema may occasionally be clotted (**Figure 241-16**). Flare is described as the appearance of "headlights in a fog" and represents the ability to see the course of the normally transparent light beam through the aqueous humor. **Flare** is caused by increased aqueous protein in the anterior chamber, which is common with inflammatory conditions such as iritis.

Examine the iris for pupil irregularity and pupillary dysfunction. Irregularity of the pupil will occur whenever one portion of the iris is

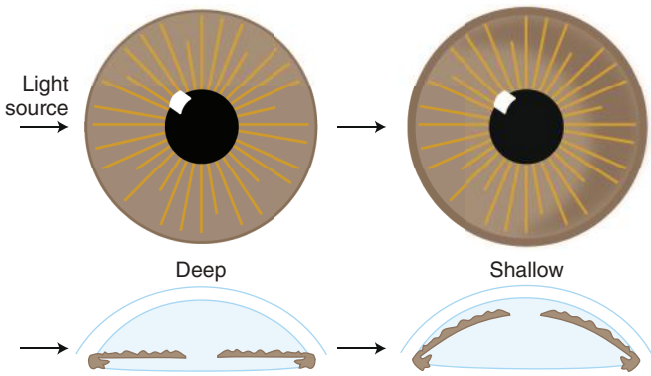

FIGURE 241-13. Estimation of depth of the anterior chamber by oblique illumination. Note the shadow cast in the shallow chamber. [Reproduced with permission from Riordan-Eva P, Whitcher J: *Vaughn & Asbury's General Ophthalmology,* 17th ed. New York: Lange Medical Books/McGraw-Hill, 2008.]

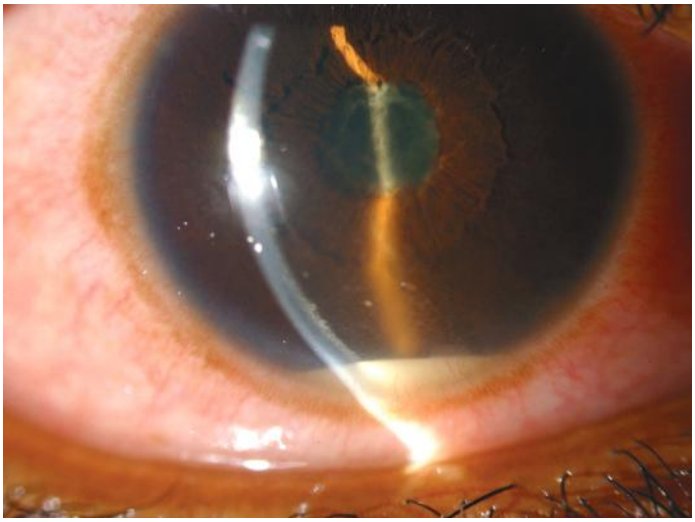

FIGURE 241-14. Hypopyon: a layering of WBCs in the inferior portion of the anterior chamber. [Courtesy of Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

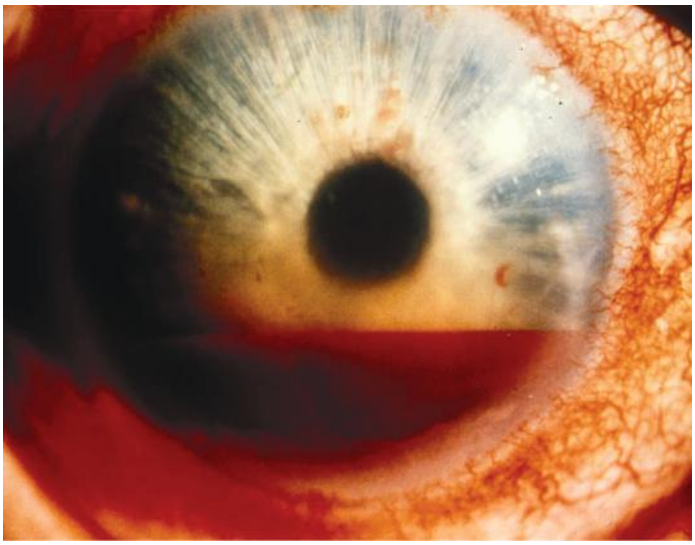

FIGURE 241-15. Hyphema secondary to blunt trauma. Note the blood filling the lower half of the anterior chamber and hazy appearance of cornea suggesting increased intraocular pressure. [Courtesy of Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

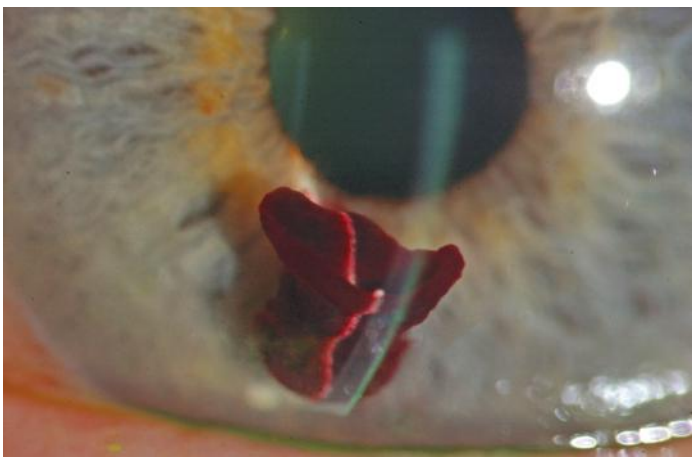

FIGURE 241-16. Hyphema appearing as a clot rather than layering out. [Courtesy of Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

tethered into place and may occur from posterior synechiae, where the iris is adhesed to the anterior lens capsule as seen in uveitis, or when any portion of the iris plugs a corneoscleral laceration causing a peaked pupil. Trauma may also cause the iris to tear at the root, termed *iridodialysis*. Assess the lens for opacities, lacerations, and subluxation.

Fluorescein Examination The final part of the slit lamp examination is done after fluorescein is instilled into the eye. Fluorescein binds to damaged corneal epithelium and fluoresces green under a **Wood's lamp** or light through a cobalt-blue filter. **Always remove contact lenses, as fluorescein will cause permanent staining of the lenses.** Touching the fluorescein strip directly to the cornea will cause staining mimicking a linear abrasion. The best way to apply fluorescein dye is to apply several drops of eye-irrigating solution or saline onto a paper fluorescein strip, and then lightly apply the moistened end of the fluorescein strip into the inferior conjunctival fornix. Ask the patient to blink several times to distribute the fluorescein. Then examine the cornea for streaming of fluorescein-tinged aqueous humor (positive Seidel test) seen in full-thickness laceration of the cornea (**Figure 241-17**). **The Seidel test can be negative (no streaming) with a small or spontaneously sealing corneal laceration.** Ask the patient to blink to wash out the fluorescein, and then examine the cornea with the cobalt blue filter on the slit lamp. A corneal abrasion will fluoresce bright green. A Wood's lamp (ultraviolet light) may also be used to look grossly (without the slit lamp) for corneal abrasions, but microscopic/punctate abrasions will be missed without use of a slit lamp.

Funduscopic Examination Note the size, shape, and sharpness of the borders of the optic disk, the cup-to-disk ratio, the size ratio of the arteries to veins (normal 2:3), any nicking where the arteries and veins cross, the texture and color of the retina as well as the presence of lesions (e.g., hemorrhages or exudates) of the retina or vessels (e.g., aneurysms), and the color and size of the macula. To locate lesions of the retina note the direction (e.g., superonasal) and distance from the disk in terms of disk diameters. Opacities of the lens may obscure the view of the retina, and lens opacities appear as black spots of various shapes. Lesions in the vitreous, such as vitreous hemorrhage, will also obscure the view. Vitreous hemorrhage will have an irregular shape and may have a reddish hue.

The **direct hand-held ophthalmoscope** is used to examine the fundus. Pharmacologic dilatation will greatly enhance the view of the disk, macula, and proximal retinal vessels. Dilation is achieved by using one drop of 1% tropicamide in Caucasian patients and one drop each of 1% tropicamide and 2.5% phenylephrine in all others. An **indirect ophthalmoscope** provides an excellent three-dimensional view of the optic nerve and retina but requires extensive practice to use and generally is not a tool for the nonophthalmologist.

The Welch Allyn Panoptic™ direct ophthalmoscope allows a five times larger view of the fundus than the standard direct ophthalmoscope and provides a better view of the fundus with an undilated pupil (**Figure 241-18**). It also allows for more distance between the patient

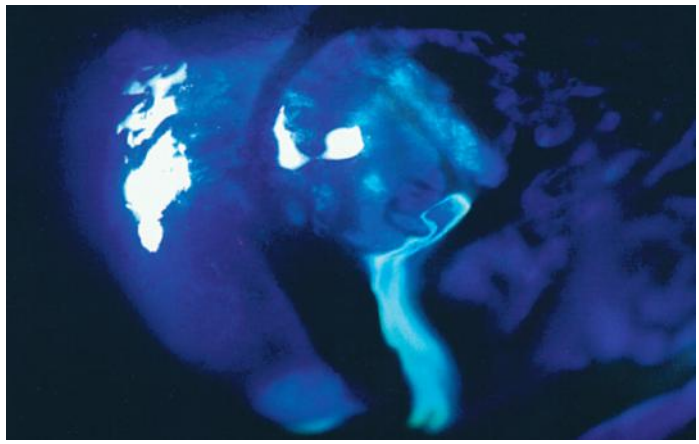

FIGURE 241-17. Positive Seidel test showing aqueous humor leaking through a full-thickness corneal wound. Aqueous humor will turn fluorescein lime-green under a cobalt-blue light as it oozes through the wound while being observed through the slit lamp.

and examiner, for the comfort of both. The Panoptic™ device attaches to a standard Welch Allyn handle.

Use the Panoptic as follows:

1. Remove your and the patient's glasses; seat the patient upright or with the patient's stretcher set as upright as possible. Position yourself in a direct line of vision to the patient's eyes.
2. With the scope turned off, focus on an object at least 10 ft away.
3. Set the aperture dial to small ("home" position—green line).
4. Turn on the scope and adjust to maximum brightness.
5. Ask the patient to be still and look straight ahead, and tell him or her that the eyecup will touch the brow.
6. Place your hand on the patient's forehead, and position the scope 6 in. away at a 15- to 20-degree angle to the temporal side.
7. Locate the red reflex, and move the scope toward the patient keeping the red reflex in view.
8. Maximum view should be obtained when the eyecup is compressed by half.
9. If you have a dominant eye and prefer to use that for the examination, you may examine the opposite eye without switching your eye on the scope.
10. Make sure you wipe off the eyepiece with antiseptic/antibacterial solution after use, or change eyepieces between patients.

Papilledema **Papilledema** is bilateral edema of the head of the optic nerve due to increased intracranial pressure. Any disease process that increases the intracranial pressure and inhibits vascular or axoplasmic flow in the optic nerve causes congestion and edema of the nerve head. Bilateral papilledema is a common finding in malignant hypertension, pseudotumor cerebri, intracranial tumors, and hydrocephalus. The disk margins are blurred, the cup is diminished or absent, and the nerve head is elevated with vascular congestion (**Figure 241-19**). Frequently, flame-shaped hemorrhages are seen on or adjacent to the nerve head. A distinguishing feature of papilledema is prolonged preservation of visual acuity (frequently patients are visually asymptomatic).

Intraocular Pressure The eye remains consistently "inflated" because of a delicate balance between intraocular aqueous fluid production and outflow. Intraocular pressure can decrease due to reduced ciliary body production (some cases of iritis and uveitis) or loss of globe integrity (perforating injury). Intraocular pressure increases when intraocular fluid production exceeds outflow (glaucoma, hyphema). Measure intraocular pressure in all cases of vision loss, eye pain (suspected glaucoma), and acute or remote trauma. **Do not attempt to measure intraocular pressure if globe rupture from blunt or penetrating trauma is suspected**, as the pressure placed on the globe during pressure measurement may cause extrusion of intraocular contents. **The normal intraocular pressure is 10 to 20 mm Hg.** Digital palpation of the globe may give a rough estimation, using the examiner's eye or tip of the nose as control. Provide topical eye anesthetic when devices are used to measure pressure. To measure pressure, the lid must be open, and the patient must look straight ahead. Hold the lids open, with your fingers compressing the patient's lids against the bony rims of the orbit. Avoid placing any pressure on the globe with your fingers when holding the lids open, because this will cause a falsely high reading. Document the method used for determining intraocular pressure. In recording the pressure, refer to **Table 241-1**.

Schiötz Tonometer The **Schiötz tonometer** is a device using a plunger to indent the cornea. Counterweights are placed on top of the plunger, and the reading off the tonometer scale is correlated to numbers on a chart supplied with the tonometer to give a pressure reading. **The direct Schiötz scale reading is *not* the intraocular pressure.** Schiötz tonometry is inaccurate and not well tolerated by patients, and the instrument is difficult to sterilize, leading to potential spread of infection (**Figure 241-20**). The Tono-Pen® XL (Reichert, Inc., Depew, NY), Goldman® applanation tonometer, and pneumatonometer have supplanted the use of the Schiötz tonometer.

Tono-Pen® The **Tono-Pen® XL** and similar electronic devices have disposable latex covers and measure pressure by indentation of the cornea. The Tono-Pen® XL is touched to the cornea 4 to 10 times and will read out an average pressure reading (**Figure 241-21**).

Applanation Tonometer Use of the **Goldman® applanation tonometer** requires training and practice and is a method used by optometrists and ophthalmologists. **The cone must be sterilized between patients.** The cone of the tonometer is touched to the cornea after topical anesthesia, and fluorescein is instilled into the eye (without irrigation). When looking through the slit lamp, two half circles are seen and properly aligned by

adjusting the dial on the tonometer, from which the pressure is read (**Figures 241-22** and **241-23**).

COMMON OPHTHALMIC MEDICATIONS USED IN THE ED

Topical anesthetics are needed for eye examination, intraocular pressure measurement, and corneal foreign body removal. Mydriatics and cycloplegics are needed for a more thorough eye examination. Ophthalmic antibiotics are prescribed for conjunctivitis and corneal abrasions. Antiviral medications are used for herpes simplex. Glaucoma may be treated with various combinations of topical nonselective and β_1-blockers, selective α_2-agonists, carbonic anhydrase inhibitors, cholinergic agents, and prostaglandin analogs. Allergic conjunctivitis is treated with topical nonsteroidal anti-inflammatory drugs, mast cell stabilizers, selective H_1 antagonists, or corticosteroids.

Table 241-2 lists common agents used in the ED and those that the consulting ophthalmologists may ask the emergency medicine physician to prescribe.

THE RED EYE

The differential diagnosis of the red eye is extensive. Key differentiating factors are the presence or absence of pain, itching, photophobia, systemic symptoms, discharge and injections, visual loss, and changes in the cornea, pupils, and intraocular pressure. **Table 241-3** lists various causes of the red eye with key differentiating features. Many of these conditions are discussed more extensively in the text.

TABLE 241-2 Ophthalmic Medications Used in the ED

Type	Generic Name	Trade Name	Indication	Cautions	Usual Dose
Mydriatic-cycloplegic					
Sympathomimetic	2.5% phenylephrine	Mydfrin® AK Dilate®	Pupil dilation, no cycloplegia, usually adjunctive to an anticholinergic	Hypertension, glaucoma; do not use after chemical injury to the eye	1 drop, onset 20–30 min, duration several hours
Anticholinergic	Cyclopentolate	Cyclogyl®	Short-term mydriasis and cycloplegia for examination	Glaucoma; higher concentrations in children can cause agitation	0.5% in children, one drop; 1% in adults, one drop; onset 30 min, duration ≤24 h
Anticholinergic	Tropicamide	Mydriacyl® Tropicamide Ophthalmic Solution	Short-term mydriasis and cycloplegia for examination	Glaucoma	One to two drops of 0.5% or 1% solution, onset 20 min; duration of action 6 h
Anticholinergic	Homatropine	Isopto Homatropine®	Intermediate-term pupil dilation, cycloplegia, treatment of iritis	Glaucoma, avoid in children	One to two drops of 2% solution; onset 30 min; duration of action 2–4 d; for iritis one to two drops twice a day
Antihistamine/ decongestant	Naphazoline and pheniramine	Naphcon-A® Visine A®	Conjunctival congestion/itching	Do not use >72 h; avoid in narrow angle glaucoma; hypertension; do not use with contact lenses in place	One drop three to four times a day
Antihistamine	Olopatadine	Patanol®	Allergic conjunctivitis	Do not administer while contact lenses are present	0.1% solution, one drop twice daily, onset of action 30–60 min, duration 12 h
Topical anesthetics	Tetracaine ophthalmic solution	—	Anesthetic for eye examination, foreign body removal	Sensitivity to ester-type anesthetics; no prolonged use; delays healing	0.5% solution, one to two drops; onset of action 1 min, duration 30 min
	Proparacaine ophthalmic solution	Alcaine® Ophthetic®	Anesthetic for eye examination foreign body removal		0.5% solution, one to two drops; onset of action 20 s, duration 15 min
Antibiotics	Erythromycin ophthalmic ointment	—	Conjunctivitis Do not use for corneal abrasion if a contact lens wearer	Not agent of choice for contact lens wearers	$^1/_2$ in. applied to lower eyelid two to four times a day
	Ciprofloxacin	Ciloxan® Ophthalmic Solution and Ointment	Conjunctivitis, corneal abrasion if a contact lens wearer	—	Solution: one to two drops when awake every 2 h for 2 d; ointment, $^1/_2$ in. applied to lower eyelid three times a day for 2 d
	Tobramycin	Tobrex® Ophthalmic Solution and Ointment	Conjunctivitis, corneal abrasions if a contact lens wearer	—	0.3% solution, one to two drops every 4 h; 0.3% ointment, $^1/_2$ in. applied to lower lid two to three times/d
	Gentamicin	Garamycin® Genoptic®	Conjunctivitis, corneal abrasion if a contact lens wearer	—	0.3% solution, instill one to two drops every 4 h; 0.3% ointment, $^1/_2$ in. applied to lower lid two to three times/d
	Sulfacetamide sodium	Bleph-10 Ophthalmic Solution 10%®	Conjunctivitis	Do not use for corneal abrasion if a contact lens wearer or if allergic to sulfa	One to two drops four times/d
	Besifloxacin	Besivance Ophthalmic Suspension®	Conjunctivitis, corneal abrasion if a contact lens wearer	—	One drop three times a day for 7 d

(*Continued*)

TABLE 241-2 Ophthalmic Medications Used in the ED (*Continued*)

Type	Generic Name	Trade Name	Indication	Cautions	Usual Dose
Antibiotics (continued)	Levofloxacin	Iquix Ophthalmic Solution® Quixin Ophthalmic Solution®	Conjunctivitis, corneal abrasion if a contact lens wearer	Corneal ulcer	One to two drops every 30 min to 2 h while awake and every 4–6 h at night
	Moxifloxacin hydrochloride	Moxeza Ophthalmic Solution® Vigamox Ophthalmic Solution®	Conjunctivitis, corneal abrasion if a contact lens wearer		One drop twice a day for 7 d
	Ofloxacin	Ocuflox Ophthalmic Solution®	Conjunctivitis, corneal abrasion if a contact lens wearer		Conjunctivitis: one to two drops every 2–4 h for 2 d, then one to two drops four times a day for 5 d. Corneal ulcer: one to two drops every 30 min while awake and one to two drops every 4–6 hours after retiring for 2 d, then one to two drops every hour while awake for 5–7 days, then one to two drops four times a day for 2 d or until treatment completion
	Polymyxin b sulfate, trimethoprim sulfate	Polytrim Ophthalmic Solution®	Conjunctivitis	Do not use for corneal abrasion if a contact lens wearer	One drop every 3 h
	Gatifloxacin	Zymaxid Ophthalmic Solution®	Conjunctivitis, corneal abrasion if a contact lens wearer		
Antivirals	Idoxuridine	Dendrid Sterile Ophthalmic Solution®	Herpes simplex keratitis		One drop every hour
	Trifluridine	Viroptic Ophthalmic Solution®	Herpes simplex keratitis		One drop every 2 h
	Ganciclovir	Zirgan Ophthalmic Gel®	Herpes simplex keratitis		One drop five times per day
Antibiotic–steroid combination	Prednisolone acetate, sulfacetamide sodium	Blephamide Ophthalmic Suspension® Brimonidine Tartrate Ophthalmic Solution®	Conjunctivitis	Do not use for corneal abrasion if a contact lens wearer or if sulfa allergy	Suspension: instill two drops into conjunctival sac every 4 h during the day and at bedtime Ointment: apply ½-in. ribbon into conjunctival sac three to four times a day and two to four times a night
	Dexamethasone, neomycin sulfate, polymyxin b sulfate	Maxitrol Ophthalmic Ointment® Maxitrol Ophthalmic Suspension®	Conjunctivitis	Do not use for corneal abrasion if a contact lens wearer	Ointment: ½ inch in conjunctival sac(s) up to three to four times a day Suspension: instill one to two drops four to six times a day up to every hour
	Neomycin sulfate, polymyxin b sulfate, prednisolone acetate	Poly-Pred Ophthalmic Suspension®	Conjunctivitis	Do not use for corneal abrasion if a contact lens wearer	One to two drops every 3–4 h
	Dexamethasone, tobramycin	TobraDex Ophthalmic Ointment® TobraDex Ophthalmic Suspension® TobraDex ST Ophthalmic Suspension®	Conjunctivitis	Do not use for corneal abrasion if a contact lens wearer	Suspension: one to two drops every 4–6 h ST: one drop every 4–6 h Ointment: ½-in. ribbon three to four times a day
	Loteprednol etabonate, tobramycin	Zylet Ophthalmic Suspension®	Conjunctivitis	Do not use for corneal abrasion if a contact lens wearer	One to two drops every 4–6 h

Nonsteroidal anti-inflammatory drugs	Ketorolac	Acular Ophthalmic Solution® Acular LS Ophthalmic Solution® Acular PF Ophthalmic Solution® Acuvail Ophthalmic Solution®	Allergic conjunctivitis, corneal abrasions, UV keratitis		One drop four times a day for 3–4 d
	Bromfenac	Bromday Ophthalmic Solution®	Allergic conjunctivitis, corneal abrasions, UV keratitis		One drop every day
	Nepafenac	Nevanac Ophthalmic Suspension®	Allergic conjunctivitis, corneal abrasions, UV keratitis		One drop three times a day
	Diclofenac sodium	Voltaren Ophthalmic Solution®	Allergic conjunctivitis, corneal abrasions, UV keratitis		One drop four times a day
Mast cell stabilizers	Nedocromil sodium	Alocril Ophthalmic Solution®	Allergic conjunctivitis		One to two drops twice a day
	Pemirolast potassium	Alamast Ophthalmic Solution®	Allergic conjunctivitis		One to two drops four times a day
	Lodoxamide tromethamine	Alomide Ophthalmic Solution®	Allergic conjunctivitis		One to two drops four times a day
	Cromolyn sodium	Cromolyn Sodium Ophthalmic Solution®	Allergic conjunctivitis		One to two drops four to six times a day
Selective H_1 antagonist	Bepotastine besilate	Bepreve Ophthalmic Solution®	Allergic conjunctivitis		One drop two times a day
	Epinastine hydrochloride	Elestat Ophthalmic Solution®	Allergic conjunctivitis		One drop two times a day
	Emedastine difumarate	Emadine Ophthalmic Solution®	Allergic conjunctivitis		One drop up to four times a day
	Alcaftadine	Lastacaft Ophthalmic Solution®	Allergic conjunctivitis		One drop every day
	Azelastine hydrochloride	Optivar Ophthalmic Solution®	Allergic conjunctivitis		One drop two times a day
Combination mast cell stabilizers–H_1 antagonists	Olopatadine hydrochloride	Pataday Ophthalmic Solution® Patanol Ophthalmic Solution®	Allergic conjunctivitis		One drop two times a day
Nonselective β-blocker	Levobunolol hydrochloride	Betagan Ophthalmic Solution®	Glaucoma		0.5%: one to two drops once a day; twice a day for more severe or uncontrolled glaucoma 0.25%: one to two drops twice a day
	Timolol hemihydrate	Betimol Ophthalmic Solution®	Glaucoma		One drop 0.25% twice a day; may increase to maximum of one drop 0.5% twice a day
	Timolol maleate	Istalol Ophthalmic Solution® Timoptic Sterile Ophthalmic Solution® Timoptic-XE Sterile Ophthalmic Gel Forming Solution®	Glaucoma		One drop once a day
	Carteolol hydrochloride	Carteolol Hydrochloride Ophthalmic Solution® Ocupress Ophthalmic Solution®	Glaucoma		One drop twice a day
	Metipranolol	OptiPranolol Ophthalmic Solution®	Glaucoma		One drop two times a day

(*Continued*)

TABLE 241-2 Ophthalmic Medications Used in the ED (*Continued*)

Type	Generic Name	Trade Name	Indication	Cautions	Usual Dose
Selective β_1-blocker	Betaxolol hydrochloride	Betaxolol Hydrochloride Ophthalmic Solution® Betoptic S Ophthalmic Suspension®	Glaucoma		One to two drops twice a day
Selective α_2-agonists	Brimonidine tartrate	Alphagan P Ophthalmic Solution® Brimonidine Tartrate Ophthalmic Solution®	Glaucoma		One drop every 8 h
	Apraclonidine hydrochloride	Iopidine 0.5% Ophthalmic Solution® Iopidine Ophthalmic Solution®	Glaucoma		One to two drops three times a day
Combination α_2-agonist–nonselective β-blocker	Brimonidine tartrate, timolol maleate	Combigan Ophthalmic Solution®	Glaucoma		One drop every 12 h
Carbonic anhydrase inhibitors	Brinzolamide	Azopt Ophthalmic Suspension®	Glaucoma		One drop three times a day
	Dorzolamide hydrochloride	Trusopt Sterile Ophthalmic Solution®	Glaucoma		One drop three times a day
Combination carbonic anhydrase inhibitor–selective β-blocker	Dorzolamide hydrochloride, timolol maleate	Cosopt Sterile Ophthalmic Solution®	Glaucoma		One drop every 12 h
Cholinergic agents	Pilocarpine hydrochloride	Isopto Carpine Ophthalmic Solution®	Glaucoma; contraindicated in pupillary block glaucoma		Two drops three to four times a day
Prostaglandin analog	Bimatoprost	Lumigan Ophthalmic Solution®	Glaucoma		One drop once a day
	Travoprost	Travatan Z Ophthalmic Solution®	Glaucoma		One drop once a day
	Latanoprost	Xalatan Ophthalmic Solution®	Glaucoma		One drop once a day
	Loteprednol etabonate	Alrex Ophthalmic Suspension®	Allergic conjunctivitis, uveitis		One drop four times a day
	Difluprednate	Durezol Ophthalmic Emulsion®	Allergic conjunctivitis, uveitis		One drop four times a day
	Fluorometholone acetate	Flarex Ophthalmic Suspension® FML Forte Ophthalmic Suspension® FML Ophthalmic Ointment® FML Ophthalmic Suspension®	Allergic conjunctivitis, uveitis		One to two drops four times a day
	Loteprednol etabonate	Lotemax Ophthalmic Ointment® Lotemax Ophthalmic Suspension®	Allergic conjunctivitis, uveitis		Ointment: ½ inch four times a day Suspension: one to two drops four times a day
	Prednisolone acetate	Omnipred Ophthalmic Suspension® Pred Forte Ophthalmic Suspension® Pred Mild Ophthalmic Suspension®	Allergic conjunctivitis, uveitis		Two drops four times a day
	Rimexolone	Vexol 1% Ophthalmic Suspension®	Allergic conjunctivitis, uveitis		One to two drops every hour while awake

Note: Blue-eyed individuals are sensitive to mydriatics and cycloplegics and tend to have a longer duration of action, whereas brown-eyed individuals may require a double dose for adequate mydriasis.

Abbreviation: UV = ultraviolet.

TABLE 241-3 Differential Diagnosis of the Red Eye

Diagnosis	Pain	Itching	Photophobia	Systemic Symptoms	Visual Acuity	Discharge	Injection	Cornea	Pupils	IOP
Chalazion	Mild-moderate lid	No	No	No	Normal	No	Minimal localized	Normal	Normal	Normal
Hordeolum	Mild-moderate lid	No	No	No	Normal	No	Minimal localized	Normal	Normal	Normal
Blepharitis	Mild – foreign body sensation	Yes	Yes	No	Normal	Morning crusting, tearing	Diffuse	Normal	Normal	Normal
Dacryocystitis	Mild-moderate medial canthus	No	No	Fever if severe	Normal	No	Localized	Normal	Normal	Normal
Ectropion	Irritation	No	No	No	Normal	Watery	Lid margin and diffuse	Normal	Normal	Normal
Corneal abrasion	Yes	No	No unless associated iritis (after several hours)	No	Normal unless central or with associated iritis	Watery	Diffuse	Visible abrasion	Normal or constricted with associated iritis	Normal
Ultraviolet keratitis	Severe	No	No unless associated iritis (after several hours)	No	Decreased	Watery	Diffuse	Punctate lesions	Normal or constricted with associated iritis	Normal
Superficial keratitis	Mild	No	No	No	Normal	Watery	Diffuse	Punctate lesions	Normal	Normal
Corneal ulcer	Moderate	No	No	No	No unless central or with associated iritis	Watery	Diffuse	Visible ulcer	Normal	Normal
Corneal foreign body	Moderate	No	No	No	Normal unless central	Watery	Diffuse	Visible foreign body	Normal	Normal
Chemical burn	Moderate-severe	No	No	No	Normal unless central	Watery	Diffuse—none with severe alkaline burn	Cloudy if severe	Normal	Normal
Bacterial conjunctivitis	None or irritation	No	No	No	Normal	Purulent	Diffuse bulbar and palpebral	Normal, punctate lesions if associated keratitis	Normal	Normal
Viral conjunctivitis	None or irritation, severe with EKC	No	No	Occasional URI symptoms, fever with EKC	Normal	Watery	Diffuse bulbar and palpebral	Normal, punctate lesions if associated keratitis	Normal	Normal
Allergic conjunctivitis	None	Yes	No	Sneezing, rhinorrhea	Normal	Watery	Diffuse bulbar and palpebral	Normal	Normal	Normal
Stevens-Johnson syndrome	Foreign body sensation, burning	Yes	Yes	Fever, tachycardia, hypotension, skin and mucous membranes involved	Decreased	Watery	Diffuse	Punctate lesions, corneal ulcer, neovascularization, hazy, perforation	—	—
Orbital cellulitis	Pain with eye movement	No	No	Fever	Normal, decreased late	No	Yes	Normal	Normal	Occasionally increased
Preseptal cellulitis	Mild—no pain with eye movement	No	No	Fever	Normal	No	Yes	Normal	Normal	Normal
Episcleritis	Mild	No	No	Usually none; occasional rheumatologic symptoms	Normal	Watery	Focal	Normal	Normal	Normal
Scleritis	Severe, tender to palpation	No	No	Usually none; occasional rheumatologic symptoms	Decreased with advanced disease	Watery	Diffuse, occasionally violaceous color	Normal	Normal	Normal, may be increased

Abbreviations: EKC = epidemic keratoconjunctivitis; IOP = intraocular pressure; URI = upper respiratory infection.

OCULAR INFECTIONS AND INFLAMMATION

PRESEPTAL (PERIORBITAL) AND POSTSEPTAL (ORBITAL) CELLULITIS

Orbital and periorbital infections exist in a spectrum of increasing severity: preseptal (periorbital) cellulitis, postseptal (orbital) cellulitis, subperiosteal abscess, orbital abscess, and cavernous sinus thrombosis, from least to most severe. Preseptal cellulitis and postseptal cellulitis, although both of an infectious etiology and involving periocular tissues, are very different entities with different morbidities. **Preseptal cellulitis (periorbital cellulitis)** is an infection of the eyelids and periocular tissues that is anterior to the orbital septum. It is generally benign and may be treated in the outpatient setting. **Postseptal cellulitis (orbital cellulitis)** is an infection of the orbital soft tissues posterior to the orbital septum. It may be life- and vision-threatening and must be treated as an inpatient with IV antibiotics and occasionally surgical drainage. **Endophthalmitis** is an infection of the globe and is a completely separate entity.

The outward appearance of the patient with postseptal cellulitis may be very similar to that of the patient with preseptal cellulitis. Preseptal and postseptal cellulitis may both display excessive tearing, fever, erythema, edema, warmth, and tenderness to palpation of the lids and periorbital soft tissues. Laboratory studies do not discriminate between the two conditions, and blood cultures are not helpful. **CT scan differentiates the two conditions.** Differentiation of preseptal and postseptal cellulitis is essential. A misdiagnosis can result in significant neurologic disability and death. The differential diagnosis for preseptal and postseptal cellulitis is listed in **Table 241-4**.

TABLE 241-4 Differential Diagnosis of Preseptal and Postseptal Cellulitis

Postseptal cellulitis
Subperiosteal abscess
Orbital abscess
Cavernous sinus thrombosis
Dacryoadenitis
Dacryocystitis
Hordeolum
Bacterial and viral conjunctivitis
Contact dermatitis
Herpes zoster
Herpes simplex

Preseptal Cellulitis **Preseptal cellulitis** is usually associated with upper respiratory tract infections, especially paranasal sinusitis, and may result from eyelid problems such as hordeolum, chalazion, insect bites, and trauma. Preseptal cellulitis is primarily a disease of childhood, with most patients <10 years of age. The most common organisms are *Staphylococcus aureus* and *S. epidermidis*, *Streptococcus* species, and anaerobes. Since the introduction of the *Haemophilus influenzae* type B vaccine, *H. influenzae* has become a rare cause of preseptal cellulitis in children.

Upper respiratory symptoms, low-grade fever, redness and swelling of the eyelid, and excessive tearing (epiphora) are signs and symptoms of preseptal cellulitis. **The eye itself is not involved, and visual acuity and pupillary reaction are maintained, and full painless ocular motility is preserved.**

CT scan of the orbit is not necessary for uncomplicated cases of preseptal cellulitis; however, when there is decreased ocular motility or other signs of orbital involvement, or in the young child in whom examination may be unreliable, or if there is any concern for postseptal cellulitis, obtain a CT scan of the orbit with contrast. MRI is also an option.

The nontoxic, adult patient and older child with mild preseptal cellulitis may be managed as outpatients with oral antibiotics (amoxicillin/clavulanic acid or a first-generation cephalosporin), hot packs, and close follow-up in 24 to 48 hours. For the young child and more severe cases of preseptal cellulitis, consider hospitalization; treatment with a third-generation cephalosporin such as ceftriaxone and vancomycin is often added for the possibility of methicillin-resistant *S. aureus*. Obtain ophthalmology consultation in young children (see Chapter 119, Eye Emergencies in Infants and Children).

Postseptal or Orbital Cellulitis **Postseptal cellulitis** occurs most frequently from the spread of paranasal sinusitis. The ethmoid sinus is most frequently implicated, probably due to perforation of the thin lamina papyracea. Trauma, intraorbital foreign body, spread of periorbital skin infection, seeding from bacteremia, and ocular surgery are also predisposing factors. The infection is often polymicrobial, with *S. aureus*, *S. pneumoniae*, and anaerobes being most common; however, *H. influenzae* should be considered in unimmunized young children and mucormycosis in diabetics and immunocompromised patients.

Orbital cellulitis is characterized by an insidious onset with preceding upper respiratory symptoms, including rhinitis, facial pressure, and fever. The patient will often complain of pain when moving the eyes. There may be a decrease in visual acuity. On examination, signs referable to orbital involvement are present, including limitation of extraocular muscle movement , chemosis, proptosis, abnormal pupillary response, and decreased visual acuity. **Involvement of cranial nerves 3, 4, or 6 suggests cavernous sinus thrombosis.**

Postseptal cellulitis may lead to vision loss and requires an aggressive approach with hospitalization and institution of IV antibiotics (see Chapter 119, Eye Emergencies in Infants and Children). Any patient

suspected of having postseptal cellulitis clinically or by CT scan of the orbit should have immediate ophthalmologic consultation. Antibiotics should be broad spectrum with both aerobic and anaerobic coverage. Choices include second- or third-generation cephalosporins, ampicillin-sulbactam, ticarcillin-clavulanate, and carbapenems. A fluoroquinolone is used for penicillin-allergic patients, and metronidazole or clindamycin is added for anaerobic coverage. Adjuvant therapy includes a topical nasal decongestant such as oxymetazoline. Consider emergent **lateral canthotomy** if the intraocular pressure is elevated or an optic neuropathy is present. Patients with orbital abscess require operative drainage and debridement in addition to antibiotics. Complications include cavernous sinus thrombosis, frontal bone osteomyelitis, meningitis, subdural empyema, epidural abscess, and brain abscess that should be evident on CT or MRI scan.

LIDS

Stye (External Hordeolum) A **stye** is an acute bacterial infection (usually *Staphylococcus*) of the follicle of an eyelash and adjacent sebaceous glands (Zeis) or sweat glands (Moll). It is located at the lash line and has the appearance of a small pustule at the margin of the eyelid (**Figure 241-24**). An **internal hordeolum** is an acute bacterial infection of the meibomian glands associated with the eyelashes. Signs and symptoms are similar to a stye except that the pustule occurs on the inner surface of the tarsal plate. Signs and symptoms include pain, edema, and erythema of the eyelid. Warm compresses and erythromycin ophthalmic ointment twice daily for 7 to 10 days are usually sufficient treatment. Removal of the offending eyelash could be considered. Systemic antibiotics may be necessary if there is significant surrounding cellulitis. Should incision and drainage be considered, refer to an ophthalmologist.

Chalazion A **chalazion** is an acute or chronic inflammation of the eyelid secondary to blockage of one of the meibomian or Zeis oil glands in the tarsal plate (**Figure 241-25**). The condition tends to be subacute to chronic and is associated with a (usually) painless lump that develops in the lid or at the lid margin, occasionally with mild erythema. Clinical differentiation of an acute chalazion from an internal hordeolum may be impossible, but treatment is the same. Treatment of chronic or recurrent chalazia may require injection of corticosteroids into the lesion or incision and curettage/drainage depending on the size. Refer to an ophthalmologist in 1 to 2 weeks.

Blepharitis **Blepharitis** is a common cause of prolonged red eye due to inflammation of the eyelash follicles along the edge of the eyelid. The most common cause is overgrowth of *S. epidermidis*, and the inflation is largely a reaction to the deltalike toxin produced by the bacteria. The disorder is associated with seborrheic dermatitis, atopic dermatitis, and occasionally eyelash infestation with lice or infection with *S. aureus*. Typical symptoms include conjunctival injection; crusting, swollen, pruritic eyelids; and occasional complaint of eye pain. It is most commonly treated with careful daily cleansing of the edges of the eyelids and eyelashes. In severe cases, antibiotic drops or ointment at night may be required.

FIGURE 241-25. Chalazion. [Courtesy of Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

Conjunctivitis **Conjunctivitis** is an inflammatory condition of the conjunctiva and is a common cause of the red eye. It is usually viral in etiology and is a benign self-limited condition. **The task is to sort out the occasional case of serious bacterial infection or corneal herpetic involvement that may result in vision loss without aggressive treatment.** Causes of conjunctivitis are viral, bacterial (including gonococcal and chlamydial), parasitic, or fungal infections and allergic, toxic, or chemical irritation. **Keratoconjunctivitis** is the term used to indicate corneal involvement, usually in the form of punctuate ulcerations.

Bacterial Conjunctivitis Symptoms of **bacterial conjunctivitis** are painless, unilateral, or bilateral mucopurulent discharge (**Figure 241-26**), frequently causing adherence of the eyelids on awakening. The conjunctiva is injected, and the cornea is clear *without* fluorescein staining. Chemosis (edema of the conjunctiva) is common, and preauricular lymphadenopathy is usually absent, except in gonococcal infections. Typical pathogens are *Staphylococcus* and *Streptococcus* species. Perform fluorescein stain of the cornea (especially in infants) to avoid missing a corneal abrasion, ulcer, or herpetic dendrite. Consider culture and sensitivity of the discharge in severe cases. Treatment consists of a topical ocular antibiotic four times daily for 5 to 7 days. Treatment with a broad-spectrum agent is safe for patients 2 months of age and older. Trimethoprim–polymyxin B is very effective and avoids potential allergies to sulfa and neomycin preparations. Wearers of soft contact lenses should be treated with a fluoroquinolone (besifloxacin, gatifloxacin, levofloxacin, moxifloxacin, or ofloxacin) or aminoglycoside (tobramycin) to treat *Pseudomonas*. Gentamicin is seldom used because of the high incidence of ocular irritation.

Gonococcal conjunctivitis is a cause of ophthalmia neonatorum, and **chlamydial conjunctivitis** is also a disease of the newborn (see Chapter 119, Eye Emergencies in Infants and Children, for discussion of ophthalmia neonatorum and chlamydia conjunctivitis).

Viral Conjunctivitis The most common cause of **viral conjunctivitis** is adenovirus, which generally resolves spontaneously with only symptomatic

FIGURE 241-26. Bacterial conjunctivitis. Note the mucopurulent discharge, conjunctival injection, and lid edema in a pediatric patient with *Haemophilus influenzae* conjunctivitis. [Reproduced with permission from Knoop K, Stack L, Storrow A: *Atlas of Emergency Medicine,* 2nd ed. © 2002, McGraw-Hill, New York.]

treatment. Several systemic viral diseases, such as measles, influenza, and mumps, may also cause conjunctival injection. Viral keratoconjunctivitis may be caused by **herpes simplex** and **herpes zoster**, and, if left untreated, may result in corneal scarring and loss of vision. **Epidemic keratoconjunctivitis** (**Figure 241-27**) is a more severe type of adenovirus infection that is highly contagious and tends to occur in epidemics. It is often preceded by cough, high fever, malaise, and myalgias. Symptoms are marked eye redness, photophobia, foreign body sensation, and tearing. Physical examination findings are similar to viral conjunctivitis, except they are more severe.

Viral conjunctivitis is often preceded by an upper respiratory infection. Symptoms include a complaint of "red eye" and mild to moderate watery discharge. There is no eye pain unless there is some degree of keratitis. Generally, one eye will be involved initially, with the other eye becoming involved within days. Physical examination reveals unilateral or bilateral conjunctival injection, occasional chemosis and small subconjunctival hemorrhages, and preauricular lymphadenopathy. Slit lamp examination demonstrates follicles (small, regular, translucent bumps) on the inferior palpebral conjunctiva (**Figure 241-27**). Punctate fluorescein staining represents keratitis (**Figure 241-28**). Make sure to examine the cornea with fluorescein to avoid missing a herpetic dendrite.

Treatment consists of cool compresses; ocular decongestants such as Naphcon-A®, one drop three times daily as needed for redness and conjunctival congestion; and artificial tears five or six times a day. Viral conjunctivitis can take 1 to 3 weeks to run its course and is very contagious. Instruct the patient to wash hands frequently and use separate towels. The examiner should wear gloves to avoid self-contamination, and the slit lamp, exam table, and exam chair should be disinfected after patient contact. If, after a history and physical examination, it is still uncertain if the conjunctivitis is viral or bacterial, prescribe ocular antibiotics until the patient is reexamined by an ophthalmologist.

Allergic Conjunctivitis Allergens can cause watery discharge, redness, and itching. Physical findings may include erythematous swollen eyelids and injected and edematous conjunctiva with papillae (irregular mounds of tissue with a central vascular tuft) on the inferior conjunctival fornix (**Figure 241-29**). Try to identify and eliminate the offending allergen. Treatment is cool compresses four times daily and topical drops, depending on the severity of symptoms. Mild symptoms may be treated with artificial tears alone. Moderate symptoms may additionally require a topical antihistamine/decongestant, mast cell stabilizers, or nonsteroidal anti-inflammatory drugs, and severe symptoms may justify the use of topical steroids. We generally recommend against the use of ocular steroids except by an ophthalmologist because occult herpetic infection is always a possibility (see following section on herpes simplex virus infection of the cornea). **Should ocular steroids be chosen as a treatment option, consult an ophthalmologist first.**

Subconjunctival Hemorrhage The fragile conjunctival vessels can rupture from trauma, sudden increased venous pressure related to Valsalva maneuvers (sneezing, coughing, vomiting, straining), hypertension, or spontaneously (**Figure 241-30**). The eye examination is normal other than the presence of the subconjunctival hemorrhage. Reassurance is the only treatment necessary, and the hemorrhage usually resolves within 2 weeks. If multiple recurrent episodes occur, coagulation studies and further investigation are warranted.

CORNEA

Herpes Simplex Keratoconjunctivitis **Herpes simplex virus** can affect the eyelids, conjunctiva, and cornea. The patient may give a history of oral or genital herpes infection and complain of photophobia,

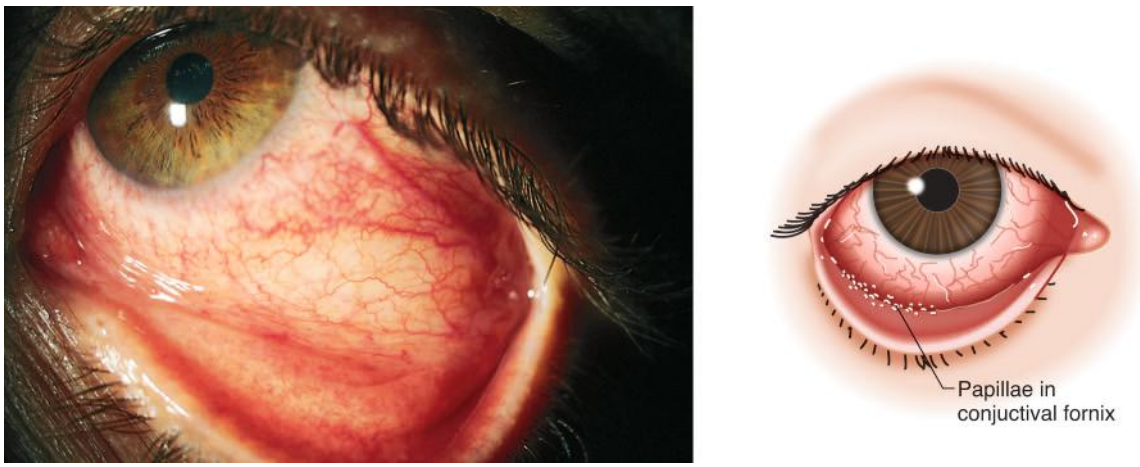

FIGURE 241-27. Epidemic keratoconjunctivitis (EKC). Diffuse bulbar conjunctival injection and inferior palpebral papillae as seen in EKC. The erythema is usually much more intense than in this photo. [Reproduced with permission from Knoop K, Stack L, Storrow A: *Atlas of Emergency Medicine,* 2nd ed. © 2002, McGraw-Hill, New York.]

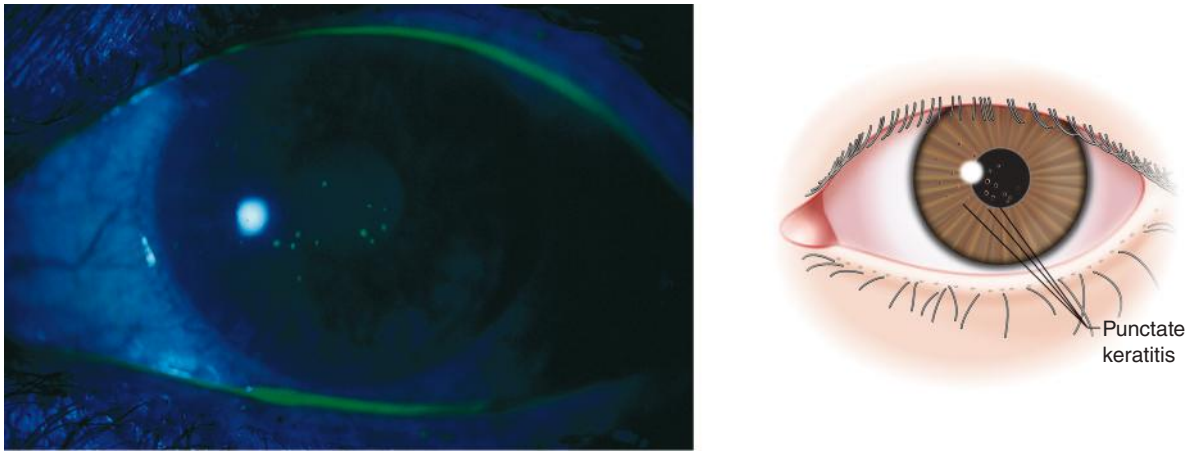

FIGURE 241-28. Fluorescein stain demonstrating punctate staining as seen with epithelial keratitis in epidemic keratoconjunctivitis. The keratitis is usually much more widespread than demonstrated here. [Reproduced with permission from Knoop K, Stack L, Storrow A: *Atlas of Emergency Medicine,* 2nd ed. © 2002, McGraw-Hill, New York.]

pain (which may be mild), eye redness, and decreased vision. The eyelid may have the typical herpetic vesicular eruptions. The infection tends to be unilateral with a palpable preauricular node. The conjunctiva can be injected, but ocular herpes simplex frequently presents with only corneal findings on physical examination. The findings can be subtle and are easily missed. The dendrite of herpes keratitis is an epithelial defect that can be seen with fluorescein staining and classically has a linear branching pattern with terminal bulbs (**Figure 241-31**), or may be a "geographic ulcer," which is an amoeba-shaped ulceration with dendrites at the edge. **Herpetic infection may be very difficult to diagnose**, as infection may present as involvement of the cornea with a neurotrophic ulceration, which is a smooth-edged ulcer over an area of underlying stromal disease; as stromal edema and/or white infiltrates with intact epithelium and an associated mild iritis with keratitic precipitates; or as an isolated uveitis, without epithelial or stromal involvement and with an elevated intraocular pressure. Corneal sensation may be decreased and should be checked before instillation of anesthetic drops. The diagnosis of herpes simplex is usually clinical, but check with the ophthalmologic consultant to see if cultures are desired.

Herpes simplex keratitis can progress to corneal scarring and requires prompt treatment with topical antiviral agents. **An initial outbreak of herpes simplex virus involving the lids is treated with an oral acyclovir derivative such as acyclovir (Zovirax®) or famciclovir (Famvir®). For conjunctival involvement, prescribe topical trifluridine (Viroptic®), one drop nine times a day.** Idoxuridine (Dendrid®), one drop every 1 hour during the day and every 2 hours at night, can be substituted for those who are allergic. Erythromycin ophthalmic ointment can be added to prevent secondary infection.

Oral acyclovir or other derivative agents do not prevent progression of corneal epithelial disease to deeper involvement of the stroma or uveal tract. Do not prescribe topical steroids, and refer patients to an ophthalmologist in 24 to 48 hours.

Herpes Zoster Ophthalmicus **Herpes zoster ophthalmicus** is shingles involving the first division (V1) of the trigeminal nerve distribution with ocular involvement. The rash usually does not cross the midline and involves only the upper eyelid, although rarely the cheek (V2) and mandible (V3) may be affected. **Involvement of the nasociliary nerve is associated with cutaneous lesions on the tip of the nose (Hutchinson sign) and predicts a high likelihood of ocular involvement.** Symptoms that may precede the rash are pain and paresthesias in a dermatomal distribution; fever, headache, and malaise; and red eye, blurred vision, and eye pain/photophobia. Eye involvement may take the form of epithelial keratitis, stromal keratitis, uveitis, retinitis, and choroiditis. Optic neuritis and other cranial nerve palsies may occur, as well as elevated intraocular pressure. The cornea can have a pseudodendrite, which is a poorly staining mucous plaque with no epithelial erosion (unlike herpes simplex virus, which has a true dendrite with epithelial

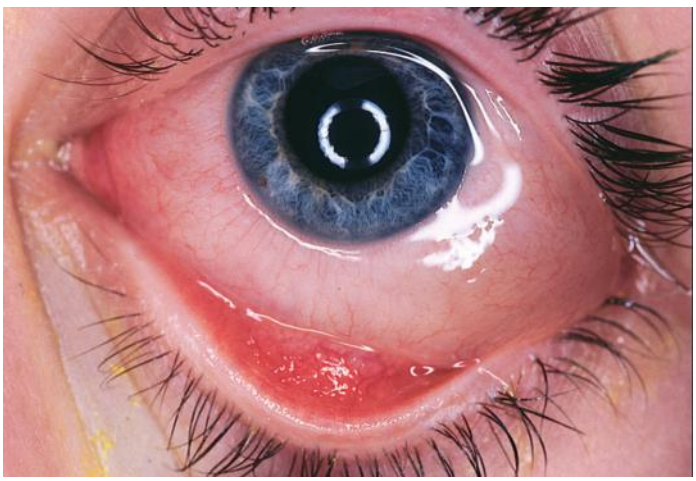

FIGURE 241-29. Prominent chemosis may be seen in allergic conjunctivitis. [Reproduced with permission from Knoop K, Stack L, Storrow A: *Atlas of Emergency Medicine,* 2nd ed. © 2002, McGraw-Hill, New York.]

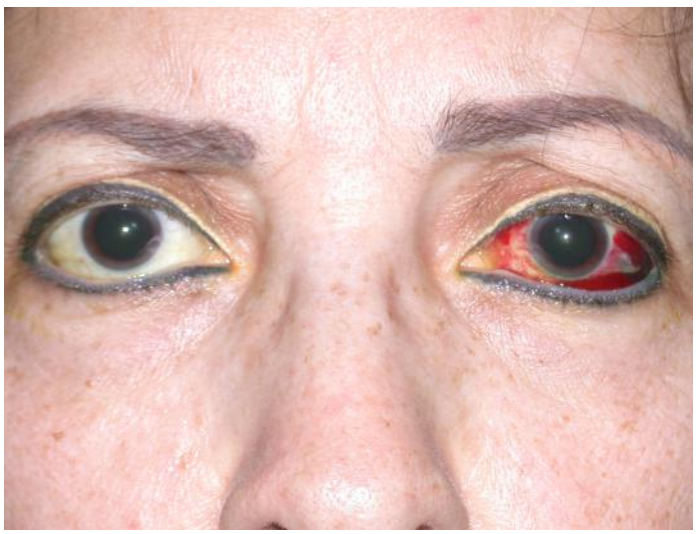

FIGURE 241-30. Spontaneous subconjunctival hemorrhage. [Courtesy of Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

erosion and staining). The anterior chamber on slit lamp examination can show the cells and flare of iritis. Consider the possibility of associated immunocompromise in patients <40 years old.

Skin involvement is treated with cool compresses, and patients presenting with a rash for <1 week should be treated with oral antiviral medications for 7 to 10 days. Choices include acyclovir, 800 milligrams five times a day; famciclovir, 500 milligrams three times a day; or valacyclovir, 1000 milligrams three times a day. Cutaneous lesions are treated with bacitracin or erythromycin ointment to prevent secondary bacterial infection. Conjunctivitis is treated with erythromycin ophthalmic ointment twice a day. Iritis can be treated with topical steroids such as prednisolone acetate 1%, one drop four to five times a day, but consultation with an ophthalmologist is recommended first. Pain reduction can be achieved with topical cycloplegic agents (cyclopentolate 1%, one drop three times daily). If herpes zoster ophthalmicus is diagnosed, in particular, when the orbit, optic nerve, or cranial nerves are involved, or if the patient is immunocompromised or systemically ill, consider admission and IV acyclovir.

Corneal Ulcer A **corneal ulcer** is a serious infection involving multiple layers of the cornea and develops secondary to breaks in the epithelial barrier, so that infectious agents invade the underlying corneal stroma. The initial disruption of the epithelial layer can be due to desquamation, trauma, or direct microbial invasion. Exposure keratitis from incomplete lid closure secondary to **Bell's palsy** can cause corneal desiccation and sloughing of the epithelium, allowing bacteria to gain access to the underlying stroma and create an ulcer. Trauma can also breach the epithelium and inoculate the cornea. *S. pneumoniae* and *S. aureus* are common causes of corneal ulceration. Contact lens users can develop *Pseudomonas* infection (**Table 241-5**). Wearing of soft contact lenses is a very common cause of corneal ulcers, and the incidence increases dramatically in those who use extended-wear lenses and wearers who sleep with them in place. Fungi and viruses have also become a more common cause of corneal ulcer due to the widespread use of both topical and systemic immunosuppressant medications.

The history should include an inquiry into the use of contact lenses, previous ocular surgery or injury, recent trauma, and presence or history of genital herpes. Medication history should include questions about the use of topical or systemic steroids or other immunosuppressants.

Patients may complain of redness and swelling of lids and conjunctivae, discharge from the eye, ocular pain or foreign body sensation, photophobia, or blurred vision. Visual acuity is decreased if the ulcer is located in the central visual axis or if uveal tract inflammation is present. The eyelids and conjunctiva may be erythematous with a mucopurulent discharge. Associated iritis may cause a miotic pupil and consensual photophobia due to ciliary spasm. Examination of the cornea reveals a round or irregular ulcer with a white, hazy base extending into the underlying stroma due to WBC infiltration, or with heaped-up edges (**Figure 241-32**). Slit lamp examination reveals flare and cell from iritis and occasionally a hypopyon.

TABLE 241-5 Causative Organisms in Corneal Ulcer

Bacteria
Pseudomonas aeruginosa
Streptococcus pneumoniae
Staphylococcus species
Moraxella species
Viruses
Herpes simplex
Varicella zoster
Fungi
Candida
Aspergillus
Penicillium
Cephalosporium

Diagnosis is made by the clinical appearance. The organism is identified by scraping of the ulcer and culture of the offending organism, generally done by the ophthalmologist. The differential diagnosis as to causative organisms is listed in **Table 241-5**.

Corneal ulcers need to be treated aggressively with topical antibiotics. Emergent ophthalmologic consultation for culture of the ulcer and institution of appropriate antibiotics should be considered. Once cultures are obtained, topical antibiotics are started. A fluoroquinolone such as ciprofloxacin (Ciloxan®) or ofloxacin (Ocuflox®), one drop every hour in the affected eye, is the current recommended treatment. If the suspicion is high for viral or fungal infection, a topical antiviral medication (e.g., natamycin, amphotericin B, or fluconazole) should be given.

Cycloplegic drops such as cyclopentolate 1% are often used due to pain from accompanying iritis. Topical steroids are relatively contraindicated in viral infections but may decrease the incidence of scarring and perforation. Steroid eye drops should not be initiated by the emergency physician unless advised to do so by the ophthalmologist. **Do not patch the eye because of the risk of *Pseudomonas* infection, which can cause rapid, aggressive ulceration with corneal melting and perforation.** All corneal ulcers should be referred to an ophthalmologist to be seen within 12 to 24 hours. Complications of corneal ulcers include corneal scarring, corneal perforation, development of anterior and posterior synechiae, glaucoma, and cataracts.

FIGURE 241-32. Corneal ulcer is seen at 5 o'clock. [Courtesy of Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

Ultraviolet Keratitis Light in the ultraviolet range can cause death of corneal epithelial cells. Classically described as "snow blindness," **ultraviolet keratitis** is also caused by unprotected exposure to arc welders and tanning beds and is often called "*welder's flash*." Ultraviolet keratitis may occur if protective glasses are not applied tightly to the face, allowing light to hit the cornea obliquely. Effects are cumulative, so multiple short exposures are the same as one long exposure. Corneal cells do not die immediately, so symptoms develop after a delay of up to 6 to 12 hours with slow onset of foreign body sensation and mild photophobia, progressing to severe pain and photophobia. Patients sometimes are awakened from sleep after midnight by pain. Physical examination may reveal blepharospasm, conjunctival injection, and prominent tearing. Topical anesthetic drops are often required to complete the eye examination. Slit lamp examination reveals diffuse punctate corneal edema, and instillation of fluorescein reveals diffuse punctate corneal abrasions. Treatment may include double patching of both eyes if the patient requests, and the use of cycloplegics, topical antibiotics (erythromycin), and oral analgesics. Healing occurs in 24 to 36 hours.

UVEAL TRACT

Uveitis/Iritis Iritis is inflammation of the anterior segment of the uveal tract. It is not a true ocular emergency, but does require follow-up by an ophthalmologist. Iritis is caused by inflammation of various local and systemic etiologies. Pain in iritis is caused by irritation of the ciliary nerves and ciliary muscle spasm. Ciliary spasm irritates the trigeminal nerve and can cause photophobia. Keratitic precipitates are deposits of inflammatory cells on the corneal endothelium. A proteinaceous transudate from uveal vessels occurs in the anterior chamber and causes flare seen with the slit lamp. WBCs released from the uveal vessels may be seen in the anterior chamber with the slit lamp and are termed *cells* (as in "flare and cells"). Cells appear as snowflakes in a headlight beam at night.

The patient will complain of unilateral pain, although the pain may be bilateral with systemic disease. There may be complaints of conjunctival injection, photophobia, and decreased vision. There is usually no discharge. Complaints of systemic symptoms, including arthritis, urethritis, and recurrent GI symptoms, are not unusual. Past medical history should include exposure to tuberculosis, history of genital herpes, or history of previous similar symptoms, and the associated diagnosis. Ask about recent trauma or exposure to welding without protective goggles.

Inspection of the eye may reveal a perilimbal flush (injection is greatest around the limbus) or diffuse conjunctival injection without mucopurulent discharge. Photophobia is usually present. **Consensual photophobia (shining light on the unaffected eye causes pain in the affected eye) is highly suggestive of iritis.** The pupil is usually miotic and poorly reactive. Visual acuity may be decreased with severe inflammation and clouding of the aqueous humor. Slit lamp examination will reveal flare and cells in the anterior chamber, culminating in a hypopyon with severe disease. Intraocular pressure may be decreased if the ciliary body is involved secondary to decreased production of aqueous humor. Fluorescein staining of the cornea may show abrasions, ulcerations, or dendritic lesions.

The diagnosis of iritis is based on the typical history and the finding of flare and cells in the anterior chamber on slit lamp examination. The differential diagnosis is listed in **Table 241-6**.

Blocking the pupillary sphincter and ciliary body with a long-acting cycloplegic agent, such as homatropine (duration 2 to 4 days) or tropicamide (duration 24 hours), will decrease pain. Refer the patient to an ophthalmologist in 24 to 48 hours.

TABLE 241-6 Differential Diagnosis of Iritis

Systemic diseases	Malignancies
Juvenile rheumatoid arthritis	Leukemia
Ankylosing spondylitis	Lymphoma
Ulcerative colitis	Malignant melanoma
Reiter syndrome	Trauma/environmental
Behçet's syndrome	Corneal foreign body
Sarcoidosis	Post-traumatic (blunt trauma)
Infectious	Ultraviolet keratitis
Tuberculosis	
Lyme disease	
Herpes simplex	
Toxoplasmosis	
Varicella zoster	
Syphilis	
Adenovirus	

VITREOUS HUMOR

Endophthalmitis Endophthalmitis is inflammation (usually infectious) of the aqueous or vitreous humor that frequently leads to loss of vision. The most frequent cause is postsurgical, followed by penetrating ocular injuries and, rarely, hematogenous spread. History may include ocular surgery, hammering with steel, working with high-speed machinery such as grinders or weed whackers, or ocular trauma. Symptoms may include headache, eye pain, photophobia, vision loss, and ocular discharge. Physical examination may reveal erythema and swelling of the lids, conjunctival and scleral injection, chemosis, hypopyon, and evidence of uveitis. If suspected, immediate ophthalmologic consultation is required. Treatment may include aspiration of the vitreous or pars plana vitrectomy, and administration of intravitreal antibiotics and steroids, in addition to systemic antibiotics. Admission is required except for postoperative cases.

Vitreous Detachment and Hemorrhage The vitreous is avascular and attached firmly to the anterior eye at the ora serrata, posteriorly at the optic nerve head, and along the major retinal vessels. Liquefaction of the vitreous can cause detachment from the retina, with or without accompanying hemorrhage. Symptoms are sudden onset of floaters, especially with eye movement. Traction at vascular areas due to trauma or pathologic neovascularization can cause vitreous hemorrhage. The most common causes of vitreous hemorrhage are proliferative diabetic retinopathy, posterior vitreous detachment in the elderly, and ocular trauma such as shaken baby syndrome in infants. An unusual cause is subhyaloid hemorrhage associated with subarachnoid hemorrhage. **History includes sudden painless vision loss and sudden appearance of black spots, cobwebs, or generalized unilateral hazy vision.** Past medical history may include diabetes or sickle cell disease. Examination of the retina of the affected eye may be impossible due to the hemorrhage. Examination of the contralateral retina may give clues to the diagnosis. Important differential diagnoses include sickle cell disease, diabetic retinopathy, retinal detachment, central retinal vein occlusion, subarachnoid hemorrhage, and lupus erythematosus. Consult ophthalmology if the diagnosis is suspected. Check the INR of patients receiving warfarin (Coumadin®) and withhold antiplatelet therapy. Ocular US can rule out retinal detachment.

TRAUMA TO THE EYE

CONJUNCTIVAL ABRASION, LACERATION, AND FOREIGN BODY

The conjunctiva has less innervation than the cornea, so **conjunctival abrasions** are far less symptomatic than corneal abrasions. The patient may complain of a scratchy foreign body sensation, mild pain, tearing, and, rarely, photophobia. Vision should not be affected unless there is a full-thickness conjunctival laceration with globe penetration. Physical examination may reveal mild conjunctival injection or subconjunctival hemorrhage. A conjunctival abrasion is seen with fluorescein staining.

Conjunctival lacerations may bleed, the edges of the bulbar conjunctiva may retract with underlying sclera visible to the naked eye, and fluorescein stain may pool in the defect. Perform the Seidel test to exclude globe perforation. **The Seidel test can be negative if a full-thickness laceration is small or has spontaneously closed.** Inspect the conjunctiva for a foreign body. Conjunctival foreign bodies usually can

be removed with a moistened, cotton-tipped applicator after anesthetizing the eye with a topical anesthetic. Evert the upper eyelid and inspect under the highest magnification available to avoid missing any additional foreign bodies. Frequently, small wooden particles such as sawdust will blend into the conjunctiva when moistened by the tears and be difficult to find without slit lamp magnification.

Superficial conjunctival abrasions and lacerations without any other associated ocular injury only require erythromycin ophthalmic ointment 0.5% four times a day for 2 to 3 days or no treatment if very small. Suturing of lacerations is almost never required. Any suspicion of globe laceration requires immediate ophthalmologic referral.

CORNEAL ABRASION, LACERATION, AND FOREIGN BODY

The corneal epithelium is fragile and easily damaged. It is richly innervated and therefore very painful when injury occurs. Corneal epithelium regenerates quickly, so healing time for abrasions is short, usually within 24 to 48 hours. Intact corneal epithelium is resistant to infection, but damaged epithelium is a portal of entry for bacteria, viruses, and fungi. Most abrasions not treated immediately will develop an associated inflammatory iritis.

Corneal Abrasion Abrasions may be caused by contact lens wear, fingernails, makeup brushes, and foreign objects blown into eyes while driving or on windy days or that drop into the eye while working overhead (construction) or under a car (mechanics). Injury to the cornea causes intense pain that may be delayed several hours after the inciting event. Initial symptoms are a foreign body sensation, photophobia, and tearing. Ask about the work environment and the mechanism of injury if known, because corneal abrasions sustained using high-speed machinery, such as grinders, lawn mowers, or weed whackers, and hammering metal against metal are associated with corneal laceration and perforation of the globe.

Inspection of the eye may reveal conjunctival injection, tearing, and lid swelling. Blepharospasm may occur with severe pain, requiring a topical anesthetic to accomplish the examination and obtain the visual acuity. Relief of pain with topical anesthesia is virtually diagnostic of corneal abrasion. Photophobia may be evident when shining a light into the affected or the opposite eye. Decreased visual acuity may occur if the abrasion is in the central visual axis or if there is an associated iritis, but otherwise vision should be normal. The corneal abrasion is often visible to the naked eye as an irregular area of light reflection off the cornea.

Slit lamp examination may show flare and cells from iritis if the abrasion is large and >24 hours old, but there is no corneal infiltrate. Examine the entire thickness of the cornea for full-thickness laceration, and the Seidel test should be negative. The abrasion usually appears as a superficial, irregular corneal defect appearing bright green under the cobalt blue light after instillation of fluorescein (**Figure 241-33**). A series of small, fine-lined vertical corneal abrasions seen with fluorescein staining suggests the presence of a foreign body embedded in the tarsal conjunctiva of the upper lid. Multiple linear corneal abrasions or punctuate keratitis also suggest a retained foreign body under the upper lid.

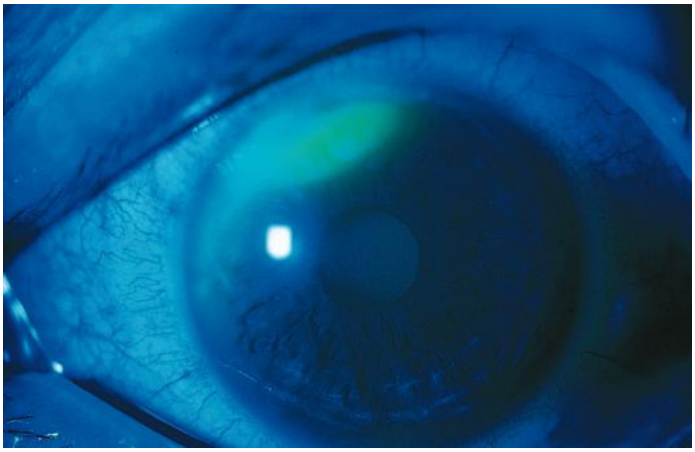

FIGURE 241-33. Corneal abrasion. [Reproduced with permission from Knoop K, Stack L, Storrow A: *Atlas of Emergency Medicine,* 2nd ed. © 2002, McGraw-Hill, New York.]

Some slit lamps (Haag-Streit) have a measuring dial attached to the mechanism that varies the length of the slit beam. If your slit lamp is equipped with this feature, you can vary the length of the slit beam on the cornea until it corresponds to the length or width of the abrasion. The reading on the wheel equals the length of the slit beam in millimeters. This additional feature allows you to document the dimensions of the abrasion precisely, thereby enabling subsequent examiners to evaluate the wound's healing response objectively.

Because the majority of corneal abrasions heal spontaneously, treatment is aimed at relieving pain and preventing infection. Cycloplegics relax the ciliary body and relieve pain from spasm as well as decreasing secondary iritis. Patching the eye does not promote healing, but some patients feel better with the eye patched. Loss of depth perception results from patching one eye, so patients should not drive a car. Abrasions from fingernails, vegetable matter, or a contact lens should not be patched, as they are at higher risk of infection.

If an abrasion is >2 mm or very painful, prescribe a **cycloplegic agent** (cyclopentolate 1% or homatropine 5%), one drop three to four times a day at home, to help control discomfort. The duration of action for each agent is much shorter in the inflamed eye, so a several times a day dosing schedule is recommended. **Cyclopentolate** 1%, one drop three times daily, wears off within 24 hours. Homatropine should be reserved for very large, painful abrasions and lasts several days. **Avoid atropine because the effect lasts for approximately 2 weeks.** Topical nonsteroidal anti-inflammatory drugs such as ketorolac and diclofenac give some degree of pain relief and do not impair healing in patients with corneal abrasions. Topical antibiotics can be provided (**Table 241-7**).

Large abrasions or abrasions in the central visual axis should be checked by an ophthalmologist in 24 hours; small abrasions should be checked in 48 to 72 hours. **Never prescribe topical anesthetics, as they inhibit corneal healing and obliterate the normal corneal protective mechanism** (blinking when material gets into the eye).

Applying an Eye Patch An eye patch may be preferred for comfort for some patients with corneal abrasions or may be needed to prevent keratitis in a patient with Bell's palsy. When an eye patch is properly applied, the eyelid will not move under the eye patch. Assemble supplies—two cotton oval eye pads and multiple pieces of tape pretorn to approximately 5 in. (13 cm). To properly apply an eye patch, have the patient sit with both eyes closed. Have the patient keep both eyes closed until the patch is applied and secure. Take one cotton oval eye pad, fold it in half, and hold the eye pad gently but firmly over the closed lid of the eye to be patched. Then take another eye patch, do not fold it in half, and place it over the first patch. Very deep set eyes may require a third patch. Keep holding firmly but gently. Then tape the patch in place, applying the tape in an X-fashion over the eye pad. Now have the patient open his or her eyes. If the patch is properly placed and taped, the lid under the patch will remain closed. If the patient says the lid can open, remove the patch and try again.

Corneal Laceration Full-thickness **corneal lacerations** can be identified by a misshapen iris, macro- or microhyphema, decrease in visual acuity, and shallow anterior chamber. The Seidel test should be positive. **However, small corneal lacerations can close spontaneously, the**

TABLE 241-7 Suggested Ophthalmic Antibiotics for Corneal Abrasions

Situation	Antibiotic
Not related to contact lens wear	Erythromycin ophthalmic ointment three to four times a day
Related to contact lens wear	Ciprofloxacin, ofloxacin, or tobramycin ointment three to four times a day
Organic source	Erythromycin ointment three to four times a day

Seidel test will be negative, and there may be no gross distortion of globe anatomy (see Figure 241-48). Corneal lacerations occur in young children from a wide variety of objects—sharp sticks, fingernails, thorns, broken glass, or sharp toys.[2] Objects as diverse as bungee cords and eyelash curlers[3,4] can cause globe perforation. A history of eye irritation while working with metal fragments or high-speed machinery suggests the possibility of a corneal laceration. Pain out of proportion to physical findings, decrease in visual acuity, or other unexplained ocular symptoms may be the only symptoms or signs of a small full-thickness corneal laceration. Evaluate the entire thickness of the cornea during slit lamp examination to identify a corneal laceration.

If there is any suspicion of penetrating injury, obtain a CT of the orbit to identify changes in globe anatomy or contour or a foreign body within the globe, and consult ophthalmology. The sensitivity of CT for the detection of occult globe perforation is reported as 56% to 68%,[5] further emphasizing the need for a high index of suspicion. Unrecognized corneal lacerations can quickly result in endophthalmitis or traumatic cataract. Once endophthalmitis develops, vision is at great risk.

Corneal Foreign Bodies Corneal foreign bodies are usually superficial and benign, but penetration of a foreign body into the globe can cause loss of vision. Foreign bodies are generally small pieces of metal, wood, or plastic that become embedded in the cornea. The presence of a corneal foreign body causes an inflammatory reaction, dilating blood vessels of the conjunctiva and causing edema of the lids, conjunctiva, and cornea. When the foreign body is present for >24 hours, WBCs may migrate into the cornea and anterior chamber as a sign of iritis.

The patient will usually complain of a "foreign body" sensation during blinking. Tearing, blurred vision, and photophobia are common. Ask about details surrounding the onset of symptoms, including patient activity. If a cause is not obvious, ask about all activities in the previous 24 hours, especially activities that cause high-velocity projectiles. High-velocity globe penetration injuries include grinding, hammering metal on metal, or operation of other high-speed machinery. Visual acuity should be normal. Inspection of the eye may reveal edema of the eyelid and diffuse or focal/perilimbal conjunctival injection.

Occasionally, the foreign body may be visible with the naked eye. Evert the lid to identify and remove other foreign bodies that may be present. When a metallic foreign body is present for more than a few hours, a **rust ring** (**Figure 241-34**) develops around the metal. Foreign bodies present for >24 hours may be surrounded by a white ring representing a WBC infiltrate. Anterior chamber flare and cells and a corneal foreign body are identifiable on slit lamp examination (**Figure 241-35**). **The presence of a gross hyphema or a microhyphema evident in the anterior chamber on slit lamp examination suggests globe perforation.** If the foreign body has penetrated the cornea, the tract of the projectile *may* be seen. The Seidel test *may* be positive with penetration of the globe.

FIGURE 241-35. Corneal foreign body. [Courtesy of Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

Corneal Foreign Body Removal Corneal foreign bodies should be removed carefully, with the patient and physician seated at each other's eye level, and under the best magnification available. Anesthetize the cornea with a local anesthetic such as 0.5% proparacaine. Sometimes, anesthetizing both eyes is helpful, because that can eliminate reflex blinking during attempts at foreign body removal. Irrigate with normal saline first, as a very superficial foreign body may be irrigated off the cornea. Next, try to dislodge the foreign body with a moistened cotton applicator. Efforts at removal may themselves cause corneal abrasion.

If the foreign body is tightly adherent to or embedded in the cornea, inspect the cornea using optical sectioning to assess the depth of penetration (**Figure 241-12**). **Full-thickness corneal foreign bodies should be removed by an ophthalmologist.**

For superficial foreign bodies, a 25-gauge needle (using needle bevel up) or a sterile foreign body spud (1 mm diameter) on an **Alger brush** (a low-speed, low-torque, battery-operated hand-held drill) can be used to remove the foreign body. Use slit lamp magnification to ensure safe foreign body removal. Before the removal, prepare a moistened cotton applicator and set it aside on the slit lamp table. The upper lid can be held open by an assistant or by the clinician's nondominant hand. Many slit lamps have an attached "fixation light" that can be moved in front of the unaffected eye to give the patient a steady target to concentrate on. Using either the 25-gauge needle or the Alger brush, place the tip into the slit lamp beam using the naked eye. With the tip close to the cornea, look through the slit lamp and move the tip into contact with the cornea. Using the bevel-up edge of the tip of the 25-gauge needle, hook the edge of the foreign body and dislodge it. You may then lift it off the cornea using the previously moistened cotton applicator. Alternatively, using the spinning tip of the Alger brush, the foreign body may be dislodged and removed with the cotton applicator as above.

After successful foreign body removal, discharge the patient with a prescription for topical antibiotics, cycloplegics, and oral analgesics. Administer tetanus toxoid as appropriate. Provide ophthalmology follow-up the next day if the foreign body is in the central visual axis or if there is a residual rust ring. Otherwise, after complete removal of the foreign body, advise follow-up if symptoms persist at 48 hours.

Rust Ring Removal Metallic foreign bodies can create rust rings that are toxic to the corneal tissue (**Figure 241-34**). If a rust ring is present, the spud or an ophthalmic burr can remove superficial rust, but rust often reaccumulates by the next day, requiring additional burring. **It is therefore not necessary to remove a rust ring in the ED if the patient can be seen by an ophthalmologist the next day.** Once the metallic foreign body is removed, the rust ring area softens overnight and can be more easily removed in the office the next day. The deeper the stromal involvement, the higher is the risk of corneal scarring, so if rust ring removal is done in the ED, only perform superficial burring. **No ED drill burring should take place if the rust ring is located in the visual**

axis (pupil) owing to the risk of causing visually significant scarring. Such conditions require that an ophthalmologist remove the stromal rust in the office within 24 hours.

LID LACERATIONS

Eyelid lacerations that involve the lid margin, those within 6 to 8 mm of the medial canthus or involving the lacrimal duct or sac, those involving the inner surface of the lid, wounds associated with ptosis, and those involving the tarsal plate or levator palpebrae muscle need repair by an oculoplastic specialist. Lacerations medial to the lacrimal puncta are at high risk of canalicular involvement. Suspect involvement of the levator palpebral muscle in the presence of a horizontal laceration with ptosis or when orbital fat is seen protruding through the laceration, indicating a breach of the orbital septum.

Consider the possibility of corneal laceration and globe rupture in all full-thickness lid lacerations. Ocular injuries such as corneal abrasion, traumatic hyphema, and globe rupture are seen with lid lacerations in up to two thirds of cases. Lid lacerations require a thorough examination using a slit lamp to exclude other associated ocular injuries.

Deep lacerations medial to the punctum potentially can transect the canalicular system. These injuries need to be seen by an ophthalmologist for evaluation of the nasolacrimal duct system's integrity. Instillation of fluorescein dye in the eye with subsequent appearance in the wound indicates loss of canalicular integrity. If a canalicular laceration is discovered, the patient will need to go to the operating room within 24 to 36 hours for repair and Silastic® tube stenting. Because a meticulous repair by an experienced eye surgery team is preferable, it is not unreasonable for the ophthalmologist to discharge a patient seen late in the evening or on the weekend with arrangements for surgical repair to take place within the next 36 hours. Patients discharged pending repair should be placed on oral and topical antibiotics and told to use cold compresses. Oral cephalexin (Keflex®), 500 milligrams twice or four times daily, and topical erythromycin ophthalmic ointment four times daily are reasonable choices.

Partial-thickness lid lacerations not meeting the preceding criteria can usually be repaired in the ED, with referral for ophthalmologic evaluation in 2 to 3 days. Use a soft, absorbable or nonabsorbable 6-0 or 7-0 suture. Have the suture ends closest to the cornea tucked under more distant sutures to avoid corneal irritation (**Figure 241-36**). Cut the ends of each suture 1 cm long. When the second suture is tied, take the long ends of the first suture into the loop of the knot of the second suture. This keeps the ends of the first suture secure. Do this for every successive suture. Do not incorporate the ends of the suture into the wound itself, but make sure the suture ends are kept to the side of the wound margin. Sutures are removed from the bottom.

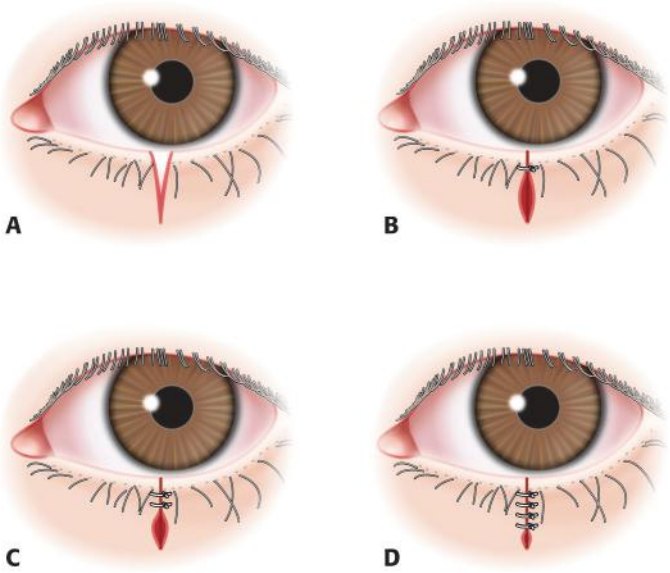

FIGURE 241-36. **A** through **D.** Each suture holds down the ends of the adjacent suture to prevent corneal irritation or abrasion. On this drawing, the lighter shade sutures are above the skin. Note that this illustration shows a laceration at the lid margin. Lid margin lacerations >1 mm need repair by an oculoplastic specialist.

Lacerations at the Lid Margin **Very small lacerations (<1 mm) at the lid edge only do not need suturing and can heal spontaneously.** Any laceration >1 mm at the lid edge needs repair by a specialist. Proper alignment of the lid margin during repair under magnification (loupe or microscope) is essential to preserve proper lid function and even corneal wetting with each blink. Notching of the lid can result in improper lid closure.

If there is no opportunity for the patient to see an ophthalmologist, repair should be performed as in **Figure 241-37**. Soft (gut or chromic) sutures 6-0 or smaller should be used for all repairs. One vertical mattress suture, using the meibomian gland orifices as a landmark, or two 6-0 soft sutures (one approximating the anterior and the other the posterior lamella) are used to repair the lid margin. The initial suture can be used for traction to extend the lid and facilitate the repair. The tarsus should be repaired with 6-0 absorbable suture (polyglactin) from the external side so as to approximate the wound without the need for sutures on the conjunctival side of the lid (which would abrade the cornea with each blink). Skin closure can be performed with 6-0 or smaller soft nonabsorbable suture.

BLUNT EYE TRAUMA

The first steps are assessment of the visual acuity, anterior chamber, and integrity of the globe. The eyelids frequently swell shut, making visualization of the globe difficult. Prying the eyelids open with the fingers is difficult, usually yields an unsatisfactory view of the globe, and can raise intraocular pressure. Insertion of a paperclip bent in an appropriate shape (**Figure 241-38**) or an eyelid speculum (**Figure 241-39**) provides a significantly improved view of the cornea and anterior chamber. Use of an eyelid retractor allows your hands to remain free for examination of the globe using the slit lamp.

If the anterior chamber is flat, a ruptured globe is certain, so stop the examination, place a metal shield over the injured eye, and consult ophthalmology. A **hyphema** is also evidence of significant ocular trauma and necessitates an ophthalmology consult. If the globe appears intact and vision is preserved, check ocular motility. Restricted upgaze or lateral gaze suggests a **blow-out fracture** with entrapment (see later section, Orbital Blow-Out Fractures), and a CT scan of facial bones should be obtained. A head CT scan may be indicated to assess for associated intracranial injury. Feel the orbital rim above and below for step-off deformities. Test for cutaneous sensation along the distribution of the inferior orbital nerve (below the eye and ipsilateral side of the nose). **Perform a slit lamp examination with fluorescein staining to check for abrasions, lacerations, foreign bodies, hyphema, iritis, and lens dislocation.** Measure intraocular pressure if there are no signs of a ruptured globe. Traumatic iritis is common, causing cell and flare to be seen on slit lamp examination. The pupil can be constricted or dilated after sustaining trauma. It is important to look for pupillary irregularity because the pupil often will peak toward the site of a penetration or rupture. If the anterior chamber is of normal depth and not shallow, apply a mydriatic. Nonwhite, brown-eyed individuals frequently will require an additional drop of a mydriatic to achieve adequate dilation. If vision and ocular anatomy and function are preserved, outpatient follow-up by an ophthalmologist in the next 48 hours should be planned. If a ruptured globe is suspected due to loss of visual acuity, flat anterior chamber, obvious full-thickness laceration, or intraocular foreign body, do not manipulate the eye or measure intraocular pressure. Consult ophthalmology immediately.

Hyphema A **hyphema** is blood or blood clots in the anterior chamber (**Figures 241-15** and **241-16**). Hyphemas are traumatic or spontaneous. A traumatic hyphema usually results from bleeding from a ruptured iris root vessel. Spontaneous hyphemas frequently are associated with sickle cell disease. In addition to standard ophthalmologic history, inquire as to the use of any anticoagulant or antiplatelet medications or history of a bleeding diathesis. **A hyphema may layer out posteriorly when the patient is**

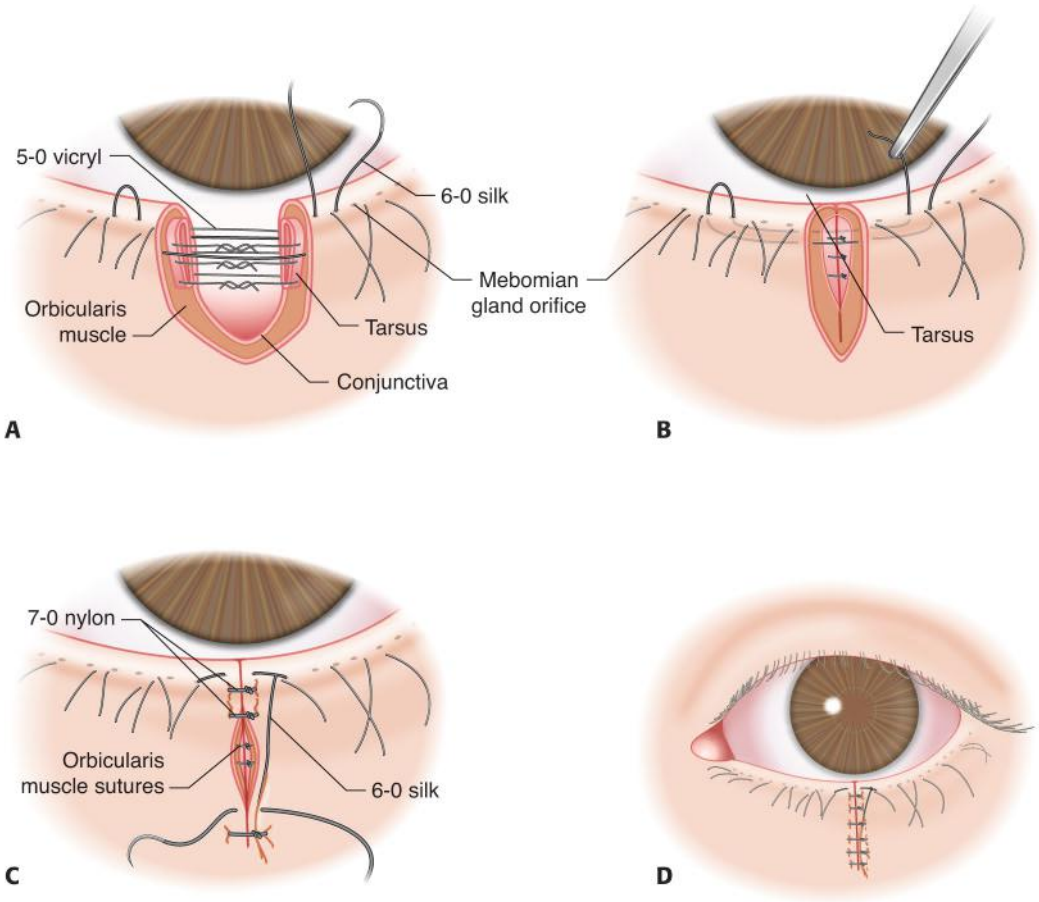

FIGURE 241-37. A through D. Full-thickness lid repair. 6-0 silk is used for lid margin. 5-0 Vicryl® is used to approximate the tarsal plate. The Vicryl® sutures should not pass through the conjunctiva on the inside of the eyelid to avoid mechanical abrasion of the cornea during blinking. 7-0 nylon is used for skin closure, and the lid margin silk suture tail can be incorporated into these sutures to avoid corneal irritation.

lying flat and may only become grossly evident when the patient is sitting upright. The complications of hyphema include increased intraocular pressure, rebleeding, peripheral anterior synechiae, corneal staining, optic atrophy, and accommodative impairment. Patients with large hyphemas, sickle cell disease, and bleeding tendency are more likely to develop vision loss. A **microhyphema** is suspension of red blood cells in the anterior chamber without the formation of a layered blood clot. It is generally seen with a slit lamp and can progress into a hyphema. The most significant complications of microhyphema include rebleeding and intraocular pressure elevation. Patients with sickle cell disease are more likely to develop these complications. The treatment of microhyphema is somewhat controversial, but the principles of management are the same as those for the hyphema.

FIGURE 241-38. Eyelid retractors fashioned from paperclips. [Reproduced with permission from Knoop K, Stack L, Storrow A: *Atlas of Emergency Medicine,* 2nd ed. © 2002, McGraw-Hill, New York.]

Hyphemas should be evaluated by an ophthalmologist in the ED. Patients at high risk for complications include those with suspected ruptured globe, those with sickle cell disease, those taking anticoagulants, or those with a bleeding diathesis.

Treatment consists of the prevention of rebleeding and intraocular hypertension. Elevate the patient's head to 45 degrees to promote settling of suspended red blood cells inferiorly to prevent occlusion of the trabecular meshwork. After consultation with the ophthalmologist, dilate the pupil to avoid "pupillary play" (constriction and dilation movements of the iris in response to changing lighting conditions), which can stretch the involved iris vessel, causing additional bleeding. Pupillary dilation *does not* compromise the angle and aqueous outflow in normal individuals, and some ophthalmologists choose to dilate hyphemas to prevent pupillary activity. Control of intraocular pressure consists of topical β-blockers, IV mannitol, topical α-adrenergic agonists (apraclonidine), and oral, topical, or IV carbonic anhydrase inhibitors such as Diamox®. **Do not give carbonic anhydrase inhibitors to patients with sickle cell disease.** Carbonic anhydrase inhibitors lower the aqueous pH in the anterior chamber, causing the red blood cells to sickle and become less flexible, thereby clogging outflow through the trabecular meshwork and increasing intraocular pressure.

Rebleeding can occur 3 to 5 days later in up to 30% of cases, sometimes causing severe elevation of intraocular pressure and necessitating surgical anterior chamber "washouts." Because of this risk, some

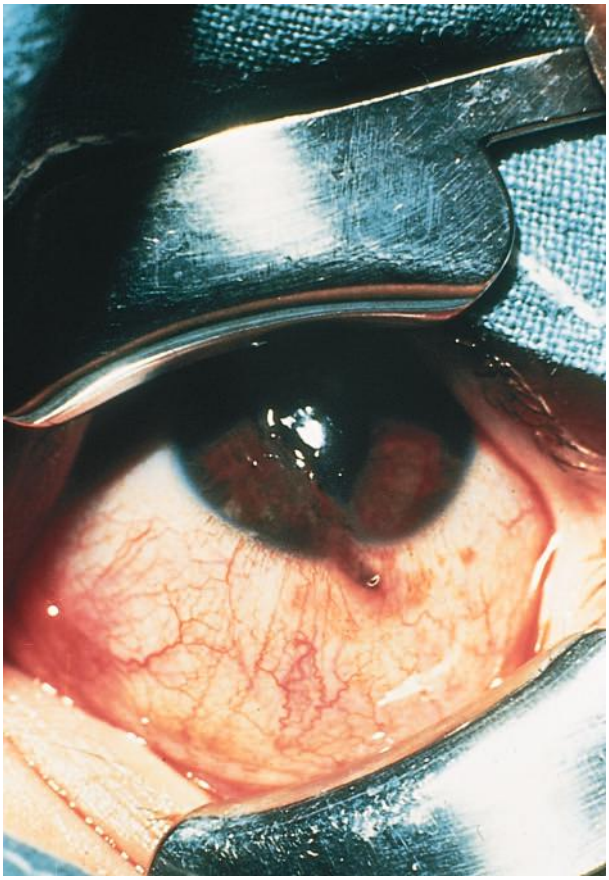

FIGURE 241-39. Commercial eyelid retractors. [Reproduced with permission from Knoop K, Stack L, Storrow A: *Atlas of Emergency Medicine,* 2nd ed. © 2002, McGraw-Hill, New York.]

ophthalmologists believe in admitting all patients with hyphemas, whereas others will choose to follow them closely as outpatients. Generally, patients with hyphemas occupying one third or less of the anterior chamber can be followed closely as outpatients. The disposition decision should be made by the ophthalmologist after examining the patient. Lower risk of rebleeding has been reported in patients who receive topical glucocorticoids. Additionally, topical steroids may prevent posterior synechiae and treat iridocyclitis. Close follow-up and serial examinations by an ophthalmologist are recommended in patients receiving topical ocular steroids to ensure no infection or corneal perforation occurs.

Orbital Blow-Out Fractures The most frequent sites of **orbital blow-out fractures** are the inferior wall (maxillary sinus) and medial wall (ethmoid sinus through the lamina papyracea). Fractures of the medial wall can be associated with subcutaneous emphysema, sometimes exacerbated by sneezing or blowing the nose. Fractures of the inferior wall with entrapment of the inferior rectus muscle can cause restriction of upgaze and diplopia (**Figure 241-40**). Orbital wall fractures are suspected on clinical examination and confirmed by CT scanning. About one third of blow-out fractures are associated with ocular trauma (abrasion, traumatic iritis, hyphema, lens dislocation/subluxation, retinal tear, or detachment); therefore, a careful eye examination in the ED is necessary. **All blow-out fractures with normal initial eye examination in the ED should be referred to an ophthalmologist for an outpatient fully dilated examination to rule out any unidentified retinal tears or detachments.** Orbital blow-out fractures without any evidence of serious eye injury do not require admission.

Isolated blow-out fractures with or without entrapment and without any eye injury do not require immediate surgery and can be referred to ophthalmology, plastic surgery, oral maxillofacial surgery, or otolaryngology (depending on the local referral patterns) for repair within the next 3 to 10 days. Oral antibiotics (cephalexin, 250 to 500 milligrams PO four times daily for 10 days) are often recommended because of the presence of sinus wall fractures.

FIGURE 241-40. Inferior wall blow-out fracture of the left eye with entrapment of the inferior rectus muscle. The patient's right eye is unable to look upward, causing diplopia on upward gaze. [Courtesy of Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

Ruptured Globe Rupture of the globe is a vision-threatening emergency that may be easily missed. The patient will usually complain of eye pain but may not have a decrease in visual acuity. Rupture of the globe presenting with a large subconjunctival hemorrhage is easily recognized, but a penetrating wound of the cornea caused by a tiny piece of metal launched from a grinder may be easily overlooked and requires a high index of suspicion to detect. Periorbital ecchymosis and maxillofacial fractures, including blow-out fracture with limitation of extraocular muscle movement , should raise one's suspicion for globe rupture.

Scleral rupture may occur from blunt or penetrating trauma. Blunt trauma directly to the eyeball (for example, a blow by a fist) will cause a sudden elevation of intraocular pressure, with the globe tending to rupture at the thinnest points of the sclera, the limbus, and at the insertion of the extraocular muscles. Any object that impacts the orbital rim at a high velocity and causes a seal around the orbit (tennis balls, racquetballs, etc.) will also cause a sudden peak in intraocular pressure and may result in rupture. A history of ocular surgery or previous ocular injury may predispose to globe rupture. Penetrating trauma may occur from bullets, BB pellets, knives, sticks, darts, needles, hammering, and lawn mower projectiles. **Any projectile injury has the potential for penetrating the eye.** The bony canal protects the globe from posterior and oblique injuries, but the eyelids afford little protection anteriorly. **Suspect globe penetration with any puncture or laceration of the eyelid or periorbital area,** and make sure to conduct a thorough slit lamp examination**.** The smaller the diameter of the offending object, the higher is the likelihood of occult injury. **Corneal abrasions occurring when hammering metal on metal; associated with the use of high-speed machinery such as lawn mowers, line trimmers (weed whackers), grinders, or drills; and sustained during explosions should always be investigated for occult globe penetration.**

Whenever globe rupture is obvious or strongly suspected, cover the eye with a metal eye shield or make a shield from a paper cup (Figures 241-41 and 241-42), and consult ophthalmology immediately without further manipulation. Elevate the head of the bed to 45 degrees. Administer broad-spectrum IV antibiotics, and give tetanus toxoid as appropriate. Provide sedation and analgesia, and administer antiemetics to prevent increased intraocular pressure and extrusion of intraocular contents from vomiting. Avoid any topical eye solutions. Give the patient nothing by mouth, anticipating surgery.

Most cases, however, will require an initial eye examination to determine the type and extent of injury before consulting ophthalmology. **If at any step of the examination globe rupture is suspected, stop the examination, place a protective shield over the eye, and consult**

FIGURE 241-41. Metal eye shield placed in suspected globe rupture to prevent inadvertent pressure on the eye. [Reproduced with permission from Knoop K, Stack L, Storrow A: *Atlas of Emergency Medicine,* 2nd ed. © 2002, McGraw-Hill, New York.]

ophthalmology. Do not measure intraocular pressure as this may result in extrusion of globe contents.

Eye examination must be careful and gentle. Manufactured or homemade eyelid retractors should be used to gently retract the lids to examine the eye and to avoid increasing intraocular pressure during examination.

Examination of the eye may reveal decreased visual acuity, an irregular or teardrop-shaped pupil, an afferent pupillary defect, shallow anterior chamber, hyphema, positive Seidel test, and lens dislocation (**Figure 241-43**). Presence of a large subconjunctival hemorrhage involving the entire sclera or hemorrhagic chemosis (bullous, raised subconjunctival hemorrhage) is very suspicious for rupture of the globe (**Figures 241-44** and **241-45**). Uveal prolapse through a scleral wound may appear as a brownish-black discoloration against the white sclera (**Figure 241-46**). One may occasionally visualize a corneal laceration (**Figure 241-47**) or an intraocular foreign body on slit lamp examination (**Figure 241-48**). The Seidel test may or may not be positive with a small corneal laceration. Funduscopic examination may reveal a poor view of the optic nerve and posterior pole due to vitreous hemorrhage. **Unfortunately, the examination may be nearly normal after globe rupture from a tiny high-speed projectile.**

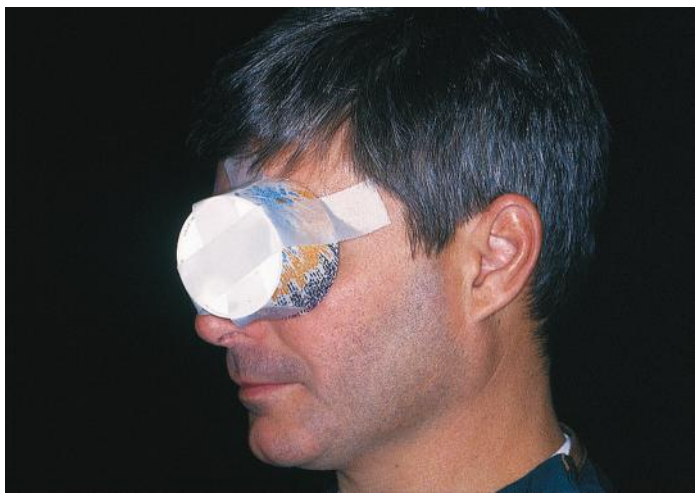

FIGURE 241-42. Protective eye shield fashioned from a paper cup. [Reproduced with permission from Knoop K, Stack L, Storrow A: *Atlas of Emergency Medicine,* 2nd ed. © 2002, McGraw-Hill, New York.]

The diagnosis is made based on a combination of history, physical examination, and selected radiologic studies. CT scan of the eye is the preferred imaging modality to detect occult open globe rupture and associated optic nerve injury. CT scan of the orbit using 2- to 3-mm cuts in both the axial and coronal planes will also localize small intraocular foreign bodies. US and both direct and indirect ophthalmoscopy after pupillary dilatation may assist in the diagnosis and can be helpful in locating and confirming the presence of orbital and intraocular foreign bodies. MRI is contraindicated if a metallic foreign body is possible.

For patients in the ED with multiple trauma and a possible ruptured globe who require rapid-sequence intubation, there is no clear consensus on the best agent to use because quick airway stabilization takes priority. Although a depolarizing agent like succinylcholine is associated with an increase in intraocular pressure, the underlying mechanism is not clear. Some studies suggest that intraocular pressure increases because of extraocular muscle contraction, although others suggest it increases because succinylcholine has a cycloplegic effect on the ciliary muscle. Pretreatment with a nondepolarizing muscle relaxant or a pretreatment dose of succinylcholine does not necessarily attenuate the increase in intracranial pressure. Use of a nondepolarizing agent like rocuronium can mitigate increases in intraocular pressure, but disadvantages are a longer onset and longer duration of action[6] (see Chapter 29, Intubation and Mechanical Ventilation).

Orbital Hemorrhage: Preseptal and Postseptal Severe blunt trauma to the orbit can occasionally cause an orbital hemorrhage. **Preseptal hemorrhage** is dramatic in appearance, but not as vision threatening as a **postseptal hemorrhage** (often called **retrobulbar hematoma**), which can cause an **orbital compartment syndrome**. A postseptal hematoma can cause an abrupt increase in intraocular pressure, resulting in decreased blood flow to the optic nerve and its blood supply and loss of vision.

Traumatic periorbital hematomas (black eyes) are common, but the extension of bleeding into the postseptal compartment is a true emergency. Differentiation of preseptal versus postseptal hematoma depends on the examination and noncontrast orbital CT findings. Clinical findings of postseptal hemorrhage are eye pain, proptosis, impaired extraocular movements, decreased vision, possibly an afferent pupillary defect, and elevated intraocular pressure. An intraocular pressure >40 mm Hg is a consideration for emergency lateral canthotomy. No matter what the intraocular pressure, if postseptal hematoma is suspected or confirmed, request emergency ophthalmology consultation. Preseptal hematomas can be observed to make sure that the hematoma is not expanding.

Lateral Canthotomy The goals of **lateral canthotomy** are to release pressure on the globe and to reduce intraocular pressure to reestablish retinal artery blood flow. To perform the procedure, place the patient in the supine position and anesthetize the lateral canthus area with 1% to 2% lidocaine with epinephrine. Place a straight Kelly clamp horizontally across the lateral canthus for about 1 to 2 minutes to crush the tissues and minimize bleeding. Remove the clamp, and with sterile scissors, make a 1- to 2-cm lateral incision in the compressed tissue at the clamp site. Then retract the lower lid to expose the lateral canthus tendon. With the scissors directed inferoposteriorly toward the lateral orbital rim, cut the inferior crus of the lateral canthus tendon. This critical incision is generally 1 to 2 cm in depth and length. If the procedure is successful, the intraocular pressure should be less than 40 mm Hg and the visual acuity should improve. If the intraocular pressure continues to remain elevated, the superior crus of the lateral canthus tendon can be cut in a similar fashion. The complications of lateral canthotomy include hemorrhage, infection, and mechanical injury. These complications generally respond to treatment better than does retinal injury from prolonged ischemia. Lateral canthotomy incisions usually heal well without suturing or significant scar formation.

Ocular Hemorrhage and Antithrombotic Therapy The use of anticoagulant and antiplatelet agents is very common in current clinical practice and can complicate the management of ocular hemorrhage from trauma. Spontaneous ocular hemorrhage has also been reported in patients taking these agents. Ocular complications in patients on oral anticoagulant therapy include subconjunctival hemorrhage, hyphema, vitreous hemorrhage, subretinal

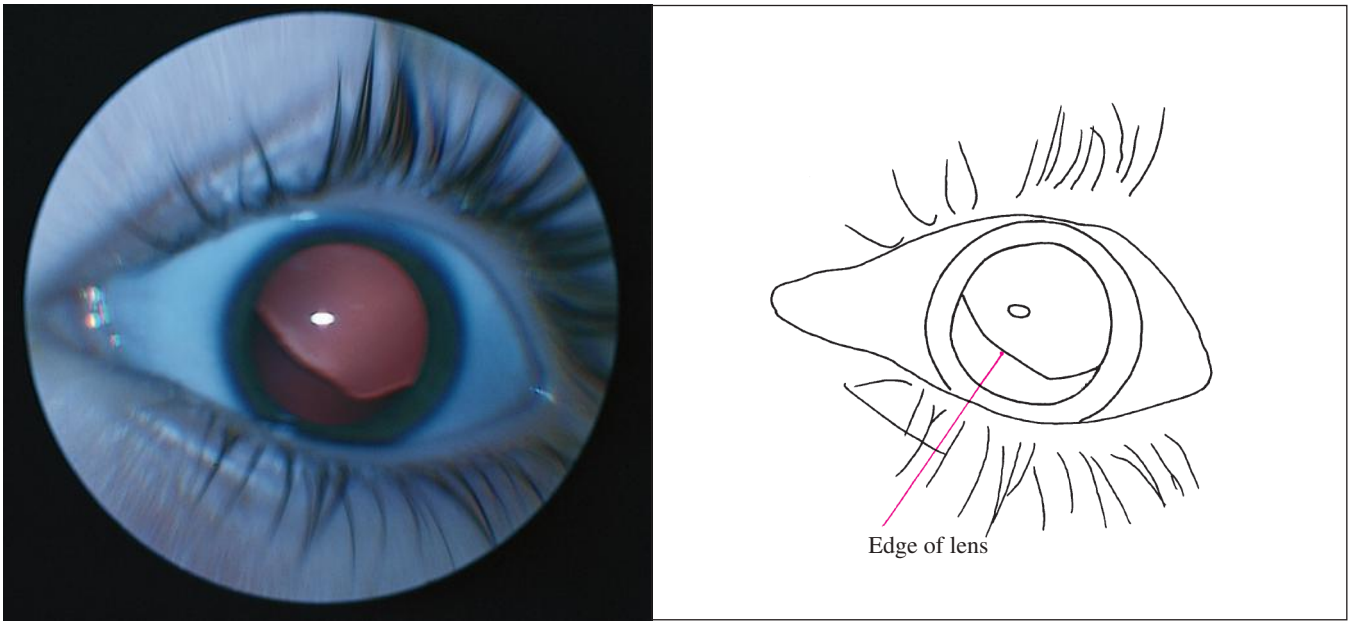

FIGURE 241-43. Lens dislocation. [Reproduced with permission from Knoop et al., *The Atlas of Emergency Medicine*, 3rd edition © 2010 McGraw-Hill Inc.; Photo contributed by Department of Ophthalmology, Naval Medical Center, Portsmouth, VA.]

hemorrhage, and choroidal hemorrhage. A higher incidence of hemorrhagic complications has been reported in patients with macular degeneration using anticoagulants or other antithrombotic drugs. Ocular hemorrhages in patients taking warfarin can potentially be vision-threatening events, but frequently they are benign and resolve without any sequelae.

There are no clear guidelines to guide treatment of ocular hemorrhage in patients taking anticoagulant and antiplatelet therapy. The severity of bleeding, INR levels, and benefits of using these agents should be taken into consideration when managing these patients. Ophthalmologic and hematology consultations should be obtained. These medications should be stopped in patients with active bleeding. Prothrombin complex concentrate, fresh frozen plasma, and vitamin K should be considered in patients taking warfarin (see chapter 239 for detailed discussion). Platelet transfusions might be beneficial to stop active bleeding in patients with thrombocytopenia or taking antiplatelet drugs. Currently, no specific reversal agent for dabigatran is available. Activated prothrombin complex concentrates, recombinant factor VIIa, or concentrates of coagulation factors II, IX, or X and dialysis should be considered in patients taking dabigatran with active hemorrhage.

CHEMICAL OCULAR INJURY

Chemical burns to the eye are a true ocular emergency. Complications of chemical burns to the eye include scarring of the cornea with permanent loss of vision and loss of the eye due to corneal perforation. Irrigation of the eyes with 1 to 2 L of normal saline must be done immediately and before any examination, including testing of vision.

Alkali and Acid Injuries **Alkali injuries** occur more frequently than acid injuries, due to the presence of alkaline substances in household cleaning agents and in building materials. The most serious alkali injuries are associated with ammonia, found in many household cleaners, and lye, a common ingredient in drain cleaners. Lye is also a component of concrete. Alkali injuries tend to be much more serious than acid injuries because they cause a liquefaction necrosis, characterized by denaturing of proteins and saponification of fats, allowing deep penetration into tissue. Acid, on the other hand, causes coagulation necrosis, with denaturing of protein forming a coagulum that acts as a barrier to further tissue penetration.

Irrigation should begin at the scene and continue in the ED. Instill a topical anesthetic and continue irrigation for at least 30 minutes. Then

check pH by touching a strip of litmus paper to the inferior conjunctival fornix. **If the pH is >7.4, continue irrigation until the pH remains neutral 30 minutes after the last irrigation.** Irrigation should be with sterile normal saline or other isotonic solution and may be instilled into the eye by hand, using bottles of eye-irrigating solution, or by a Morgan Lens® (MorTan Inc., Missoula, MT) (**Figure 241-49**) attached to a bag of an isotonic IV solution.

After irrigation and maintainance of ocular pH >7.4, perform the eye examination. Inspect the facial skin and eyelids for burns. Evert the eyelids and remove any particulate matter with a cotton applicator.

Exposure to chemical agents can cause conjunctival injection and chemosis, but severe chemical burns can cause scleral whitening, secondary to ischemia and blood vessel injury. Document visual acuity and measure intraocular pressure. Intraocular pressure may be increased if the trabecular meshwork has been damaged. Use the slit lamp to evaluate corneal injury and to detect for cells and flare in the anterior chamber. Injury to the cornea may range from punctuate defects to complete loss of epithelium. The cornea may become cloudy with severe burns (**Figure 241-50**).

After irrigation, and once time permits, identify the substance. The pH is usually listed on bottles of household cleaners. The U.S. Occupational Health and Safety Administration requires the patient's workplace to maintain Material Data Safety Sheets, a list of all the physical properties, including pH, of chemicals used at the site. Data on the pH of

known chemicals can also be obtained from a poison control center or from Poisindex®. Alkaline substances with pH <12 or acidic substances with pH >2 are thought not to cause serious injury, but duration of exposure can increase severity of injury. Circumstances surrounding the injury (e.g., battery explosion) should be determined to identify any other associated ocular or facial injuries.

Obtain ophthalmology consultation for all but minor burns: Any patient with corneal clouding or an epithelial defect after irrigation should receive prompt ophthalmology referral.

Patients with chemosis (edema of the bulbar conjunctiva overlying the white sclera) and no corneal or anterior chamber findings should be treated after irrigation with erythromycin ointment four times daily and referred for an ophthalmologic examination in 24 to 48 hours. These patients are considered to have "**chemical conjunctivitis**."

A topical cycloplegic agent should be used three times daily for pain reduction if an epithelial defect is present. **Avoid phenylephrine as a cycloplegic**, as it will constrict blood vessels, causing further ischemia to the limbus. Apply erythromycin ophthalmic ointment four times daily to affected eyes. Administer tetanus toxoid as appropriate. Consider prescribing topical corticosteroids after consultation with an ophthalmologist to control inflammation.

CYANOACRYLATE (SUPER GLUE/CRAZY GLUE)

Accidental instillation of cyanoacrylate adhesives into the eye and adnexa can cause adherence of the lids and clumps of adhesive to form on the cornea. Medicinal-grade cyanoacrylates are occasionally used to seal corneal perforations and are not toxic to the cornea, so there is rarely permanent damage to the eye. The mechanical abrasive effect of hard, irregular glue aggregates rubbing against the cornea with eye movement and blinking may cause corneal abrasions. To remove crazy glue, instill generous amounts of **erythromycin ointment** onto the eye and on the surface of the eyelids to moisten, lubricate, and provide antibiotic coverage. Clumps of glue on the surface should begin to loosen. Remove only those pieces that are easily removable. Gentle traction may separate the lids. The glue will loosen and become easier to remove in a few days.

Refer to an ophthalmologist within 24 hours for complete removal.

ACUTE VISUAL REDUCTION OR LOSS

Acute visual loss is usually divided into painful and painless visual loss for diagnostic categorization. Other differentiating features include presence or absence of a relative afferent pupillary defect, the rapidity of onset, funduscopic exam, and various physical exam and historical features. The differential diagnosis of visual loss is listed in **Table 241-8**. Many of the diagnoses are discussed in further detail in the text.

ACUTE AND PAINFUL VISION REDUCTION OR LOSS

Acute Angle-Closure Glaucoma • *Pathophysiology* Glaucoma is a group of ocular disorders characterized by increased intraocular

TABLE 241-8 Differential Diagnosis of Visual loss

Diagnosis	Eye Pain	Relative Afferent Pupillary Defect	Onset	Fundoscopic Exam	Other Findings
Central retinal artery occlusion	No	Yes	Sudden	Pale retina, cherry red spot	
Central retinal vein occlusion	No	+/–	Sudden	"Blood and thunder"/"ketchup" fundus	
Acute ischemic optic neuropathy	No	Yes	Gradual	Swollen pale disk	Signs of temporal arteritis
Acute angle-closure glaucoma	Yes	+/–	Sudden	Difficult to visualize the fundus due to corneal edema	Painful red eye, hazy cornea, midpoint pupil, narrow anterior chamber, firm globe
Optic neuritis	Yes	Yes	Gradual	Papilledema	Painful EOM, young female patient
Giant cell arteritis	Possible retro-orbital headache/pain	Yes	Gradual	Normal	Headache, myalgias
Cataract	No	+/–	Gradual	Often unable to visualize fundus	Opacity in the lens
Uveitis	Yes	No	Gradual	Normal	Flare and cells in anterior chamber, ciliary flush, consensual photophobia
Vitreous hemorrhage	No	+/–	Sudden	Opacity in the vitreous	Floaters, cobwebs
Amaurosis fugax	No	No	Sudden	Normal	Transient monocular vision loss
Transient ischemic attack	No	No	Sudden	Normal	Transient binocular vision loss
Cortical blindness	No	+/–	Sudden or gradual	Possible papilledema	Complete visual loss or homonymous hemianopsia, headache
Migraine headache	Possible retro-orbital headache/pain	No	Sudden	Normal	Visual scotomata, nausea, vomiting
Retinal detachment	No	+/–	Sudden	Retina may be difficult to visualize (portion of retina out of focus)	Possible localized visual field defect, "cloudy veil," "window shade"; suspect by history
Diabetic retinopathy	No	+/–	Gradual	Neovascularization, retinal hemorrhages	History of diabetes mellitus
Macular degeneration	No	+/–	Gradual	Drusen, macular pigment clumps	Spots in visual field
Cytomegalovirus retinitis	No	+/–	Sudden or gradual	"Tomato and cheese" pizza (retinal necrosis), retinal hemorrhages	History of human immunodeficiency virus or other immunosuppression
Methanol	No	No	Gradual	Normal	Headache, nausea, vomiting, history of ingestion
Functional visual loss	No	No	Sudden or gradual	Normal	Optokinetic nystagmus

Abbreviation: EOM = extraocular muscle movement.

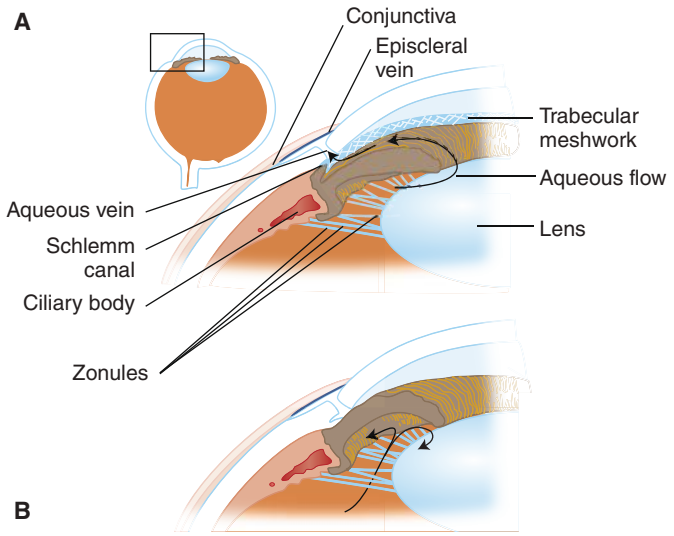

FIGURE 241-51. **A.** Normal flow of aqueous from ciliary body, through the pupil, and out through the trabecular meshwork and Schlemm canal located in the anterior chamber angle. **B.** Angle-closure glaucoma with pupillary block. Iris leaflet bows forward, blocking the chamber angle and prohibiting aqueous outflow. Meanwhile, aqueous production continues, and intraocular pressure rises.

pressure causing optic neuropathy and vision loss if left untreated. Obstruction to aqueous humor outflow is the basic underlying problem in glaucoma. In acute angle-closure glaucoma, the lens or the peripheral iris blocks the trabecular meshwork, obstructing the outflow of aqueous humor. This occurs more easily in persons whose eyes have shallow anterior chambers where the angle between the cornea and iris is reduced. A shallow anterior chamber results in a greater area of contact between the lens and iris, impeding flow of aqueous humor from the posterior to anterior chamber. This results in a pressure differential between the posterior and anterior chamber (referred to as *pupillary block*) and causes forward bowing of the iris, further narrowing the angle (**Figure 241-51**).

An acute attack is usually precipitated by pupillary dilation. Dilation increases contact between the iris and lens as the iris becomes thicker. When the pupil is mid-dilated, relative pupillary block and peripheral laxity of the iris are maximal. This increases the degree of pupillary block, increasing pressure in the posterior chamber and causing the iris to bulge forward (iris bombe). The angle between the peripheral iris, trabecular meshwork, and cornea becomes acutely closed, resulting in a precipitous increase in intraocular pressure. Intraocular pressure eventually exceeds the capacity of the corneal pump mechanism, causing the cornea to become edematous and less transparent, thus explaining the foggy vision or halos patients complain of and the hazy appearance of the cornea on physical examination.

As people age, the lens becomes less elastic and thicker, or cataracts may develop. These events can push the iris forward into greater contact with the lens, increasing the degree of pupillary block. Hypermetropic (farsighted) eyes have a shorter anterior to posterior length, a flatter cornea, and a narrower angle, increasing the risk of acute angle-closure glaucoma.

Anything causing pupillary dilatation can trigger an acute attack. The use of topical or systemic parasympatholytic agents (mydriatics, antihistamines) or sympathomimetics (epinephrine, pseudoephedrine), dim illumination, and emotionally upsetting events have all been implicated. Precipitation of acute angle-closure glaucoma has been reported with therapeutic use, and abuse of, intranasal cocaine, as well as therapeutic use of nebulized β-sympathomimetic and anticholinergic medications (e.g., albuterol and ipratropium).

Clinical Features Acute angle-closure glaucoma is abrupt in onset, painful, and may result in severe visual impairment if not treated quickly. Patients complain of sudden onset of severe eye pain or frontal or supraorbital headache. Associated symptoms include blurred vision, nausea, and vomiting. Rarely, acute angle-closure glaucoma may result in painless monocular vision loss. Acute angle-closure glaucoma may be misdiagnosed as migraine, temporal arteritis, subarachnoid hemorrhage, or intra-abdominal emergency.

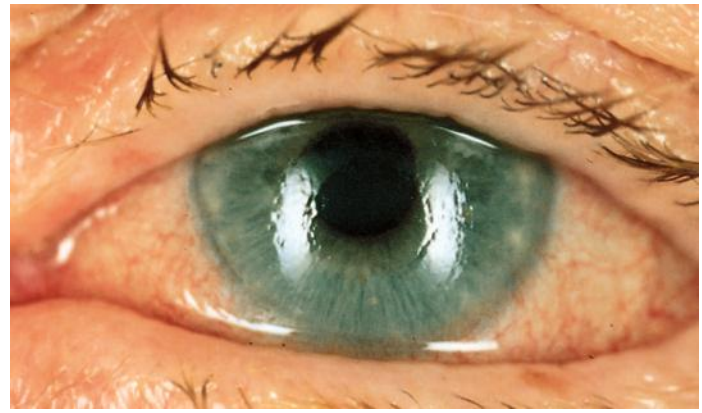

FIGURE 241-52. Acute angle-closure glaucoma. The cornea is cloudy, and there is marked conjunctival injection. [Reproduced with permission from Knoop K, Stack L, Storrow A: *Atlas of Emergency Medicine,* 2nd ed. © 2002, McGraw-Hill, New York.]

Examination reveals a fixed, midposition pupil and a hazy (cloudy/steamy) cornea with conjunctival injection (**Figure 241-52**), most prominent at the limbus. The affected eye is rock hard. Measure the intraocular pressure to establish the diagnosis (see earlier section, Intraocular Pressure), although the presence of the characteristic symptom complex—a cloudy cornea, fixed midposition pupil, and rock hard globe—is diagnostic. Normal intraocular pressure is 10 to 20 mm Hg, and may exceed 60 to 80 mm Hg in an acute attack.

Treatment There have been no controlled studies regarding medical treatment for acute angle-closure glaucoma. Treatment of acute angle-closure glaucoma involves lowering the intraocular pressure by blocking production of aqueous humor, facilitating outflow of aqueous humor, and reducing the volume of vitreous humor (**Table 241-9**). IV mannitol quickly lowers intraocular pressure and should be given if there are no contraindications. Pilocarpine frequently will not cause the iris to constrict during the acute attack until the pressure is reduced, due to pressure-induced ischemic paralysis of the iris. Topical steroids are frequently recommended. Pilocarpine 1% or 2% should be instilled into the affected eye once the pressure is lowered (usually not effective until the intraocular pressure is <50 mm Hg) to make the pupil miotic, thereby pulling the peripheral iris away from the angle. Begin treatment immediately, simultaneously with consulting ophthalmology. Definitive treatment is laser iridectomy.

Concern exists regarding precipitation of acute angle-closure glaucoma in patients with shallow anterior chambers who undergo diagnostic mydriasis, but the incidence is low. Some clinicians believe that, if

TABLE 241-9 Treatment of Acute Glaucoma

Treatment	Effect
Topical β-blocker (timolol 0.5%), one drop	Blocks production of aqueous humor
Topical α_2-agonist (apraclonidine 1%), one drop	Blocks production of aqueous humor
Carbonic anhydrase inhibitor (acetazolamide), 500 milligrams IV or PO	Blocks production of aqueous humor
Mannitol, 1–2 grams/kg IV	Reduces volume of aqueous humor
Recheck IOP hourly	—
Topical pilocarpine 1%–2%, one drop every 15 min for two doses once IOP is below 40 mm Hg, then four times daily	Facilitates outflow of aqueous humor

Abbreviation: IOP = intraocular pressure.

necessary, it may be wise to dilate these patients in the ED because precipitation of an acute attack would ideally occur when the patient can get acute care.

ACUTE PAINLESS VISUAL LOSS

Optic Neuritis Acute optic neuritis is often painless but can be painful, especially with eye movement. Visual acuity can range from mildly reduced to profound loss with no light perception. Reduction of vision occurs most commonly over days, but occasionally over hours. Visual loss is usually unilateral, but can be bilateral. Color vision is affected more commonly than visual acuity, and there may be visual field deficits.

The red desaturation test is helpful in identifying optic neuropathies. This test is performed by having the patient look with one eye at a dark red object and then testing the other eye to see if the object looks the same color. The affected eye often will see the red object as pink or lighter red. An afferent pupillary defect (**Figure 241-8**) is commonly present. Funduscopic examination will reveal a swollen and edematous optic disk (papillitis) in approximately 30% of patients. If the head of the optic nerve is normal in appearance, the patient is said to have retrobulbar neuritis.

Optic neuritis can be idiopathic or an initial presentation of multiple sclerosis. Other causes of optic neuritis include postchildhood vaccination; viral infections such as measles, mumps, chickenpox, encephalitis, herpes zoster, and mononucleosis; inflammation of structures contiguous with the optic nerve such as the meninges, orbit, and sinuses; and other infections, including syphilis, tuberculosis, *Cryptococcus*, and sarcoidosis. The differential diagnosis includes ischemic optic neuropathy (sudden onset and painless), papilledema (bilateral, painless with preserved visual acuity), hypertensive retinopathy, orbital tumor compressing the optic nerve (proptosis frequent), intracranial tumor compressing the visual pathway (seen on CT), and toxic or metabolic optic neuropathy from alcohol or various toxins such as the heavy metals or chloroquine.

Neurology and ophthalmology consultation is needed to establish a diagnosis. MRI results are important prognosticators for optic neuritis.

Central Retinal Artery Occlusion The first branch off the internal carotid artery is the ophthalmic artery, which supplies the central retinal artery, which, in turn, provides the blood supply to the inner retina. The ciliary arteries also originate from the ophthalmic artery distal to the central retinal artery and supply the outer retina by the choriocapillaries of the choroid. If the central retinal artery becomes occluded, the inner retina will infarct and become pale, less transparent, and edematous. The macula is the thinnest portion of the retina, and the intact underlying choroidal circulation remains visible through this section of retina, creating the illusion of a "**cherry red spot**." The macular area maintains its normal color, and the surrounding ischemic retina turns pale, thus causing this classic finding on funduscopy (**Figure 241-53**). Causes include carotid or cardiac embolus, retinal artery thrombosis, giant cell arteritis, vasculitis (lupus, polyarteritis nodosa), sickle cell disease, trauma, vasospasm (migraine), elevated intraocular pressure (glaucoma), hypercoagulable states, and low retinal blood flow (carotid stenosis or hypotension).

Sudden (occurring over seconds), profound, painless, monocular loss of vision is characteristic of a central retinal artery occlusion. The event is often preceded by episodes of amaurosis fugax. Physical examination will often reveal an afferent pupillary defect in addition to the pale retina and cherry red macula. **Evidence-based treatment and information about the course of the disease are lacking.** Central retinal artery occlusion is rare, thought to account for 1/10,000 ophthalmic visits.[7] There are no data on ED visits. There is no evidence supporting or refuting the success of maneuvers such as digital massage, intraocular pressure–lowering drugs, and breathing into a paper bag to increase partial pressure of arterial carbon dioxide.[8,9] There are reports discussing the use of intra-arterial tissue plasminogen activator within 20 hours of onset of symptoms.[7] **Consult an ophthalmologist and neurologist immediately when suspecting the condition, and follow institutional protocols for treatment.** Irreversible loss of visual function usually occurs after 4 hours of ischemia.

Central Retinal Vein Occlusion Thrombosis of the central retinal vein causes retinal venous stasis, edema, and hemorrhage. Risk factors include diabetes, hypertension, cerebrovascular disease, cardiovascular disease, dyslipidemia, hypercoagulable states, vasculitis, glaucoma, and compression of the vein in thyroid disease and orbital tumors. Loss of vision is variable, ranging from vague blurring to rapid, painless, and monocular loss of vision. Funduscopic examination typically reveals optic disk edema and diffuse retinal hemorrhages in all quadrants ("blood-and-thunder fundus") (**Figure 241-54**). The contralateral optic nerve and fundus generally are normal, which helps distinguish central

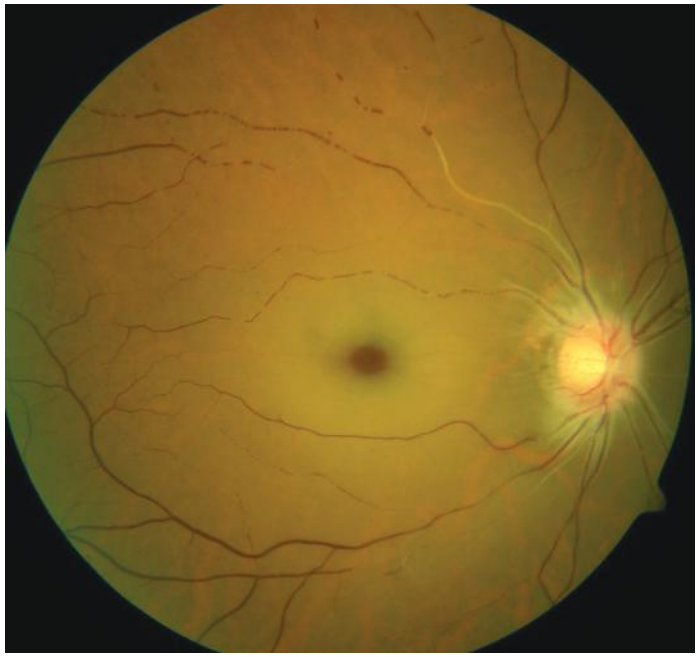

FIGURE 241-53. Central retinal artery occlusion. Note macular "cherry red spot" and retinal pallor as well as the plaques visible in the retinal vessels. [Courtesy of Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

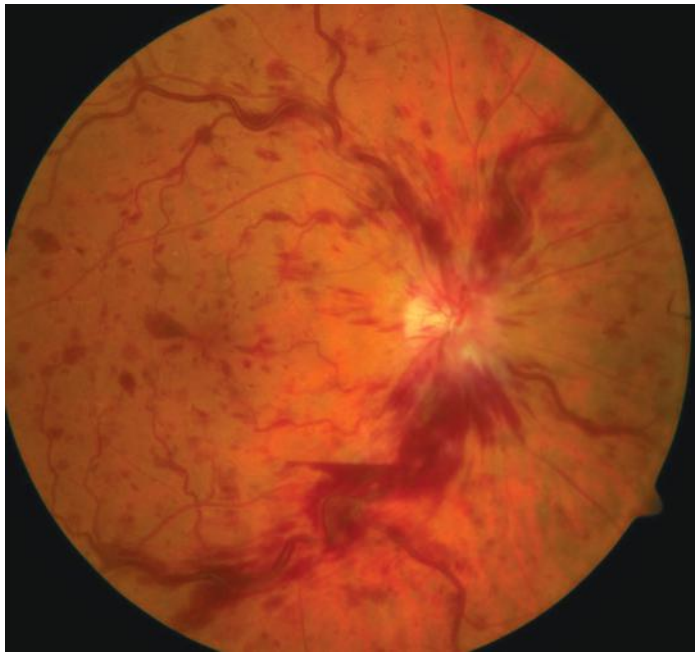

FIGURE 241-54. Central retinal vein occlusion. The disk margin is blurred, the veins are dilated and tortuous, and there is a large amount of hemorrhage typical of the "blood-and-thunder fundus." [Courtesy of Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

retinal vein occlusion from papilledema, and the diffuse retinal hemorrhages help distinguish it from optic neuritis (the peripheral retina is normal in optic neuritis). No specific treatment is available. Consult neurology and ophthalmology.

Flashing Lights and Floaters/Retinal Detachment Complaints about new-onset flashing lights and/or floaters commonly cause patients to seek urgent medical attention. The first distinction to make is if the symptoms are monocular or binocular. **Binocular complaints are almost always intracranial (i.e., ophthalmic migraines), whereas monocular complaints are almost always related to the symptomatic eye.**

The posterior segment of the eye is a large cavity filled with vitreous gel. As a person ages, this gel eventually contracts centrally and separates from the posterior wall of the eye. The vitreous is very sticky and tugs on the retina before separation, stimulating the retina, which the brain perceives as light. The average age of onset is 55 years old, but it can occur as early as the 20s in severely nearsighted people. If the vitreous gel separates successfully, then floaters occur, which may persist for years until the gel liquefies enough for the floaters to sink below the visual axis. If the gel creates enough traction on the retina before separation that it tears a hole in the retina, then fluid can go through the retinal hole and start to peel the retina off like wallpaper.

Symptoms may include flashes of light, floaters, a dark veil or curtain in the field of vision, and decreased peripheral and/or central visual acuity. This is an emergent condition requiring a retina specialist to evaluate and treat the patient. **Diagnosing a retinal detachment or tear or vitreous detachment requires a dilated indirect ophthalmoscopic evaluation by an ophthalmologist within 24 hours.** Most tears occur in the peripheral retina, which is not visualized on the direct funduscopic examination. A large retinal detachment will appear as a pale billowing parachute on dilated funduscopic examination. The diagnosis is mainly by history and confirmed by the ophthalmologist.

Temporal Arteritis **Temporal arteritis**, also called **giant cell** or **cranial arteritis**, is a systemic vasculitis involving medium-sized and large arteries. The temporal artery is the most common vessel involved. The disease causes a painless ischemic optic neuropathy with profound visual loss and contralateral ocular involvement in days to weeks if not diagnosed and treated promptly. Patients are generally >50 years of age and frequently have a history of polymyalgia rheumatica. Symptoms may include headache, jaw claudication, myalgias, fatigue, fever, anorexia, and temporal artery tenderness. Many patients may have associated symptoms of transient ischemic attacks or stroke. The physical examination frequently will reveal an afferent pupillary defect if the optic nerve circulation is involved. An elevated sedimentation rate is usually present, with the majority of biopsy-proven cases in the range of 70 to 110 mm/h. The added presence of an elevated C-reactive protein also suggests the diagnosis. Treatment consists of several doses of IV steroids followed by oral steroids. Steroids should not be delayed while waiting for a temporal artery biopsy to be performed. Biopsies will still be positive a week after initiation of steroid therapy.

CRANIAL NERVE PALSIES

BELL'S PALSY AND GENU VII BELL'S PALSY

Bell's palsy is a dysfunction of peripheral cranial nerve VII commonly of viral origin. It is palsy of the ipsilateral upper and lower face. The orbicularis muscles are involved, resulting in incomplete closure of the eyelids on the affected side and leading to corneal exposure keratitis. Prescribe viscous topical wetting agents to keep the corneal epithelium from breaking down, and patch the affected eye. Ophthalmology referral for outpatient monitoring of the cornea is warranted.

Treatment of Bell's palsy remains controversial. As of this writing, the most recent Cochrane review seems to conclude that antivirals provide no benefit over placebo in the treatment of Bell's palsy. Corticosteroids alone and antivirals with corticosteroids confer treatment benefit.[10] Consequently, the best evidence at present is to consider the administration of both antivirals and steroids, but not antivirals alone.[10]

Genu VII Bell's palsy is a stroke, masquerading as a peripheral seventh-nerve Bell's palsy, involving cranial nerve VI and the ipsilateral cranial nerve VII as it "genuflects" around the sixth-nerve nucleus. **This results in a cranial nerve VII palsy identical to a typical Bell's palsy (affecting the upper and lower face ipsilaterally) but with the added finding of the patient's inability to abduct the ipsilateral eye (cranial nerve VI palsy).** This underscores the importance of extraocular muscle testing in all Bell's palsy patients.

DIABETIC/HYPERTENSIVE CRANIAL NERVE PALSIES

Chronic diabetes and hypertension eventually can create vascular compromise to the vasa nervorum of any cranial nerve. **The pupil is spared in acute diabetic cranial nerve III palsy** due to vascular compromise of the central nerve fibers (the efferent pupillomotor fibers run in the periphery of the nerve) (**Figure 241-55**). Extraocular muscle testing will reveal an inhibition of ipsilateral medial gaze, upward gaze, and downward gaze as well as ptosis in an acute cranial nerve III palsy. Lateral gaze (abduction) will be preserved, and diplopia will be worse when the patient attempts to look toward the contralateral side due to the inability to adduct the eye (medial rectus dysfunction). In an acute cranial nerve VI palsy, lateral gaze will be diminished (abduction) on the ipsilateral side, and diplopia will be worse when the patient is trying to look to the affected side (lateral rectus dysfunction). Neuroimaging is needed in the ED to rule out an intracranial lesion.

If no other associated neurologic symptoms or findings are present, the blood sugar and blood pressure are under control, and neuroimaging does not suggest an alternative diagnosis, the patient can be discharged with ophthalmology and/or neurology follow-up.

POSTERIOR COMMUNICATING ARTERY ANEURYSM

Acute cranial nerve III palsy with ipsilateral pupillary dilatation is a posterior communicating artery aneurysm until proven otherwise. Concomitant headache is a frequent but not absolute finding. Expansion of an aneurysm of the posterior communicating artery frequently causes compression of the outer fibers of cranial nerve III. The pupillomotor fibers are located in the outer portion of cranial nerve III; therefore, the pupil becomes dilated on the affected side (**Figure 241-55**). Treatment is emergent blood pressure reduction if hypertensive, neuroimaging, and neurosurgical consultation.

HORNER'S SYNDROME

The physical findings of ipsilateral ptosis and miosis and anhydrosis are characteristic of Horner's syndrome (Figure 241-56). Interruption of the sympathetic nerve impulses controlling the Mueller muscle in the upper eyelid and the iris dilators causes these classic findings. Interruption can occur anywhere along the pathway from the brainstem to the sympathetic plexus surrounding the carotid artery (**Figure 241-57**). ED

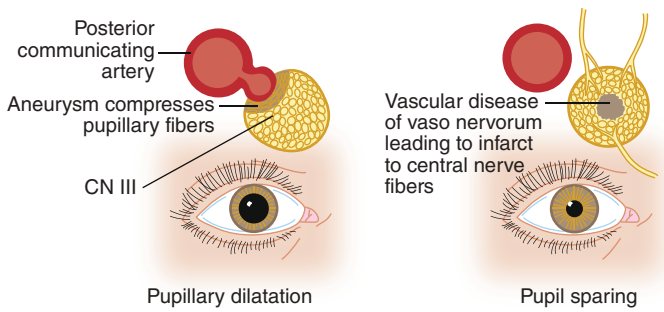

FIGURE 241-55. Posterior communicating artery aneurysm compresses the peripherally located pupillomotor fibers of cranial nerve (CN) III, causing a nerve palsy and pupillary dilatation. Diabetes and hypertension can cause microvascular compromise of the central nerve fibers, causing a nerve palsy with pupil sparing.

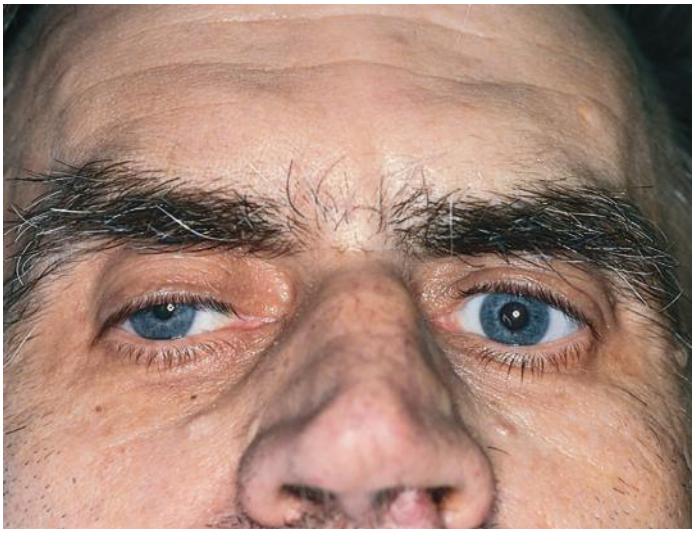

FIGURE 241-56. Horner's syndrome. Note the ptosis and miosis of the right eye. [Reproduced with permission from Knoop K, Stack L, Storrow A: *Atlas of Emergency Medicine,* 2nd ed. © 2002, McGraw-Hill, New York.]

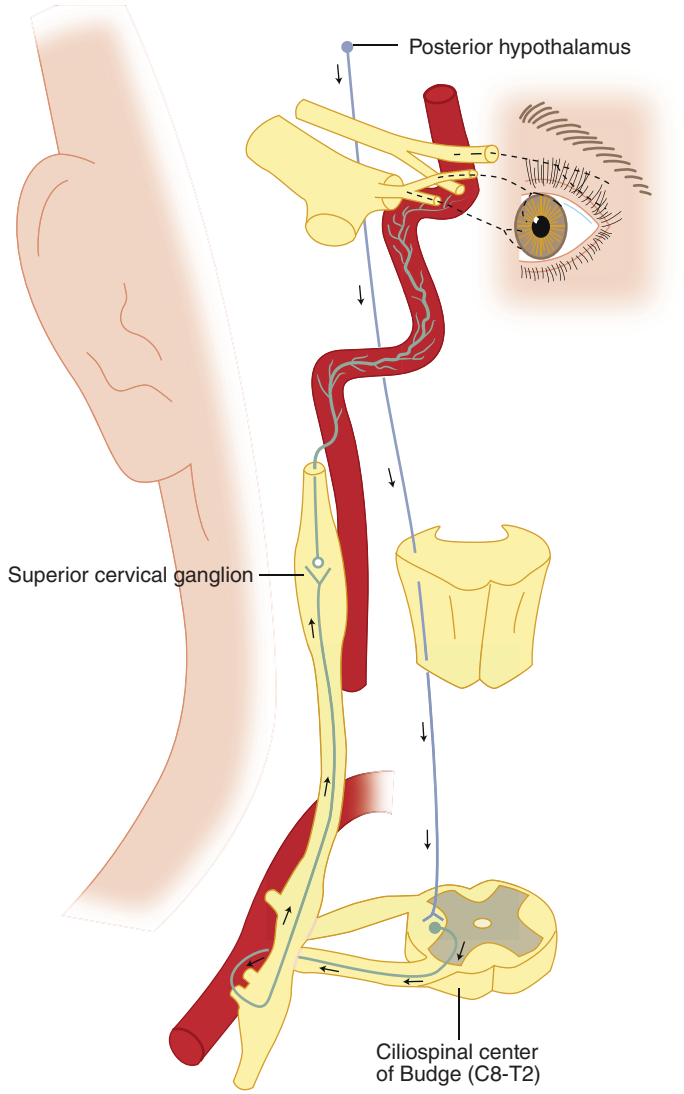

FIGURE 241-57. Sympathetic nerve pathway of the eye. An interruption anywhere along this pathway can cause Horner's syndrome.

evaluation includes a chest x-ray, CT scan of the brain and cervical region, and CT angiogram or magnetic resonance angiography of the head and neck vessels for carotid dissection. Institutional protocols determine if CT angiogram or magnetic resonance angiography is preferred.

In adults, causes of Horner's syndrome include cerebrovascular accidents, tumors, internal carotid artery dissection, herpes zoster, and trauma. In children, the causes include neuroblastoma, lymphoma, and metastasis. **Neck pain and acute Horner's syndrome suggest carotid dissection and can occur spontaneously (usually >30 years old) or as a result of blunt or penetrating neck injury.**

PSEUDOTUMOR CEREBRI (IDIOPATHIC INTRACRANIAL HYPERTENSION)

Increased intracranial pressure, papilledema, normal cerebrospinal fluid, and normal CT/MRI characterize pseudotumor cerebri. This condition can occur at any age. Patients complain of nausea, vomiting, headaches, and blurring of vision. **Patients can develop cranial nerve VI paresis, causing horizontal diplopia (double vision on lateral gaze).** A key component of examination is the identification of **visual field defects**. If CT/MRI is normal, perform lumbar puncture and record opening pressure; send cerebrospinal fluid for routine diagnostics. Consult neurosurgery for the treatment plan. Initial treatment is acetazolamide, 500 milligrams PO twice daily, and outpatient visual field monitoring.

OCULAR ULTRASONOGRAPHY

Direct visualization of intraocular structures can be limited by periorbital edema, corneal abrasions, hyphema, and cataracts. The superficial location of the eye and its cystic composition make US ideal in the assessment of a variety of ocular disorders. Ocular ultrasonography can expedite the diagnosis and management of several ocular emergencies, including retinal detachment, retrobulbar hematoma, globe perforation, lens dislocation, vitreous hemorrhage, and intraocular foreign body.[11-13] The indications for ocular ultrasonography include loss of vision/decreased vision, eye pain, eye trauma, suspected intraocular foreign body, and head injury. The ability of emergency physicians to accurately diagnose ocular pathology using bedside ocular ultrasonography has been well documented in emergency medicine literature.[11,12]

SCANNING TECHNIQUE AND NORMAL ANATOMY

Use a 7.5-to 10-mHz linear array transducer and set the unit to 'Ocular' for lower energy. Place the patient in a supine or partially upright position and have the patient keep the eyes closed (**Figure 241-58**). Apply a large amount of standard water-soluble US gel to the patient's closed eyelid so that the transducer does not touch the eyelid. US gel is not detrimental to the eye. Without applying any pressure, and asking the patient to look straight ahead with the eyes closed, scan the globe in sagittal and transverse planes. Stabilize the scanning hand over the bridge of the nose or on the forehead. Scan both eyes through closed eyelids for comparison. Examine the eyes in the neutral position and during gentle eye movements from side to side and up and down to thoroughly evaluate the orbit. Dynamic examination is crucial to identify adhesions, detachments, and membranes. The probe can also be moved side to side in both scanning planes to demonstrate the full extent of the structures in the eye. Adjust the depth so that the image fills the screen. The gain also needs to be adjusted multiple times during the examination to identify subtle abnormalities and avoid artifacts. Because the eye is a fluid-filled organ, it provides a perfect acoustic window for scanning and obtaining excellent images.[14-16]

The normal eye appears as a circular hypoechoic organ. The cornea is seen as a thin hyperechoic layer parallel to the eyelid attached to the sclera at the periphery. The iris is identified as a linear echogenic line extending from the periphery toward the lens on both sides. The anterior chamber contains anechoic fluid and is bordered by the cornea, iris, and anterior reflection of the lens. The normal lens has anterior and posterior boundary echoes with an anechoic center and is biconvex in

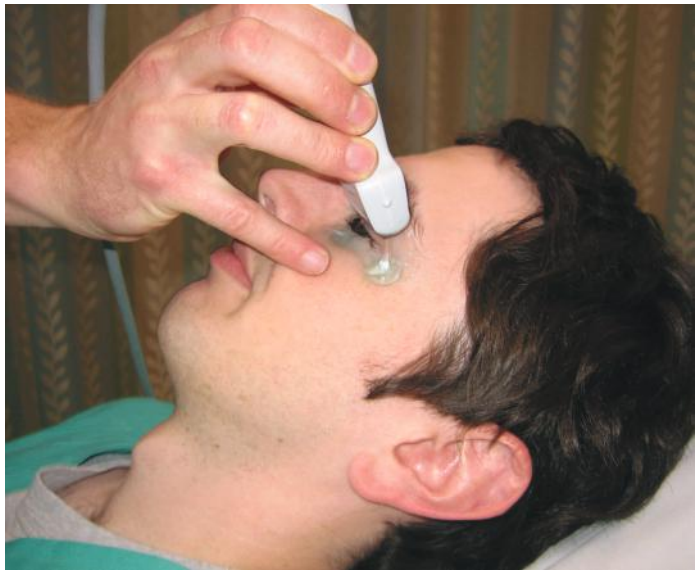

FIGURE 241-58. A high-resolution linear array US transducer is being applied to the closed eyelid. [Courtesy of Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

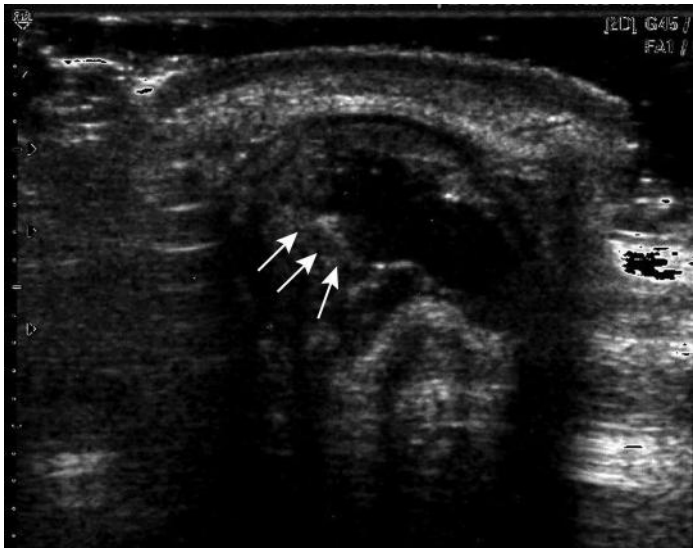

FIGURE 241-60. Extensive globe rupture from trauma. US shows abnormal, irregular shape of the eye with ocular contents displaced posteriorly (*arrows*). [Courtesy of M. Blaivas and Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

shape. The normal vitreous chamber is filled with anechoic fluid. Vitreous is relatively echo free in a young, healthy eye. Sonographically, the normal retina cannot be differentiated from the other posterior layers such as choroid and sclera (**Figure 241-59**). The evaluation of the retrobulbar space includes optic nerve, extraocular muscles, and bony orbit. The retro-orbital fat appears very echogenic. The optic nerve is visible as a hypoechoic linear region extending away from the globe posteriorly. Minor manipulations in the angulation of the probe are necessary to visualize the optic nerve. The central retinal artery and central retinal vein can be identified using Doppler.[14,15]

OCULAR TRAUMA

Assessment of patients with ocular trauma by US is of particular value when pain, soft tissue edema, and abnormalities like corneal edema, hyphema, or cataract make direct visualization of the posterior segment of the eye difficult. Ultrasound can detect a wide variety of ocular pathology from trauma including dislocated lens, globe disruption, vitreous hemorrhage, hyphema, retinal detachment, orbital emphysema, and retrobulbar hemorrhage. **Suspected ruptured globe is a relative contraindication to US examination, due to the risk of extruding globe contents associated with direct pressure on and around the eye.**[12]

US findings of globe rupture include distortion of the normal shape of the globe, decrease in the size of the globe, anterior chamber collapse, and vitreous hemorrhage.[11] Ocular trauma can lead to buckling of the sclera and scleral folds, which appear sonographically as irregularities in globe contour, highly reflective at their top and shadowing the orbital tissues (**Figure 241-60**). Sonographically, **lens dislocation** is seen as a highly reflective oval mass moving independently of the surrounding structures with eye movements. The dislocation is more readily visualized if it is complete or a cataract has formed. **Hyphema** can be identified on US as an echoic structure of variable echogenicity depending on the age of the bleed. Fresh hyphema will have low echogenicity and becomes more echogenic as it becomes organized. A **retrobulbar (pre- or postseptal) hematoma** is visualized as an echoluceny posterior to the globe.[17]

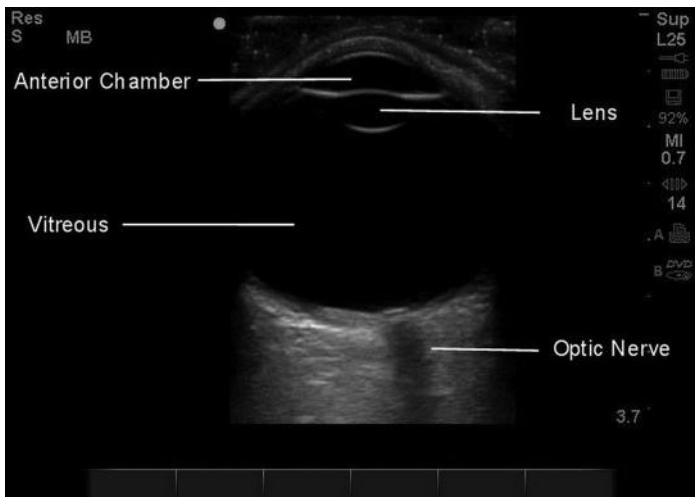

FIGURE 241-59. Normal eye in transverse view showing the anterior chamber, lens, vitreous, and optic nerve. [Courtesy of Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

INTRAOCULAR FOREIGN BODY

The presence of an intraocular foreign body may not always be apparent on clinical examination. US is a useful adjunct for detecting and localizing intraocular foreign bodies, but visualization of intraocular foreign bodies depends on their intrinsic echogenicity. Metallic objects are especially visible because of their bright echogenic acoustic profile and associated shadowing or reverberation artifacts in the echolucent vitreous, whereas materials such as wood are more difficult to detect (**Figure 241-61**). Sonographic patterns of shadowing and comet tail artifacts may help distinguish different foreign body materials. The dynamic nature of the US examination is also helpful in anatomic localization, determination of the size, and analysis of the composition of the foreign body.[18-20] With penetrating ocular injuries, a track of hemorrhage may be seen outlining the route of passage of a foreign body.

RETINAL DETACHMENT

Retinal detachment can be difficult to detect on physical examination, especially when the detachment is small. Bedside US reliably detects retinal detachment and is particularly useful when the examiner's view to the retina is obscured by periorbital edema, blood, or other opacities. For the detection of retinal detachment, ultrasonography performed by

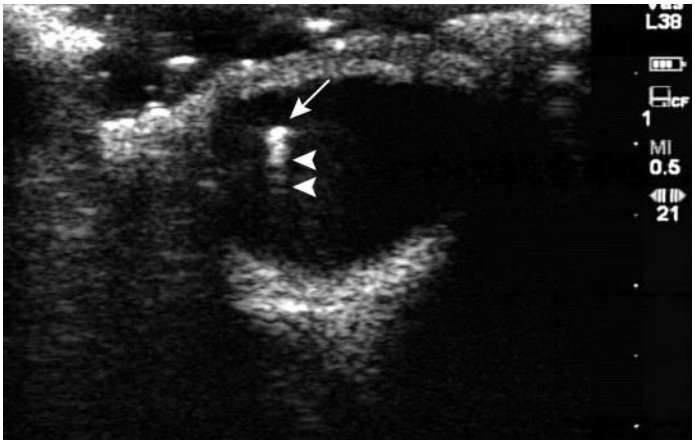

FIGURE 241-61. A hyperechoic foreign body (*arrow*) in the eye. Note the bright echogenic reverberation artifact (*arrowheads*). [Courtesy of M. Blaivas and Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

an emergency physician has a sensitivity of 97% to 100% and a specificity of 83% to 92%.[21,22]

A retinal detachment is seen as an echogenic undulating membrane in the posterior to lateral globe, protruding into vitreous (**Figure 241-62**). Even in complete retinal detachments, the typically folded surface remains bound to the ora serrata anteriorly and the optic nerve head posteriorly. Unlike choroidal detachment that doesn't change with ocular movements, retinal detachment moves with eye movements.[16] A shallow cuff of subretinal fluid may also be seen along with the detachment. On occasion, retinal detachments are also accompanied by vitreous hemorrhages.

Vitreous Hemorrhage Vitreous hemorrhage can be spontaneous or associated with trauma. Vitreous hemorrhage can interfere with vision and, if it is large, can potentially cause blindness. It appears as echogenic material in the posterior chamber. The sonographic appearance of vitreous hemorrhage depends on its age and the severity of the bleed. Increasing gain is helpful for detecting acute hemorrhages because they are often minimally echogenic. Early mild hemorrhages are seen as small dots or scattered low-amplitude reflective mobile opacities in the vitreous. As the hemorrhage matures and organizes, thick mobile membranes are formed in the vitreous. Sonographically, this is seen as vitreous filled with multiple large echoes (**Figure 241-63**). Due to gravitational forces, these opacities may also layer inferiorly. Echogenic

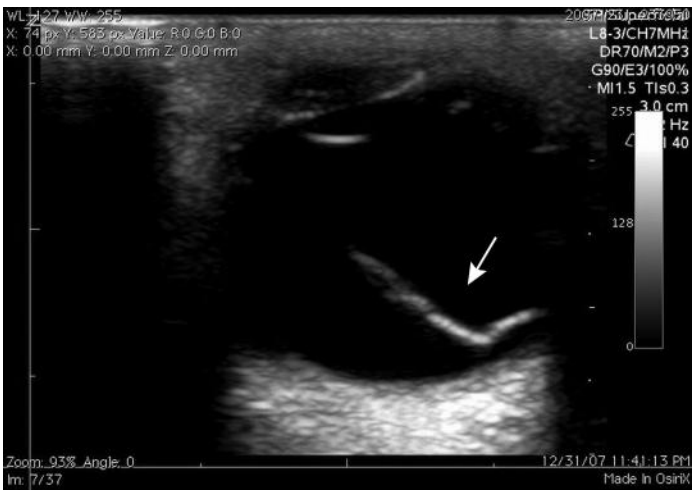

FIGURE 241-62. Retinal detachment is seen as a hyperechoic membrane in the posterior aspect of the globe (*arrow*). [Courtesy of D. Chandwani and Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

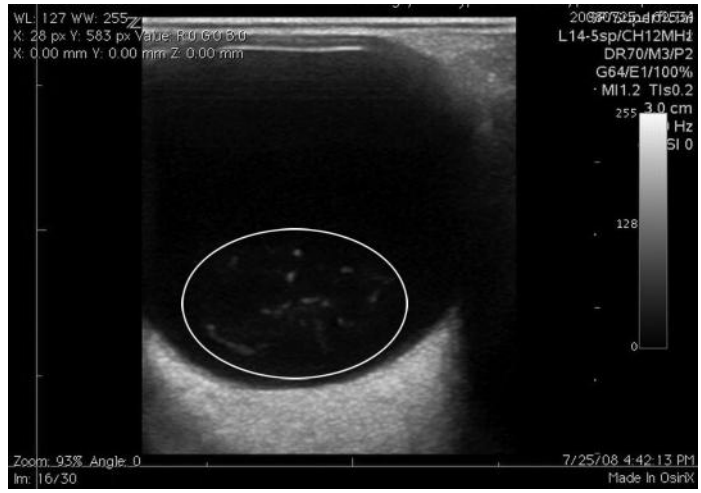

FIGURE 241-63. Bright echoes (enclosed in oval) in the posterior chamber demonstrating vitreous hemorrhage. [Courtesy of D. Chandwani and Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

stranding and scarring of the vitreous occurs as time progresses.[16,23,24] As vitreous hemorrhage becomes more echogenic, it can mimic the appearance of a retinal detachment. The main characteristics that can help in differentiating vitreous hemorrhage from retinal detachment are as follows: (1) Retinal detachment moves with eye movements unlike vitreous hemorrhage, which will remain horizontal; and (2) vitreous hemorrhages are frequently seen in the middle portion of the posterior chamber and retinal detachments almost always occur at the posterior-most portion of the eye, adjacent to the optic disk and macula.[21]

Elevated Intracranial Pressure—Optic Nerve Sheath Measurement Another novel use of bedside ocular US is the evaluation of the optic nerve sheath diameter to assess possible elevated intracranial pressure. Multiple studies have shown good correlation between intracranial pressure and sonographic optic nerve sheath diameter.[25-32] On US, a normal optic nerve sheath measures up to 5.0 mm in diameter in adults, 4.5 mm in children, and 4.0 mm in infants.[33] The measurement is obtained 3 mm posterior to the globe for both eyes. A position of 3 mm behind the globe is selected because the US contrast is greatest at this point, and the measurements are more reproducible (**Figure 241-64**). Typically, three measurements are

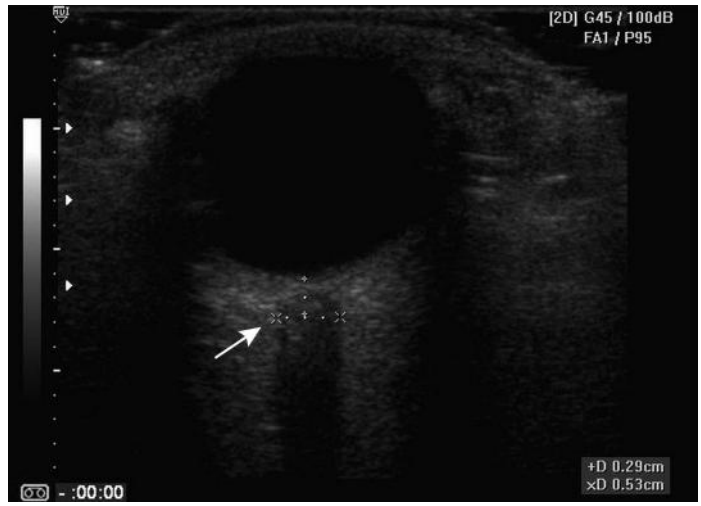

FIGURE 241-64. An optic nerve sheath measuring 5.3 mm in a patient with head injury is shown. One set of calipers measures 3 mm behind the globe, and the second measures the optic nerve sheath diameter (*arrow*). [Courtesy of M. Blaivas and Allen R. Katz, Department of Ophthalmology, University of Nebraska Medical Center.]

averaged. Current literature suggests that the cut-off value that provides the best accuracy for the prediction of intracranial pressure >20 mm Hg is 5.7 to 6.0 mm, and increased intracranial pressure should be suspected with values above this threshold. The sensitivity and specificity in detecting increased intracranial pressure using a cut-off value of 5.7 to 6.0 mm are in the range of 87% to 95% and 79% to 100%, respectively.[34]

CAUTIONS WITH OCULAR US

- **If globe rupture is suspected, avoid any manipulation or pressure upon the globe or eyelid.**
- Limit the duration of ocular US examination, especially when using spectral and color Doppler, and **set the US unit for 'ocular imaging'**. The recommended exposure limits are half that of fetal imaging.
- Various artifacts may interfere with ocular ultrasound examination. Orbital emphysema can make it difficult to visualize contents of the orbit.
- Air bubbles within the vitreous, which may appear in the setting of trauma to the globe, may resemble an intraocular foreign body.

CHAPTER 242

Ear Disorders

Kathleen Hosmer

This chapter discusses common nontraumatic conditions affecting the external, middle, and inner ear. Selected traumatic conditions include auricular hematoma, burns, and frostbite. Lacerations to the ear are discussed in the chapter 40, "Face and Scalp Lacerations." Ear disorders in children are discussed in chapter 115, "Ear and Mastoid Disorders in Infants and Children."

ANATOMY

EXTERNAL EAR

The auricle, or pinna, is the visible external portion of the ear, whose trumpet shape enables it to collect air vibrations. It consists of a thin plate of elastic cartilage with a tightly adherent covering of skin. The external auditory canal is an S-shaped skin-lined tube that extends from the auricle to the tympanic membrane (TM). The outer one third of the external auditory canal is composed of an incomplete cartilaginous tube. Its thick skin supports hair follicles plus apocrine and sebaceous glands. The inner two thirds of the canal is composed of bone covered by a thin layer of tightly adherent skin, which is easily torn by minimal trauma.

The blood supply to the external ear is derived from the posterior auricular, superficial temporal, and deep auricular arteries. Venous drainage of the external ear is into the superficial temporal and posterior auricular veins, which then drain into the external jugular vein. The posterior auricular vein frequently connects to the sigmoid sinus, providing a route for extension of infected material into the intracranial cavity.

MIDDLE EAR

The middle ear is an air-containing cavity in the petrous temporal bone. It contains the auditory ossicles, which transmit vibrations of the TM to the perilymph of the internal ear. It communicates with the nasopharynx anteriorly via the eustachian tube and with the mastoid air spaces posteriorly via the aditus ad antrum (**Figure 242-1**).

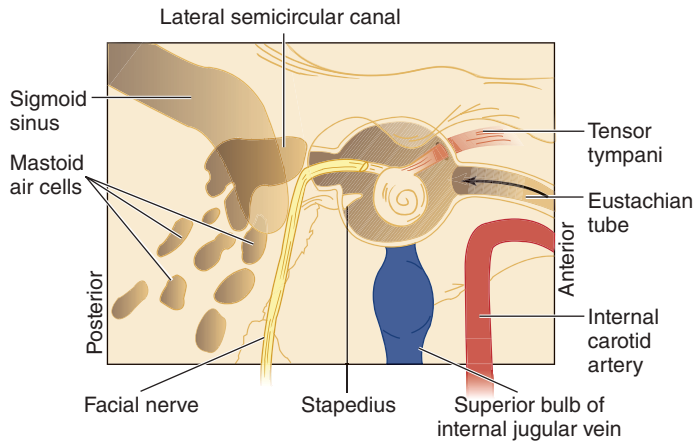

FIGURE 242-1. Sagittal section of the middle ear and related structures.

The TM is a thin, pearly gray, fibrous membrane that produces a cone-shaped light reflex anteroinferiorly when illuminated. Superiorly, the pars flaccida is the relatively slack portion of the membrane between the malleolar folds; the remainder of the membrane is tense and is called the pars tensa. The auditory ossicles are the malleus, incus, and stapes. Both the incus and the handle and lateral processes of the malleus are typically visible through the TM (**Figure 242-2**). Figure 242-1 shows the relationships of the facial nerve, sigmoid sinus, and internal carotid artery to the middle ear.

INNER EAR

The inner ear consists of the cochlea, which contains the auditory sensory receptors, and the vestibular labyrinth, which contains balance receptors. Cristae in the semicircular canals detect angular acceleration, and macules detect linear acceleration. Afferent nerves from the vestibular labyrinth connect to brainstem nuclei to maintain smooth movement of the eyes during head movement and to the cerebellum to control oculomotor and postural functions. Blood supply is from the vertebrobasilar system (**Figure 242-3**). The otolithic organs (utricle and saccule) lie in the vestibule. The internal auditory artery divides into the common cochlear artery and the anterior vestibular artery. The anterior vestibular artery provides the blood supply to the anterior and horizontal semicircular canals but not to the cochlea. Isolated occlusion of the anterior vestibular artery may therefore cause acute vestibular syndrome without hearing loss.

OTALGIA

Primary otalgia is caused by auricular and periauricular disease, whereas referred otalgia is caused by disease originating from remote structures.[1] Referred otalgia is common because the ear and several structures of the

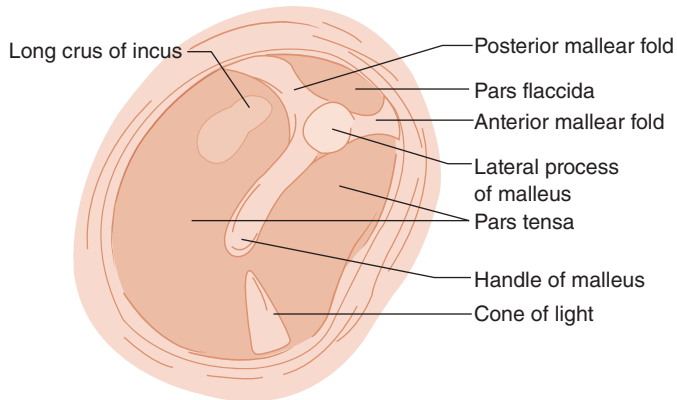

FIGURE 242-2. Right tympanic membrane as seen through the otoscope.

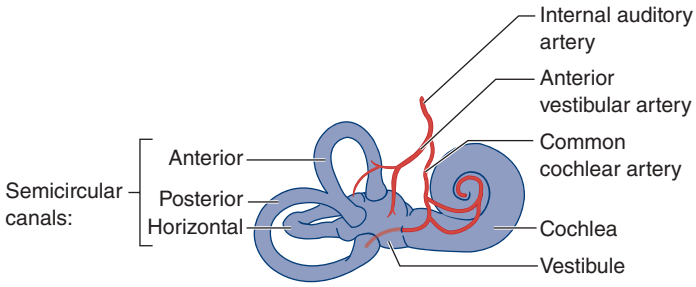

FIGURE 242-3. Schematic of the bony labyrinth containing the vestibular and auditory sensory organs.

head and neck share sensory innervation from the fifth, seventh, ninth, and tenth cranial nerves, as well as by the cervical plexus. **Table 242-1** lists common causes of primary and referred otalgia, including related neuralgias.[1]

TINNITUS

Tinnitus is the perception of sound without external stimulation. It may be constant, pulsatile, high- or low-pitched, hissing, clicking, or ringing. It is most prevalent between the ages of 40 and 70 years old.[2]

Tinnitus is divided into two types: objective and subjective. Objective tinnitus may be heard by the examiner. Subjective tinnitus is more common. Its exact origin is unknown, although it is believed to result from damage to cochlear hair cells. **Table 242-2** outlines causes of tinnitus.[2]

A number of drugs are associated with tinnitus, and some also cause hearing loss[2] (**Table 242-3**).

Accurate diagnosis usually requires referral to an otolaryngologist. Many medications have been suggested as therapies; antidepressants may help patients tolerate their tinnitus but do not change the course.

SUDDEN HEARING LOSS

Sudden hearing loss occurs over 3 days or less and is divided into sensorineural (cochlea, auditory nerve, or central auditory processing) and conductive (external ear, TM, and ossicles). Conductive hearing loss is more likely due to a reversible cause, such as otitis media, serous otitis, or a cerumen impaction. Indicators of poor prognosis include more severe hearing loss on presentation and the presence of vertigo. **Table 242-4**[3] lists causes of sensorineural hearing loss.

Viral infections, most typically mumps, have long been associated with sudden hearing loss.[4] Because of the terminal branches and interosseous location of the blood supply to the inner ear, the ear is uniquely vulnerable to a variety of vascular and hematologic diseases. Cogan's syndrome is an autoimmune disorder that presents with a bilateral hearing loss classically associated with tinnitus and vertigo.[5] Sudden hearing loss may also be caused by rupture of the TMs. Many common medications are implicated (Table 242-3).[3,5]

The evaluation begins with a complete history and physical examination. Differentiate conductive hearing loss from sensorineural hearing loss with a tuning fork. To perform the Weber test, place a vibrating tuning fork on the forehead and ask the patient where it is heard: it is normal to hear it equally in both ears; if the sound lateralizes to one ear, there is conductive hearing loss in that ear, or there is sensorineural loss in the opposite ear. To perform a Rinne test, place the vibrating tuning fork on skin over the mastoid bone of one ear, and then move the tuning fork to the entrance of the ear canal on the same side; the sound is normally heard better through air conduction at the entrance of the ear. If the sound is heard better over the mastoid bone, there is conductive hearing loss in that ear. Sudden conductive hearing loss may result from obstruction of the external auditory canal or from disturbances (or infection) of the TM or ossicles. Evaluate all current medications for possible ototoxic agents. A history of trauma or recollection of a "popping" noise preceding the hearing loss may indicate perforation of the

TABLE 242-1 Causes of Otalgia

Primary	Referred
Trauma	Temporomandibular dysfunction syndrome
Infection	Dental
Otitis externa	Abscessed teeth/dental carries
Otitis media	Malocclusion
Mastoiditis	Bruxism
Bullous myringitis	Eustachian tube dysfunction
Pinna cellulitis	Retro- and oropharyngeal
Cerumen impaction	Tonsillitis

Epstein-Barr virus	Cardiovascular disease
Toxoplasma gondii	Neurovascular disease
Syphilis	Hemorrhage (brain)
Herpes simplex virus	**Neoplastic (2.3%)**
Otologic disease (4.7%)	Vestibular schwannoma
Meniere's disease	Cerebellar angioma
Skull base or otologic surgery	**Other causes (2.2%)**
Autoimmune inner ear disease	Pregnancy related
Drug toxicity†	Nonotologic surgery

*Decreased incidence of hearing loss due to meningitis in the postimmunization era.
†See list of drugs in Table 3.

TM or ossicle dislocation. Coexistent tinnitus or vertigo may point to Ménière's disease. Also consider systemic illness.

The differential diagnosis includes both potentially reversible and potentially ominous causes (Table 242-4). If the physical examination does not identify the cause, consult otolaryngology. Treatment of idiopathic sudden sensorineural hearing loss is 60 milligrams of prednisone daily for 7 to 14 days or until follow-up, which is usually arranged within 2 weeks.[5-7]

ACUTE DIFFUSE OTITIS EXTERNA

Otitis externa includes infections and inflammation of the external auditory canal and auricle. It is divided into acute diffuse and malignant types. Acute diffuse disease is simply called *otitis externa* or *swimmer's ear.*

PATHOPHYSIOLOGY AND MICROBIOLOGY

Predisposing factors for the development of otitis externa are trauma to the skin of the external auditory canal and elevation of the local pH. Factors include frequent contact with water from swimming or bathing in hot tubs, pools, or freshwater lakes, and living in a humid environment. Trauma is most commonly due to scratching or overzealous disimpaction of cerumen. Cerumen is an acidic mixture of sebaceous and apocrine gland secretions and desquamated epithelial cells. It forms a physical barrier that protects the skin of the external auditory canal, whereas the acidic pH has antimicrobial properties.

The most common organisms are *Pseudomonas aeruginosa*, *Staphylococcus aureus*, Enterobacteriaceae, and *Proteus* species.[8] Otomycosis, or fungal otitis externa, is found in tropical climates and in the immunocompromised or after previous long-term therapy with antibiotics. Most cases are caused by *Aspergillus* or *Candida*.[9] Noninfectious causes include contact dermatitis from topical medications or resins in hearing aids, seborrhea, and psoriasis.

CLINICAL FEATURES

Acute diffuse otitis externa is characterized by pruritus, pain, and tenderness of the external ear. Physical signs include erythema and edema of the external auditory canal, which may spread to the tragus and auricle. Other signs are clear or purulent otorrhea and crusting of the external canal. As the disease progresses, the pain may become intolerable and occur with mastication or any movement of the periauricular skin. Increasing edema may eventually narrow the canal lumen and can lead to hearing impairment. In severe cases, infection may spread to the periauricular soft tissues and lymph nodes, and there may be lateral protrusion of the auricle secondary to inflammation.

TABLE 242-5 Topical Agents for Acute Diffuse Otitis Externa

Constituents	Comments
Ofloxacin 0.3%	Safe with perforations; one or two times per day
Ciprofloxacin 0.3%/dexamethasone 0.1%	Safe with perforations; two times per day
Acetic acid 2% solution	pH 4.5–6.0 (not safe with perforation)
Acetic acid 1%, hydrocortisone 2%	pH 3.0 (not safe with perforation)
Neomycin/polymyxin B/hydrocortisone	Ototoxic; higher risk of contact hypersensitivity; avoid in chronic otitis externa

TREATMENT

The treatment consists of analgesia, cleansing of the external auditory canal, acidifying agents, topical antimicrobials with or without steroids, and, in certain cases, adding an ear wick.[10,11] Cleansing may be done with gentle irrigation using hydrogen peroxide or saline, or gentle suction under direct visualization.[10] For the immunocompromised, atraumatic cleaning with aural suctioning under microscopic guidance can be done by an otolaryngologist.[10] Nonototoxic ototopical antibiotics are first-line therapy, particularly when the integrity of the TM is unknown or in the presence of a known TM perforation or tympanostomy tubes. Recommended topical agents are listed in **Table 242-5**.[11] Although there are few established cases of ototoxicity, there is a theoretical risk of both auditory and vestibular toxicity with the use of aminoglycosides, polymyxin, and acetic acid preparations.[10]

If cost is a factor and there are no known contraindications, acetic acid drops may be used because they are less expensive than the quinolones. In this case, a suspension should be used and not a solution; theoretically, a suspension has less chance of middle-ear penetration and resultant ototoxicity.

Instill the medication into the cleansed ear with the ear facing up, with this position held for 3 minutes. If edema of the external canal obstructs the lumen, insert a commercial wick to enhance delivery of topical drops throughout the full length of the canal.

For cases unresponsive to initial treatment, obtain bacterial and fungal cultures. Oral antibiotics are not routinely recommended[10] and should be reserved for febrile patients and those with periauricular extension (consider malignant otitis externa, discussed below). Instruct patients with otitis externa to avoid predisposing factors to eliminate recurrences. Strategies include ear plugs while swimming or bathing (cotton wool impregnated with petroleum jelly or commercial ear plugs), brief use of a hair dryer to remove water from the ear canal, and avoiding cotton-tipped applicators or other devices to remove cerumen.

In countries where otomycosis is more common, topical agents, such as clotrimazole 1% solution, are used.[12] Topical clotrimazole is available in the United States but not made specifically for otomycosis, and safety with ruptured TM has not been established. Fluconazole can be started (200 milligrams for one dose, then 100 milligrams daily for 3 to 5 more days);[13] however, the patient will need follow-up to determine the need for extended therapy. Patient growing *Aspergillus* in culture should be treated with voriconazole, 4 milligrams/kg PO two times daily.[9,13]

Instruct patients to follow up with their primary physician or an otolaryngologist in 1 week to be reevaluated; they should return to the ED for sudden worsening with fever or marked swelling.

MALIGNANT OTITIS EXTERNA

Malignant otitis externa is a potentially life-threatening infection of the external auditory canal involving the pinna and soft tissues with variable extension to the skull base, called *skull-base osteomyelitis*.

PATHOPHYSIOLOGY AND MICROBIOLOGY

Malignant otitis externa begins as a simple otitis externa that then spreads to the deeper tissues of the external auditory canal and infects cartilage, periosteum, soft tissue, and bone, with the normal anatomy of

the ear serving as the conduit for the spread of infection. Previously, >90% of cases were caused by *P. aeruginosa*,[13] but methicillin-resistant *Staphylococcus aureus* now accounts for 15% of cases.[14] Fungal disease occurs in diabetics and patients with immunocompromise.[15] Acquired immunodeficiency syndrome patients tend to be younger, have etiologic organisms other than *Pseudomonas*, and have a worse prognosis than patients without acquired immunodeficiency syndrome. The cerumen of diabetic patients has a higher pH than that of normal controls and represents an additional breakdown in local defense mechanisms. Small blood vessel disease of diabetics may lead to cartilaginous degeneration, further promoting the spread of infection.

CLINICAL FEATURES AND DIAGNOSIS

An individual with persistent otitis externa despite 2 to 3 weeks of topical antimicrobial therapy should be suspected of having malignant otitis externa. The typical presentation is severe otalgia (90%) and edema of the external auditory canal with otorrhea (70%).[16] Granulation tissue may be evident on the floor of the external auditory canal.

Examine both ears, inspecting both pinnas from the anterior, lateral, and posterior aspects. The infected ear will be erythematous, edematous, and more prominent than the unaffected ear. Assess nearby structures. Parotitis may be present, and trismus indicates involvement of the masseter muscle or temporomandibular joint. Cranial nerve involvement is a serious sign. The seventh cranial nerve is usually the first nerve affected by cranial extension, and the presence of dysfunction of the 9th, 10th, or 11th cranial nerve implies even more extensive disease. Lateral or sigmoid sinus thrombosis and meningitis are more serious possible complications.

Blood counts are typically normal. Erythrocyte sedimentation rate and C-reactive protein are frequently elevated but not essential for diagnosis[16] Clinical diagnosis and staging are confirmed by contrasted CT of the head or MRI.

TREATMENT

Institute antibiotics in the ED using imipenem in children; in adults, use an aminoglycoside and antipseudomonal penicillin or a cephalosporin or quinolone.[13] If fungal disease has grown from a prior culture, start voriconazole, 6 milligrams/kg IV every 12 hours. Selected cases of early infection may be managed as outpatients with oral quinolones. Mild cases are likely to completely resolve with a single course of antibiotic therapy, whereas more advanced stages may require IV antibiotics and possibly surgical debridement.

OTITIS MEDIA

Otitis media (OM) is primarily a disease of infancy and childhood (see chapter 118 for management of OM in children). While the management of OM in children and adults is similar, there are important differences in adults, highlighted below, especially for the management of OM with effusion.

PATHOPHYSIOLOGY AND MICROBIOLOGY

Viral upper respiratory tract infections precede or coincide with 70% of acute OM cases.[17] The most common associated viral pathogens are respiratory syncytial virus, adenovirus, and cytomegalovirus.[18] The most common bacterial pathogens recovered in acute OM are *Streptococcus pneumoniae* (43% to 49%), nontypable *Haemophilus influenzae* (29% to 70%), and *Moraxella catarrhalis* (15% to 28%).[17,19] The *H. influenzae* type b vaccine has no effect on nontypable *H. influenzae*. Most adults have never received this vaccine and thus remain unprotected from all *Haemophilus* flu strains. The predominant organisms involved in chronic OM are *S. aureus* (35%), *P. aeruginosa* (22%), *Aspergillus* (13%), and less commonly, anaerobic bacteria.[20] OM with effusion is differentiated from acute OM. In adults, OM with effusion is frequently associated with significant pathology: acute or chronic sinusitis in 66%, smoking-induced nasopharyngeal lymphoid hyperplasia and adult-onset adenoidal hypertrophy in 19% of cases, and head and neck tumors (mainly nasopharyngeal carcinomas) in 4.8%.[21] Adult patient with OM with effusion may also have symptoms of gastroesophageal reflux.[22]

CLINICAL FEATURES AND DIAGNOSIS

The typical ED presentation is a prodrome of an upper respiratory tract infection followed by sudden increase in otalgia, with or without fever. Otorrhea and hearing loss are variably present, while tinnitus, vertigo, and nystagmus are uncommon but possible findings. Diagnosis is clinical. The TM may be retracted or bulging. It may be red in color, indicating inflammation, or it may be yellow or white, as a result of middle-ear fluid. Pneumatic otoscopy almost uniformly demonstrates impaired mobility. Pain and new otorrhea (in the absence of external otitis) helps to confirm the diagnosis. **Always assess facial nerve function because of the nerve's proximity to the middle ear.** Guidelines are available for the diagnosis and management of OM in children,[23] but none have been published for adults. In adults, OM with effusion presents with ear discomfort or fullness or may present with decreased hearing without discomfort. OM with effusion is diagnosed based on physical exam findings of middle-ear effusion with little inflammatory changes, including pneumatic otoscopy showing an immobile TM. In adults, there will typically be other physical exam findings such as sinusitis or enlarged adenoids behind the uvula. Coexistent symptoms of reflux should be elicited.

TREATMENT

There are no treatment guidelines specifically for adults. The "wait-and-see" method recommended in children[24] has not been evaluated in adults. The preferred adult initial treatment is amoxicillin.[11] The dose in adults (weighing >40 kg) is 875 or 1000 milligrams every 12 hours, or 500 milligrams every 8 hours, for 7 to 10 days. Alternative agents include amoxicillin-clavulanate, cefdinir, or cefpodoxime. For OM unresponsive to initial therapy after 72 hours, consider changing to amoxicillin-clavulanate, levofloxacin, or moxifloxacin.

Provide pain control with acetaminophen or ibuprofen or with narcotics for severe pain. Topical agents such as antipyrine/benzocaine otic may also be given.[25] OM with effusion requires treatment with the same antimicrobials, but for 3 weeks, and prednisone may be added at follow-up. Patients with OM with effusion and coexisting symptoms of reflux should be treated with appropriate antireflux medications (see chapter 74, "Esophageal Emergencies").

Adults with OM should receive follow-up to assess treatment efficacy and to ensure that there is no anatomic obstruction to the eustachian tube, as, for example, from occult neoplasm. Any patient who presents with complications of OM or who appears septic should have urgent consultation for diagnostic and therapeutic tympanocentesis and admission for IV antibiotics.

COMPLICATIONS OF OTITIS MEDIA

Complications of OM are intratemporal and intracranial. Perforation of the TM is a common intratemporal complication and most often occurs in the pars tensa from the increased pressure of middle-ear secretions, with resultant otorrhea. Healing usually occurs in 1 week, although a chronic perforation may result. A temporary conductive hearing loss may occur from fluid in the middle ear. Hearing loss should resolve as the fluid is resorbed. Acute serous labyrinthitis may occur when bacterial toxins enter the inner ear through the round window. **Facial nerve paralysis** is an uncommon complication but requires emergent otolaryngology consultation.

Acute Mastoiditis and Cholesteatoma **Acute mastoiditis** results from spread of infection from the middle ear to the mastoid air cells by the aditus ad antrum. When this opening becomes blocked, the mastoid cavity becomes a closed space, and the mastoid air cells become inflamed and fill with fluid. The most common pathogens are *S. pneumoniae* (38%), *Streptococcus pyogenes* (11%), and *P. aeruginosa* (11%).[26] In addition to otalgia, fever, and otorrhea (especially in patient with *Pseudomonas*), patients with mastoiditis will have postauricular erythema, swelling, and tenderness, with protrusion of the auricle and obliteration of the postauricular crease. Diagnosis is suspected based

on the history and physical examination and confirmed on IV contrast CT scan. Mastoiditis requires admission for IV antibiotics, tympanocentesis, and myringotomy. For first episode, treat with ceftriaxone, 1 gram IV every 24 hours, or levofloxacin, 750 milligrams every 24 hours.[13] For recurrent episodes, treat with vancomycin, 1000 milligrams IV, and piperacillin-tazobactam, 3.375 gram initial dose IV, or imipenem. Incision and drainage of subperiosteal abscess or mastoidectomy may ultimately be required.

Aural **cholesteatomas** are collections of epidermis and exfoliated keratin within the middle ear or mastoid. As the cholesteatoma expands, it may erode the ossicular chain, bony labyrinth, or facial nerve canal. Cholesteatomas are often infected, and their intracranial extensions may be life threatening. Treatment requires otolaryngolic evaluation.

Intracranial Complications Intracranial complications of OM are more likely with chronic than with acute OM and are, in general, decreasing with the widespread use of antibiotics in the treatment of OM. However, suppurative intracranial extension is a severe complication, and suggestive signs and symptoms should be investigated appropriately. Meningitis and brain abscess are the most common intracranial complication of OM with an incidence of 0.42 per 100,000 per year.[27] The most prevalent causative organisms are *S. pneumoniae* (33%) and *Neisseria meningitidis* (23%).[27] Extradural abscess and subdural empyema are also potential complications.

Lateral Sinus Thrombosis Lateral sinus thrombosis is another ominous complication of acute OM. It arises from extension of infection and inflammation in the mastoid, with eventual inflammation of the adjacent lateral or sigmoid sinus. Reactive thrombophlebitis with mural clot formation, intraluminal empyema, or perforation of the venous wall may occur.

Headache is the most common symptom, with papilledema, sixth-nerve palsy, and vertigo being less frequently present. Angiography with venous phase and MRI are more sensitive than CT in diagnosing lateral sinus thrombosis. The employed antibiotic regimen should cover *Staphylococcus*, *Streptococcus*, and upper respiratory anaerobes, and have good penetration of the blood–brain barrier. A combination of IV penicillin or nafcillin, ceftriaxone, and metronidazole is one initial empiric regimen.[28]

BULLOUS MYRINGITIS

Bullous myringitis is a painful condition of the ear characterized by bulla formation on the TM and deep external auditory canal. The blisters are believed to occur between the highly innervated outer epithelium and the inner fibrous layer of the TM, explaining the severe otalgia. The blisters may be blood filled, serous, or serosanguineous. Reactive middle-ear effusions may accumulate. Otorrhea as a result of ruptured bullae is short lived. A reversible hearing loss is commonly associated with the condition and may be conductive, sensorineural, or mixed. This disorder is not caused by *Mycoplasma pneumoniae,* as commonly believed, but is a severe manifestation of the typical organisms that cause OM.[29] Treatment is as above for acute OM.

EAR HEMATOMA

An auricular hematoma can develop from almost any type of trauma to the ear. As a result of the lack of subcutaneous fat on the anterior surface of the auricle, blunt force applied to this area tends to shear the perichondrium from the underlying cartilage and tear the adjoining blood vessels. The cartilage depends on the perichondrial blood vessels for viability. Any interruption of the nourishing blood supply can result in necrosis. In addition, a subperichondrial collection can lead to stimulation of the overlying perichondrium, which can result in an asymmetric formation of new cartilage growth and deformity of the appearance of the external ear anatomy. The resultant deformed auricle has been referred to as "*cauliflower ear*," which is commonly seen in boxers or wrestlers secondary to repeated head/ear trauma. The auricular hematoma itself is a painful swelling that obscures the normal contour of the ear. The hematoma may accumulate immediately or several hours following an injury. Aspiration alone does not completely evacuate the clot and therefore leads to deformity and increased morbidity. The goal of treatment is to remove the fluid collection and maintain pressure in the area for several days to prevent reaccumulation of fluid.

ASPIRATION OF AND DRESSING FOR HEMATOMA OF THE EAR

Using sterile technique after local anesthesia, make a semicircular incision through the skin, and be careful not to incise the underlying perichondrium. The incision should be the minimal necessary to drain the underlying hematoma and positioned in an area with the least chance of cosmetic deformity. This is usually accomplished by incising the skin inside the inner curvature of the helix or anthelix. The hematoma can then be removed by gentle suction or curettage. Suture the incision after hematoma removal.

There are a few ways to prevent the hematoma from recurring. Place a dental roll or a firm sterile pledget coated with antibiotic ointment over the resutured site with through-and-through sutures connected to a similar bolster on the opposite side of the ear. Apply a light nonpressure dressing and reevaluate the ear within 24 hours to assure there has been no reaccumulation of the hematoma. A pressure dressing can also be employed if you do not want to suture a dental roll though the cartilage. Simply pack the helix with petroleum jelly–impregnated gauze and then place regular gauze both in front of and behind the ear. Lastly circle the head with a compressive wrap (**Figure 242-4**). Prophylactic antibiotics can be reserved for immunocompromised patients and should cover *P. aeruginosa* and *S. aureus*, the two likely participants in posttraumatic chondritis.

EAR FOREIGN BODIES

Cerumen loops/scoops, a right-angle hook, and alligator forceps are the instruments of choice for foreign body removal (**Figure 242-5**). Live objects should be drowned with a 2% lidocaine solution or viscous lidocaine, which immediately paralyzes the offending insect and provides modest topical anesthesia. The liquid can then be suctioned out with butterfly tubing and the insect removed with gentle suction or forceps under direct visualization. Remove all insect debris from the canal.

Irrigation with room-temperature water is adequate for small particles such as hard sand or cerumen and can mobilize distally positioned objects. Irrigation should not be used unless the TM is completely visualized and free of perforation. Organic matter that can expand when moistened is also a relative contraindication to irrigation.

Inspect the ear canal after removal of the foreign body to exclude injury to the canal skin, TM, and ossicles caused by the foreign body or its extraction. Small abrasions heal spontaneously. Topical antibiotics should be considered in cases where there was more serious cutaneous damage or where the foreign body consisted of organic material or generated a local inflammatory reaction (Table 242-5).

CERUMEN IMPACTION

Symptoms of cerumen impaction are decreased hearing, a sensation of pressure or fullness in the ear, dizziness, tinnitus, or otalgia. These symptoms are often precipitated by the use of cotton-tipped applicators. Most of the time, cerumen loops/scoops can be used to remove impacted cerumen (Figure 242-5). In particularly difficult cases or when the canal is completely occluded, softening of the material can be accomplished using half-strength hydrogen peroxide, sodium bicarbonate, mineral oil, or an over-the-counter preparation such as Debrox® (carbamide peroxide otic). Left in place for 30 minutes, such preparations soften the cerumen and facilitate its removal. If irrigation is the treatment of choice, it can usually be accomplished with an ear syringe, a flexible 18-gauge IV catheter, or a syringe attached to the tubing of a butterfly infusion catheter. Pretreatment with triethanolamine polypeptide oleate (Cereuminex®) improves success rates.[30] Use body-temperature irrigant to minimize the development of vertigo. Insert the catheter into the cartilaginous canal (external third) and gently irrigate along the superior portion of the external auditory canal. Using this technique, the pressure of the stream is directed toward the wall of the canal and not the TM.

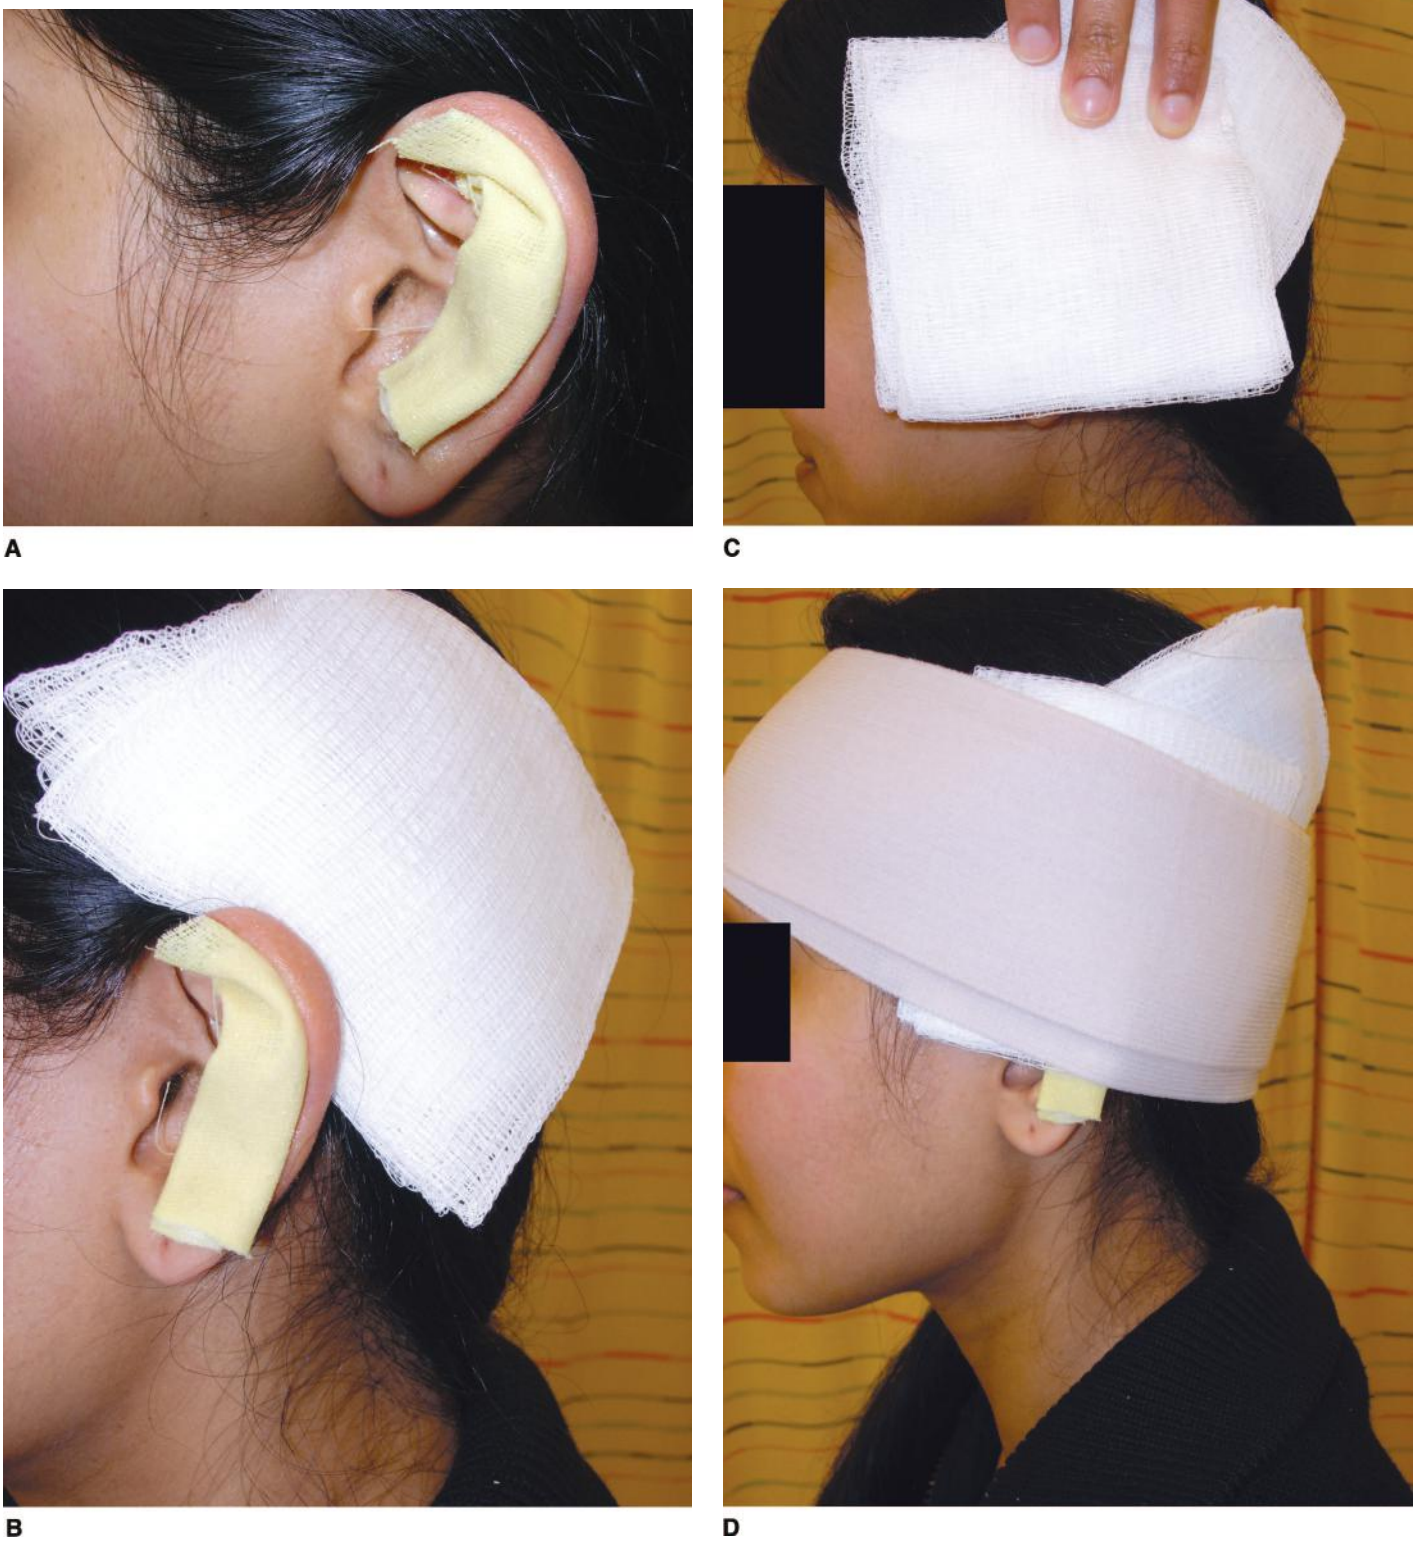

FIGURE 242-4. Stepwise progression to build an auricular bandage to help compress a drained hematoma in the auricle of the ear. Use a petroleum jelly–impregnated gauze inside the helix of the ear (**A**) and then add dry gauze to both the back (**B**) and front (**C**) of the ear. **D.** Wrap it lightly to add slight compression to hold the perichondrium to the auricular cartilage.

FIGURE 242-5. Different-shaped ear scoops and loops are useful to remove cerumen from an impacted ear. Miniature alligator forceps can be used to extricate foreign bodies from the external ear canal.

Irrigation of the canal when the middle ear is not infected often causes a temporary redness of the TM.

The most common iatrogenic injury associated with syringing of the ear is traumatic TM perforation. Predisposing factors for perforation include previous ear surgery, a previous or current history of OM, and severe otitis externa. When in doubt, it is safer to defer irrigation to an otolaryngologist. When determining if a perforation has occurred, it is important to rely on symptoms (sudden hearing loss, severe otalgia, or vertigo) rather than signs, because visualization of the TM may be impaired by the irrigating fluid and debris. In case of suspected perforation, reassurance, analgesia, and otolaryngology referral in 1 to 2 weeks are indicated. Prophylactic antibiotics are not necessary. If injury to ossicles is suspected, emergency ear, nose, and throat consultation is warranted.

TYMPANIC MEMBRANE PERFORATION

TM perforations can occur secondary to middle-ear infections or as a result of barotrauma, blunt/penetrating/acoustic trauma, or, on rare occasions, lightning strikes. Perforation is also discussed in the chapter 7, "Bomb, Blast, and Crush Injuries." When perforation is secondary to blunt or noise trauma, the perforation almost always occurs in the pars tensa, usually anteriorly or inferiorly. The pars tensa, the largest area of the TM, is only a few cell layers thick and thus is easily torn.

Symptoms are acute onset of pain and hearing loss, with or without bloody otorrhea. There may also be associated vertigo or tinnitus, but this is usually transient unless there has been injury to the inner ear or rupture of the round or oval windows. The TM should be completely visualized and the canal must be cleared of blood and debris.

Most TM perforations heal spontaneously. Patients with perforations secondary to blunt or noise trauma that are isolated injuries can be safely discharged and referred to a specialist for further evaluation and a formal audiogram as soon after the injury as possible. Patients should be instructed not to allow water to enter the canal of the ear. Topical or systemic antibiotics are not needed unless foreign material is suspected of remaining in the canal or in the middle ear. Perforations in the posterosuperior quadrant or those secondary to penetrating trauma have a greater likelihood of ossicular chain damage and should be referred to an otolaryngologist within 24 hours.

CHAPTER 243

Face and Jaw Emergencies

Stephanie A. Lareau
Corey R. Heitz

FACIAL CELLULITIS, ERYSIPELAS, AND IMPETIGO

Cellulitis and erysipelas are discussed in detail in the chapter 147, "Soft Tissue Infections." Impetigo is discussed in the chapter 136, "Rashes in Infants and Children." The differential diagnosis of facial infections is provided in **Table 243-1**.[1]

Cellulitis is a superficial soft tissue infection that lacks anatomic constraints.[2-4] Facial cellulitis is caused most commonly by *Streptococcus pyogenes* (group A β-hemolytic) and *Staphylococcus aureus*,[4] with an increasing predominance of methicillin-resistant *S. aureus*.[5] Less commonly, cellulitis may represent extension from deep space infections (see "Masticator Space Infection" section below). In children, buccal cellulitis from *Haemophilus influenzae* is now very uncommon if children have received the *H. influenzae* type b vaccine.[6]

Bedside US can exclude or identify facial abscess (**Figure 243-1**). CT can identify deep-seated, extensive infections that involve the soft tissues of the neck or pharynx.

Treatment is provided in **Table 243-2**. Duration of therapy is not well studied, but recommendations range from 7 to 14 days.[3,5,7,8] Treatment failures range from 15% to 20% for β-lactams (cephalexin, dicloxacillin, and amoxicillin-clavulanate) as well as for the anti–methicillin-resistant *S. aureus* therapies[9] due to the failure to cover methicillin-resistant *S. aureus* and streptococcal species, respectively. Cephalexin appears to be the most cost-effective therapy based on a probability of 37% for infection with *S. aureus* and a 27% methicillin-resistant *S. aureus* prevalence.[10] In selected cases, traditional β-lactam therapy may be added to anti-methicillin-resistant *S. aureus* therapy, but this strategy increases cost and potential for adverse effects of the medication.

Erysipelas is most common in the lower extremities (66% to 76%)[11-13] but is classically described as a disease of the face (see Figure 152-3). The nasopharynx is typically the source of bacteria.[14] In the majority of cases, erysipelas is caused by *S. pyogenes*.[3,4] Bullous erysipelas is a more severe form of the disease, and half of the infections reported in a 2004 case series were due to methicillin-resistant *S. aureus*.[15] Penicillin is the antibiotic treatment of choice[3,13] but is chosen as empiric therapy in a minority of cases.[11,12,16,17] If the suspicion exists of a staphylococcal infection (i.e., bullae, trauma, or the presence of a foreign body), alternatives include dicloxacillin, amoxicillin-clavulanate, or a cephalosporin[3] (Table 243-2). One randomized, prospective trial compared the use of a macrolide, roxithromycin, with penicillin and found no difference in efficacy.[18]

Impetigo is a discrete, superficial bacterial epidermal infection, characterized by amber crusts (nonbullous) or by fluid-filled vesicles (bullous) (see Figures 141-14 and 141-15). It is most common in children. *S. aureus* alone or in combination with *S. pyogenes* (group A β-hemolytic) is the most common cause of nonbullous impetigo. Bullous impetigo is always caused by *S. aureus*.[3,19,20] Treatment should cover streptococcal and staphylococcal species. Topical therapy is sufficient for uncomplicated patients with only a few nonbullous lesions.[21] Mupirocin, retapamulin, or fusidic acid ointment is recommended; however, some resistance is developing.[3,20,22,23] Consider oral antibiotics for extensive lesions or lesions that do not respond to topical therapy alone. Erythromycin and cloxacillin are superior to penicillin, but there is no clear preference between macrolides, β-lactamase–resistant penicillins, and cephalosporins.[3,19] Preferred choices are penicillinase-resistant penicillins (cloxacillin, dicloxacillin, amoxicillin-clavulanic acid) or first-generation cephalosporins (cephalexin).[3] For methicillin-resistant *S. aureus*, treat with trimethoprim-sulfamethoxazole or clindamycin[3] (**Table 243-3**).

SALIVARY GLAND INFECTIONS

There are three groups of salivary glands: the parotid, submandibular, and sublingual. The facial nerve passes through the superficial portion of the parotid gland, and the parotid (Stensen's) duct opens into the

TABLE 243-1 Differential Diagnosis of Superficial Facial Infection

	Historical Features		
	Onset/Timing	Risk/Inciting Factors	Physical Findings
Infectious			
Cellulitis	Gradual	Skin breaks, foreign bodies, prostheses, immunosuppression	Diffuse erythema without clear borders, pain
Impetigo	Acute	Infants, children	Discrete vesicles or bullae; patches of crusty skin
Erysipelas	Gradual	Elderly, infants and children, immune deficiency, diabetes, alcoholism, skin ulceration, impaired lymphatic drainage	Well-defined, raised area of erythema, pain
Viral exanthem	Often acute	Preceding or concurrent viral illness, fever	Variable
Parotitis	Gradual	Dehydration, diabetes, immunosuppression	Swollen angle of mandible, potentially visible sialolith
Necrotizing fasciitis	Rapid	Trauma, may be minor or not apparent	Crepitus, skin necrosis, may be subtle
Cutaneous anthrax	Gradual	Animal contact	Black eschar with surrounding erythema
Herpes zoster	Acute	Elderly, immunosuppression	Exquisitely tender erythematous or vesicular rash following a dermatome
Malignant otitis externa	Gradual	Diabetes, water exposure	Ear pain with drainage, facial swelling, tragal tenderness
Trauma			
Soft tissue contusion	Acute	Associated trauma	Tender swelling
Burn	Acute	Occupational, recreational exposure	May be difficult to distinguish from cellulitis
Inflammatory			
Insect envenomation	Acute	Environment supporting insect life	Diffuse, red, puffy
Apical abscess with secondary buccal swelling	Gradual	Usually associated dental pain/caries	Similar to cellulitis; may have intraoral/gingival findings
Contact dermatitis	Gradual or acute	Often identifiable exposure	Variable; maculopapular, itchy rash
Immunologic			
Systemic lupus erythematosus	Gradual	Female-to-male ratio, 9:1	Erythema in classic "malar" distribution
Angioneurotic edema	Acute	Exposure to angiotensin-converting enzyme inhibitor, allergen	Lip, oral mucosal swelling, sometimes facial
Vancomycin flushing reaction	Acute	Recent exposure to vancomycin	Facial erythema, warmth

mouth opposite the upper second molar. The submandibular and sublingual glands lie below the plane of the tongue. The submandibular ducts open into the mouth at either side of the frenulum of the tongue. The multiple sublingual ducts open into the sublingual fold or directly into the submandibular duct.[24]

Signs of salivary gland infections are unilateral or bilateral facial swelling. Recurrent symptoms, dry mouth and eyes, or joint symptoms suggest etiologies such as immunologic or collagen vascular disorders. Other medical conditions, such as nutritional disorders, toxic exposures, diabetes, dehydration, medication usage (i.e., phenothiazines), pregnancy, and obesity, can result in salivary gland enlargement. On physical examination, determine the location of the swelling to identify the gland involved. Multiple gland involvement suggests infection. A palpable tender mass may be a sign of tumor or obstruction by a stone. The differential diagnosis of salivary gland swelling is provided in **Table 243-4**.[24]

VIRAL PAROTITIS (MUMPS)

Viral parotitis is an acute infection of the parotid glands, characterized by unilateral or bilateral parotid swelling. It is most often caused by the paramyxovirus and may be caused less commonly by influenza, parainfluenza, coxsackie viruses, echoviruses, lymphocytic choriomeningitis virus, and even human immunodeficiency virus.[25] It is most common in children under the age of 15 years old, but since November 2014, clusters of mumps have been reported in adult members of professional hockey teams. The virus is spread by airborne droplets, incubates in the

TABLE 243-2 Antibiotic Therapy for Facial Infections

Cellulitis	Oral therapy: dicloxacillin, cephalexin, clindamycin; vancomycin and cephalosporins are alternatives Suspected MRSA: trimethoprim-sulfamethoxazole, clindamycin, doxycycline, minocycline, linezolid Parenteral therapy: nafcillin, vancomycin, clindamycin Total duration 7–10 d
Erysipelas	Oral therapy: penicillin (only if MRSA is unlikely) Methicillin-sensitive *Staphylococcus aureus* suspected: amoxicillin-clavulanate, cephalexin, dicloxacillin Bullous erysipelas (or MRSA suspected): trimethoprim-sulfamethoxazole, clindamycin, doxycycline, or minocycline Parenteral therapy: vancomycin, nafcillin, clindamycin Total duration 7–10 d
Impetigo	Topical: mupirocin or retapamulin ointment alone or with oral therapy Oral therapy: dicloxacillin, amoxicillin-clavulanate, cephalexin Alternative: azithromycin MRSA suspected: clindamycin or trimethoprim-sulfamethoxazole Total duration 7 d[3]
Suppurative parotitis	Parental therapy: nafcillin, amoxicillin-clavulanate or ampicillin-sulbactam; if penicillin allergic, clindamycin or the combination of cephalexin with metronidazole, or vancomycin with metronidazole Hospital acquired or nursing home patients: consider vancomycin Total duration: 10–14 d
Masticator space infection	Parenteral therapy: IV clindamycin is recommended; alternatives include ampicillin-sulbactam, cefoxitin, or the combination of penicillin with metronidazole Oral therapy: clindamycin or amoxicillin-clavulanate Total duration: 10–14 d

Abbreviation: MRSA = methicillin-resistant *Staphylococcus aureus.*

TABLE 243-3 Antibiotic Doses for Facial Infections

Antibiotic	Dosage
Oral Antibiotics	
Amoxicillin/clavulanate	875/125 milligrams twice per day
Azithromycin	500 milligrams first day, 250 milligrams 4 more days
Cephalexin	500 milligrams four times per day
Clindamycin	300–450 milligrams three times per day
Dicloxacillin	500 milligrams four times per day
Doxycycline	100 milligrams twice per day
Metronidazole	500 milligrams every 8 h
Minocycline	100 milligrams twice per day
Penicillin V	500 milligrams four times per day
Trimethoprim-sulfamethoxazole	1 double-strength tablet twice per day
Parenteral Antibiotics	
Antibiotic	**Dosage**
Ampicillin-sulbactam	1.5–3.0 grams every 6 h
Clindamycin	600 milligrams every 8 h
Cefazolin	1 gram every 8 h
Metronidazole	1 gram loading dose, then 500 milligrams every 8 h
Nafcillin	1–2 grams every 4 h
Penicillin G	2–3 million units every 6 h
Vancomycin	1 gram every 12 h

upper respiratory tract for 2 to 3 weeks, and then spreads systemically. Vaccine protection is not 100%, and outbreaks occur in settings of close contact, such as schools, colleges, sports teams, and camps.[26]

After a period of incubation, one third of patients experience a prodrome of fever, malaise, headache, myalgias, arthralgias, and anorexia during a 3- to 5-day period of viremia.[25] The classic salivary gland swelling then follows. Unilateral swelling is typically followed by bilateral parotid involvement. The gland is tense and painful, but erythema and warmth are notably absent. Stensen's duct may be inflamed, but no pus can be expressed.[25]

Diagnosis is clinical and treatment is supportive. Salivary gland swelling typically lasts from 1 to 5 days. The patient is contagious for 9 days after the onset of parotid swelling, and children with mumps should be excluded from school or day care for this interval.

Mumps is usually benign in children but can be severe in adults. Unilateral **orchitis** affects 20% to 30% of males (with a predisposition of ≥8 years of age), whereas **oophoritis** affects only 5% of females. Other complications of the mumps virus include mastitis, pancreatitis, aseptic meningitis, sensorineural hearing loss, myocarditis, polyarthritis, hemolytic anemia, and thrombocytopenia.[25] Immunocompetent patients with isolated viral parotitis or orchitis can be managed as outpatients. Admit patients with systemic complications.

SUPPURATIVE PAROTITIS

Suppurative parotitis is a serious bacterial infection of the parotid gland that occurs in patients with compromised salivary flow. It is caused by the retrograde migration of oral bacteria into the salivary ducts and parenchyma.[25] Predisposing factors include recent anesthesia, dehydration, prematurity or advanced age, sialolithiasis, oral neoplasms, salivary duct strictures, tracheostomy, and ductal foreign bodies.[25] Medications that cause either systemic dehydration or decreased salivary flow specifically can cause parotitis. These include diuretics, antihistamines, tricyclic antidepressants, phenothiazines, β-blockers, and barbiturates.[25] Several chronic illnesses also predispose patients to suppurative parotitis, such as human immunodeficiency virus, hepatic or renal failure, diabetes mellitus, hypothyroidism, malnutrition, Sjögren's syndrome, depression, anorexia, bulimia, hyperuricemia, and cystic fibrosis.[25]

Most cases of suppurative parotitis are caused by *S. aureus*, with *S. pneumoniae*, *S. pyogenes*, and *H. influenzae* as more infrequent pathogens.[3,25] Anaerobes such as *Bacteroides* species, peptostreptococci, and fusobacteria may be found in up to 43% of isolates. In the immunocompromised host, gram-negative organisms such as *Escherichia coli* and *Pseudomonas* may be seen.

The onset of suppurative parotitis is rapid, and the skin over the parotid gland is red and tender. Pus may be expressed from the Stensen's duct. There is often fever and trismus.

Suppurative parotitis is diagnosed clinically, with evidence of purulent drainage from Stensen's duct. Cultures of Stensen's duct drainage can guide therapy in the patient not responding to first-line antibiotics.[27] Imaging is not helpful unless an abscess is suspected, in which case US or CT is diagnostic.

Because suppurative parotitis is caused by states of decreased salivary flow, treatment should optimize salivary flow. Hydrate the volume-depleted patient. Massage and apply heat to the affected gland. Stimulate salivation using sialagogues, such as lemon drops. When possible, discontinue drugs that cause dry mouth, and attempt to correct underlying medical problems.[27]

Treat patients with oral antibiotics if they can tolerate oral liquids and have no evidence of systemic illness. Admit for parenteral antibiotics patients who have trismus and cannot tolerate oral liquids, are immunocompromised or incapable of complying with an outpatient treatment regimen, or have not shown improvement after 48 hours of outpatient treatment.[27]

Antimicrobial therapy consists of agents that cover both staphylococcal and streptococcal species (Tables 243-2 and 243-3). The initial choice for oral therapy includes amoxicillin-clavulanate; in penicillin-allergic patients, use clindamycin or a combination of cephalexin with metronidazole.[3,27] When parenteral therapy is indicated, choices include nafcillin, ampicillin-sulbactam, or a combination of vancomycin with

TABLE 243-4 Differential Diagnosis of Salivary Gland Swelling

	Historical Features		
	Onset	Risks/Inciting Factors	Clinical Features
Infectious			
Viral parotitis (mumps)	Gradual	Nonimmunized	Prodromal illness, unilateral tense swelling, absent warmth/erythema
Buccal cellulitis	Gradual	*Haemophilus influenzae* infection in nonimmunized	Erythematous, tender
Suppurative parotitis	Rapid	Dehydration, immunosuppression, chronic illness, recent anesthesia	Painful buccal swelling, fever, pus expression from Stensen's duct
Masseter space abscess	Gradual	Dental infection, post trauma	Trismus, posterior inferior facial swelling
Tuberculosis	Gradual	Exposure, immunosuppression	Chronic crusting plaques
Immunologic			
Sjögren's syndrome	Gradual	—	Dry mouth, eyes, sclerosis
Systemic lupus	Gradual	Female sex, Asian or African American race	No signs of infection
Sarcoidosis	Gradual	Female sex, African American race	No signs of infection
Other			
Neoplasm	Gradual	—	No erythema, warmth
Sialolithiasis	Gradual	Dehydration, chronic illness	Swelling, tenderness, no signs of infection

metronidazole. In hospitalized or nursing home patients, the possibility of methicillin-resistant *S. aureus*, for which vancomycin is appropriate,[27] must be considered. In neonates, treat with gentamicin and antistaphylococcal antibiotics combined with hydration. If there is no improvement in 24 to 48 hours, surgical drainage is required.

SIALOLITHIASIS

Sialolithiasis is the development of a calcium carbonate and calcium phosphate stone (sialolith) in a stagnant salivary duct. Salivary calculi can develop in any age group but usually are symptomatic in men between the third and sixth decades.[28] More than 80% of stones occur in the submandibular gland, with most of the remainder in the parotid.

The symptoms of pain, swelling, and tenderness may resemble those of parotitis. It may be hard to distinguish parotitis from sialolithiasis, and the two conditions may coexist. Sialolithiasis is typically unilateral. The pain and swelling of sialolithiasis are colicky and exacerbated by meals.

The diagnosis is clinical. A stone may be palpated within the duct, and the gland is firm.[28] Intraoral radiographs are more sensitive than extraoral films in identifying salivary calculi. The calculi are radiopaque in about 70% of cases. US and thin-cut CT also will identify sialoliths but are usually obtained only if abscess is in the differential diagnosis. ED bedside US has been shown in a case report to be a useful diagnostic tool to determine number, size, and location of stones (**Figure 243-2**).[29] A conservative course of treatment should precede imaging studies. Occasionally on CT, the diagnosis of sialolithiasis is made by the typically glandular swelling and inflammatory changes (signifying ductal obstruction) without an obvious stone seen in the duct (**Figure 243-3**).

Treatment is outpatient therapy with analgesics, antibiotics if there is concurrent infection, massage, and sialagogues, such as lemon drops.[28] Palpable stones in the distal duct may be digitally "milked" from the duct. Complications of salivary duct obstruction include recurrent or persistent obstruction, strictures, infection, and gland atrophy.[28]

MASTICATOR SPACE INFECTION

The masticator space consists of four potential spaces bounded by the muscles of mastication (**Figure 243-4**). These spaces include the masseteric (or submasseteric), superficial temporal, deep temporal, and pterygomandibular spaces.[30] The spaces are all contiguous. Masticator space infections occur when one or more bacterial agents invade all of these spaces. Bacteria may gain entry to the space from dental infections, trauma, surgery, or injections. Infections of the masticator space are polymicrobial and generally anaerobic, although aerobic oral streptococcal species may predominate briefly.[4,30] Typical organisms include species of *Streptococcus*, *Peptostreptococcus*, *Bacteroides*, *Prevotella*, *Porphyromonas*, *Fusobacterium*, *Actinomyces*, *Veillonella*, and anaerobic spirochetes.[4,30]

The most frequent acute clinical findings are facial swelling, pain, erythema, and trismus. When infection occurs in the masseteric space, there is facial swelling posteriorly and inferiorly, with mild to moderate trismus. If the temporal space is infected, there is soft tissue swelling over the temporalis muscle and trismus. Trismus without swelling suggests pterygomandibular space abscess. In chronic infection, the patient can be afebrile but may complain of intermittent trismus.[31] Constitutional signs may include fever, malaise, dehydration, dysphagia, nausea, or vomiting. In more advanced cases, systemic signs of sepsis are present. The differential diagnosis includes other sources of lateral facial pain and swelling (Table 243-4).

FIGURE 243-2. US image of sialolithiasis. [Photo contributed by R. Gordon, MD.]

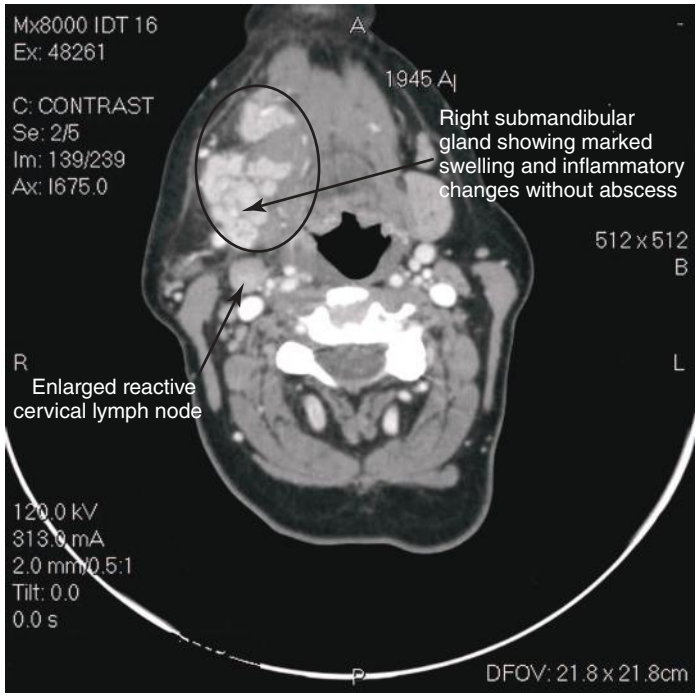

FIGURE 243-3. Marked enlargement of the right submandibular gland. This contrasted CT image shows marked enlargement of the right submandibular gland and surrounding inflammatory changes without an obvious stone or abscess formation. [Image used with permission of John Wightman, MD.]

Ultrasonography is helpful in differentiating abscesses from cellulitis (Figure 243-1), for the diagnosis of lymphadenitis, and to identify internal jugular thrombosis.[29] Contrast-enhanced CT is the preferred diagnostic tool for masseteric and related deep space infections.[30-32] CT can define the extent of the abscess and distinguish cellulitis from abscess in all spaces except the retropharyngeal.[30] MRI can be considered if infection is thought to reach the skull base.[29]

The patient's condition determines therapy. Because all the subordinate spaces of the masticator space communicate with each other and ultimately with the tissue planes that extend down the neck to the mediastinum, the extent of the infection should be defined efficiently and treatment begun promptly. Airway compromise is rare in unilateral masticator space infection. Treatment is airway control, stabilization, and treatment of infection. Administer antibiotics in the ED (Table 243-3), and admit the patient. IV clindamycin is recommended, with alternatives including ampicillin-sulbactam, cefoxitin, or the combination of penicillin with metronidazole.[4,30] Antibiotics are continued for 10 to 14 days. The macrolides (e.g., erythromycin) are generally no longer used for masticator space infections.[30] Otolaryngology consultation is recommended.

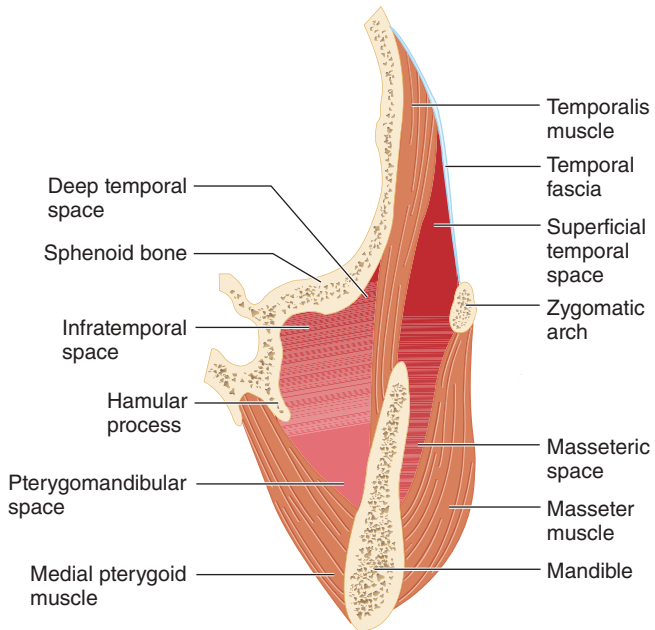

FIGURE 243-4. Masticator space.

TEMPOROMANDIBULAR JOINT DISORDERS

The temporomandibular joint combines both a hinge and gliding action. The articular surfaces of the joint are separated by the articular disk, or meniscus, which assists in the hinge action between the mandibular condyle and the disk and in the gliding action between the disk and temporal bone.[33]

TEMPOROMANDIBULAR JOINT DYSFUNCTION

Temporomandibular joint dysfunction causes pain of the joint and its surrounding anatomic structures. Assess for temporomandibular joint injury when evaluating direct jaw trauma or acute dental injury.[34] Most studies have found no significant correlation between occlusal parameters or bruxism and signs or symptoms of temporomandibular joint disorders.[35,36] Over time, degenerative joint disease (osteoarthritis) may result from chronic internal derangement or occur secondary to systemic disease such as rheumatoid arthritis or systemic lupus erythematosus.[34]

The chief complaint is usually pain localized to one of the muscles of mastication or pain with chewing in one or both temporomandibular joints. The masseter muscle is the most frequently identified painful area, followed by the temporalis, sternocleidomastoid, splenius capitis, and trapezius muscles.[35] Physical findings may include limitation in the range of motion of the mandible. Palpate the muscles of mastication to find areas of sensitivity, induration, rigidity, and swelling. Palpate the condylar heads with the teeth together and then with the teeth apart. The differential diagnosis of temporomandibular joint dysfunction includes jaw trauma, including fracture and dislocation; odontogenic pain, including from abscess, carie, or trauma; otologic referred pain, including from otitis media, otitis externa, and foreign body; and temporal arteritis.

Temporomandibular joint dysfunction is diagnosed by history and physical examination. Isolated temporomandibular joint clicking without pain or other dysfunction is not diagnostically sufficient.[35] For acute trauma, the panoramic x-ray view (Panorex) of the mandible is usually the initial imaging of choice. Panorex also provides information about the teeth and other parts of the jaw that may be contributing to pain.[37] CT is appropriate in the assessment of potentially complex fractures, infections, and neoplastic disease.

The oral maxillofacial surgeon manages fractures and should be consulted for trismus and significant mandible displacement. Otherwise, for uncomplicated fractures and nontraumatic conditions, give simple analgesics, including nonsteroidal anti-inflammatory drugs and, if necessary, narcotics. Advise the patient to eat soft foods until definitive treatment is provided. The management of chronic temporomandibular dysfunction may ultimately require referral to a dentist, maxillofacial surgeon, or pain specialist.

TRIGEMINAL NEURALGIA

Trigeminal neuralgia, or **tic douloureux**, is characterized by facial pain in the distribution of cranial nerve V. The cause is not known. Some postulate there is peripheral nerve injury or disease that increases afferent firing or a failure of central inhibition. Compression of the nerve by vessels, tumors, or inflammation is also a potential cause.[38]

Trigeminal neuralgia is characterized by paroxysms of severe unilateral pain in the trigeminal nerve distribution lasting only seconds, with normal findings on neurologic examination. There is no pain between paroxysms. Trigeminal neuralgia is divided into two categories. **Classic trigeminal neuralgia** includes idiopathic cases and cases due to microvascular

compression. **Secondary, or symptomatic, trigeminal neuralgia** is due to tumor, multiple sclerosis, or other structural abnormalities.

The history is key for diagnosis. Pain is a severe, shocking or stabbing, and brief, lasting seconds to minutes. Complete resolution occurs between episodes. Pain is clearly in the distribution of cranial nerve V. Classically, the pain is unilateral, although it can be bilateral. Triggers include light touch, chewing, or a light breeze. Pain can be accompanied by facial spasms. Physical exam is unremarkable.

Treatment is most often medical, but severe cases may require surgical intervention. Carbamazepine, started at 100 milligrams PO twice a day and then increased in dosage as needed, is an effective treatment. Baclofen has also been shown to be successful.[39] Patients with trigeminal neuralgia may present to the ED because symptoms are of recent onset or recurrent and should be started or restarted on carbamazepine. Pain control is rarely an issue because the paroxysms are so brief. Refer patients to a neurologist.

BELL'S PALSY

Bell's palsy is the most common cause of unilateral facial paralysis. The cause, however, is not clear. A leading theory is that as the facial nerve exits the temporal bone, edema and ischemia result in compression of the nerve. Inflammatory, demyelinating, or compressive processes have all been suggested, including infections (herpes simplex virus, herpes zoster, Lyme disease, syphilis, Epstein-Barr virus, cytomegalovirus, human immunodeficiency virus, mycoplasma), microvascular disease (diabetes and hypertension), and medications, including chemotherapeutics.[40]

Symptoms of Bell's palsy include acute onset of unilateral upper and lower facial paralysis, posterior auricular pain, decreased tearing, hyperacusis (oversensitivity to certain frequency and volumes), and otalgia. Some of these symptoms may develop prior to the classic facial paralysis. Onset is typically sudden, with a peak of symptoms in 48 hours.[40]

Diagnosis is confirmed by thorough history and physical exam. Examination reveals **weakness and/or paralysis of both the upper and lower portion of the face on the affected side.** Flattening of the forehead and nasolabial folds on the affected side is present. Careful neurologic exam is useful in ruling out other conditions, such as stroke. In addition, examine the ear to ascertain presence of cranial herpes zoster, which along with stroke and Guillain-Barré syndrome accounts for >85% of misdiagnoses.[41] Laboratory studies are not needed.

There is much controversy surrounding the treatment for Bell's palsy. Goals of emergency care include increasing the chances of recovery of facial nerve function and protection of the eye. The American Academy of Neurology guidelines state that steroids are highly likely to be effective and increase the likelihood of recovery.[42] When initiated within the first 72 hours of symptom onset, steroids improve chances of full recovery. The recommended dosing is 1 milligram/kg up to 60 milligrams/d for 6 days, followed by a 10-day taper. Use of antivirals, such as acyclovir or valacyclovir, is controversial. According to the American Academy of Neurology's 2012 guidelines, benefits from antivirals have not been established and are thought be modest at best.[41] A variety of other therapies including physical therapy, acupuncture, and surgical decompression have also been used with variable success. Cessation of the offending agent is indicated if the medications or chemotherapy is implicated. Apply ocular lubricants to protect against corneal abrasions, and it may be necessary to tape the patient's eyelid, especially during sleep.

MANDIBLE DISLOCATION

The mandible can be dislocated in an anterior, posterior, lateral, or superior direction. **Anterior dislocation is most common and occurs when the mandibular condyle is forced in front of the articular eminence.** Muscular spasm then traps the mandible in anterior dislocation, and the mandible is elevated before retraction. Factors that predispose patients to symptomatic anterior dislocation include a shallow glenoid fossa, increased muscle tone (such as during a seizure), and a loss of joint capsule tone from previous trauma. Spasm of the temporalis and lateral pterygoid muscles tends to prevent reduction once dislocation has occurred. Dislocations are usually bilateral but can be unilateral.[33] Posterior dislocations are rare. They follow a blow that may or may not break the condylar neck. In posterior dislocation, the mandibular condyle is thrust backward against the mastoid, and the condylar head may prolapse into the external auditory canal.[33] Lateral dislocations are often associated with mandibular fracture. With a lateral dislocation, the condylar head is forced laterally and then superiorly into the temporal space. Superior dislocations occur from a blow to the partially open mouth that forces the condylar head upward. Associated injuries include cerebral contusions, facial nerve palsy, and deafness.

Acute jaw dislocation causes severe pain, difficulty in speaking or swallowing, or malocclusion after a blow to the jaw or a seizure or, sometimes, spontaneously. There may be loose or missing teeth and areas of sensory deficit at the chin or mouth. With anterior dislocation, pain is localized anterior to the tragus. Symptoms may develop after extreme mouth opening from laughing, yawning, vomiting, taking a large bite, or trauma, or iatrogenically during dental extraction, general anesthesia, and tonsillectomy.[33] With anterior dislocations, the lower jaw is prominent appearing, and there is visible and palpable preauricular depression from the displacement of the mandibular condyle. There also will be difficulty with jaw movement. If the dislocation is unilateral, there is deviation of the jaw away from the dislocation. **When a posterior dislocation is considered, examine the external auditory canal.** Confirm that hearing is at baseline. With lateral dislocations, the condylar head is palpable in the temporal space, and there are always signs of jaw fracture (e.g., malocclusion). **Posterior, lateral, or superior dislocations result from severe trauma.** The differential diagnosis includes mandibular fracture, traumatic hemarthrosis, acute closed locking of the temporomandibular joint meniscus, and temporomandibular joint dysfunction.[33]

In the cooperative patient with a **spontaneous atraumatic anterior dislocation**, the diagnosis is clinical. In other dislocations, including any traumatic dislocation, obtain radiographs. The panoramic (Panorex) view usually demonstrates the pathology and excludes other mandibular injury. In patients with more serious trauma, where there may be a superior dislocation or intracranial injury, CT will provide more information.

Perform reduction in the ED for closed anterior dislocations without fracture.[33] A short-acting IV muscle relaxant (e.g., midazolam) may help to decrease muscle spasm. Appropriate airway and hemodynamic monitoring is required. Procedural sedation has been used successfully.[43] Alternatively, local anesthetic can be placed into the joint space. Using aseptic technique, place a 21-gauge needle into the preauricular depression just anterior to the tragus and inject 2 mL of 2% lidocaine[44] (**Figure 243-5**).

REDUCTION OF ANTERIOR TEMPOROMANDIBULAR JOINT DISLOCATION

The most commonly used technique requires the patient to be firmly seated with the head against the wall or chair back, positioned so that the examiner's flexed elbow is at the level of the patient's mandible. Apply a

FIGURE 243-5. Site for injection of local anesthesia for reduction of dislocated mandible. Place a 21-gauge needle into the preauricular depression just anterior to the tragus and inject 2 mL of 2% lidocaine.

FIGURE 243-6. Reduction of dislocated mandible technique in a seated patient. The thumbs are placed over the molars, and pressure is applied downward and backward.

few layers of gauze over gloved thumbs for protection, in case the mandible snaps closed after reduction.[33]

Facing the patient, place gloved thumbs in the patient's mouth, over the occlusal surfaces of the mandibular molars, as far back as possible. Curve your fingers beneath the angle and body of the mandible. Using the thumbs, **apply pressure downward and backward (toward the patient)**. Slightly opening the jaw may help disengage the condyle from the anterior eminence (**Figure 243-6**). When the dislocation is bilateral, it may be easier to relocate one side at a time.

In the second technique, with the patient recumbent and supine, stand at the head of the bed, place the thumbs on the molars, and apply downward and backward pressure (toward the stretcher) (**Figure 243-7**).[33]

In addition to the above common methods, other approaches include the ipsilateral, in which the thumb is externally used to apply downward pressure on the displaced condyle; the wrist pivot method, in which the healthcare provider's thumbs are placed on the mentum, applying

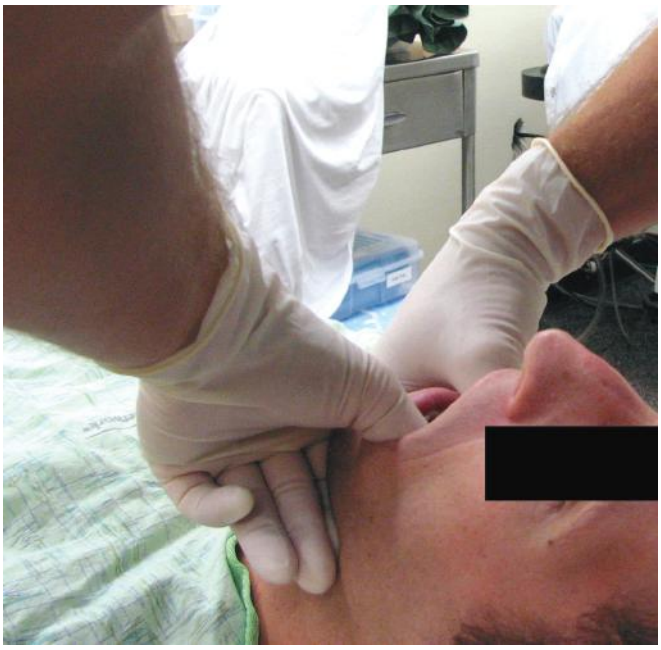

FIGURE 243-7. Alternate mandibular reduction technique, with the examiner behind and above the reclined patient. Place the thumbs on the molars and apply downward and backward pressure (toward the stretcher).

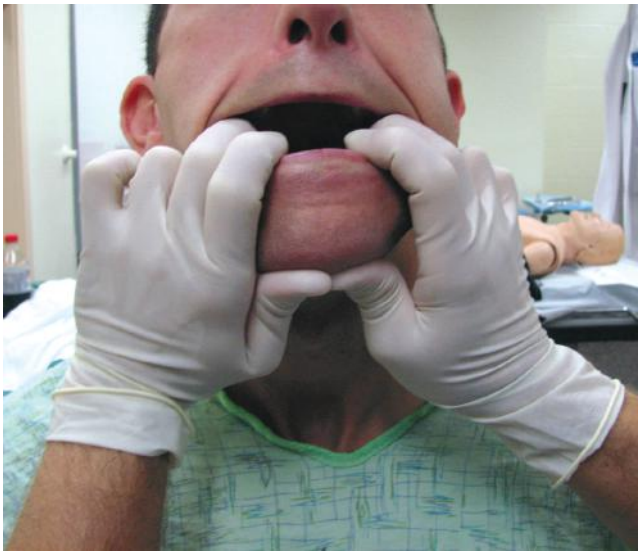

FIGURE 243-8. Wrist pivot method for mandibular reduction. The operator's thumbs are placed on the mentum, applying upward force, while the fingers apply downward force on the body of the mandible.

upward force, while the fingers apply downward force on the body of the mandible (**Figure 243-8**); and the gag reflex approach. In the gag reflex method, the provider stimulates the patient's soft palate with a tongue blade or dental mirror, thereby producing muscle relaxation and descent of the mandible, resulting in relocation of the condyle.[33]

After successful reduction, the patient should be able to close his or her mouth immediately. Postreduction radiographs usually are not needed unless the procedure was difficult or traumatic or there is significant postreduction pain. Complications from the reduction itself are unusual but can include iatrogenic fracture or avulsion of the articular cartilage.

Dislocations that are open, superior, associated with fracture, have any nerve injury, or are irreducible by closed technique should be referred urgently to an otolaryngologist or maxillofacial surgeon.

Following successful reduction of an acute dislocation, patients may be discharged home, placed on a soft diet, and cautioned against opening their mouths >2 cm for the following 2 weeks.[33] Advise patients to support the mandible with a hand when they yawn. Nonsteroidal analgesics may help the initial discomfort. Elective referral to an oral maxillofacial surgeon is recommended. In severe cases, intermaxillary fixation may be required to control jaw motion during healing. Chronic dislocations may require operative intervention.

CHAPTER 244

Nose and Sinuses

Henderson D. McGinnis

EPISTAXIS

EPIDEMIOLOGY

Epistaxis occurs most frequently in children under 10 years old and in those over 70 years old.[1] Local causes of epistaxis include digital trauma, a deviated septum, dry air exposure, rhinosinusitis, neoplasia, or chemical

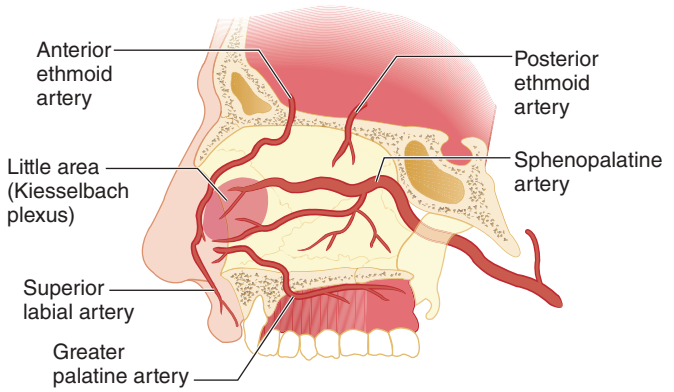

FIGURE 244-1. Arterial blood supply to the nasal cavity. The most common site of nasal hemorrhage is at Little's area of the nasal septum. The most common origin of posterior epistaxis is from the sphenopalatine artery.

irritants such as inhaled corticosteroids or chronic nasal cannula oxygen use. Systemic factors that increase the risk of bleeding include chronic renal insufficiency, alcoholism, hypertension, vascular malformations such as hereditary hemorrhagic telangiectasia, or any kind of coagulopathy, including warfarin administration, von Willebrand's disease, or hemophilia.[2]

ANATOMY AND PATHOPHYSIOLOGY

The superior labial branch of the facial artery joins the anterior ethmoidal and terminal branch of the sphenopalatine artery to form Kiesselbach plexus on the anterior nasal septum, which is the source of 90% of nosebleeds and can usually be visualized with anterior rhinoscopy (**Figure 244-1**). The most likely source for posterior bleeds is the sphenopalatine artery, which is a terminal division of the internal maxillary artery (branch of the external carotid system). Endoscopic or open surgical techniques are needed to visualize the vessel.[2,3] Sensory innervation is detailed in **Figure 244-2**.

CLINICAL FEATURES

A directed history and physical examination is usually sufficient to identify the source of acute epistaxis. Ask about prior or recurrent epistaxis, duration and severity of the current episode, and laterality.

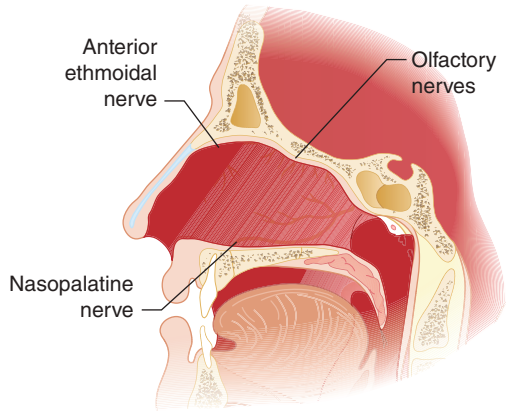

FIGURE 244-2. Sensory innervation of the external nose. [Reproduced with permission from Reichman EF, Simon RR: *Emergency Medicine Procedures*. © 2004, Eric F. Reichman, PhD, MD, and Robert R. Simon, MD.]

Ask specifically about nonsteroidal anti-inflammatory drugs, warfarin, heparin, or aspirin use. Alcohol or cocaine abuse, trauma, prior head and neck procedures, and a personal and family history of coagulopathy should be assessed.

Make preparations for nasal examination and tamponade. The ED should have a preprepared, readily available epistaxis kit or cart. The kit should include a nasal speculum, bayonet forceps, headlamp, suction catheter, cotton pledgets, 0.05% oxymetazoline and 4% lidocaine solutions, silver nitrate swabs, and some combination of absorbable and nonabsorbable materials for anterior and posterior packing.

Assemble a good light source, suction, and a nasal speculum. Have the patient seated and in the "sniffing" position. The sniffing position is achieved by having the patient flex and extend the head while keeping the base of the nose straight ahead. With the patient in this position, brace the speculum by resting the index finger on the tip of the nose and insert the speculum with the handle parallel to the floor. Open the blades in a cephalad-to-caudad direction to visualize the bleeding site and facilitate the performance of direct hemostatic techniques.

DIAGNOSIS

Differentiating an anterior versus posterior source of bleeding is important for treatment and disposition; failure to identify the source of bleeding is associated with rebleeding and return for treatment.[4] The division between anterior and posterior bleeding in the ED is often based on the ability to visualize the site of bleeding with a light source and a nasal speculum.[5] Generally, the diagnosis of posterior hemorrhage is only made in the ED once measures to control anterior bleeding have failed. Clinical features suggestive of a posterior source include elderly patients with either inherited or acquired coagulopathy, a significant amount of hemorrhage visible in the posterior nasopharynx, hemorrhage from bilateral nares, or epistaxis uncontrolled with either anterior rhinoscopy or an anterior pack.[6] Laboratory evaluation or other ancillary studies are not required unless management of comorbid illness requires it or the hemorrhage is poorly controlled. In the latter case, collect blood for CBC, type and cross-match, and coagulation studies if coagulopathy is suspected.

TREATMENT

Initial ED management for epistaxis begins with a rapid primary survey addressing potential airway or hemodynamic compromise. Obtain IV access in patients with severe bleeding, and request cross-matched blood if there is hemodynamic instability. The need for transfusion is more common in patients with posterior epistaxis and those on anticoagulants.[7] Reversal of coagulopathy with blood products can be considered based on clotting studies and individual patient context. Rapid reduction of blood pressure during an episode of acute epistaxis is generally not advised.[8] For uncontrolled epistaxis requiring packing or surgical intervention, gentle reduction of persistent hypertension reduces hydrostatic pressure and thereby may aid clot formation.[8]

DIRECT NASAL PRESSURE

First, ask the patient to blow the nose to expel clots to prepare mucosa for topical vasoconstrictors. Instill a topical vasoconstrictor such as oxymetazoline or phenylephrine. The patient should lean forward in the "sniffing" position and pinch the soft nares between the thumb and the middle finger for a full 10 to 15 minutes, breathing through the mouth. If the patient is uncooperative, fashion a hands-free pressure device made from two tongue depressors that are taped together between halfway and two thirds of the way up the depressors. Place the device on the nose and leave it undisturbed for 10 to 15 minutes. These initial measures are often sufficient to achieve hemostasis and facilitate further examination by anterior rhinoscopy.

CHEMICAL CAUTERIZATION

If two attempts at direct pressure have failed, chemical cauterization with silver nitrate is the next appropriate step for mild bleeding. Before cautery, anesthetize the nasal mucosa using three cotton pledgets soaked in a 1:1 mixture of 0.05% oxymetazoline and 4% lidocaine solution.[2] Do not attempt chemical cautery unless the bleeding vessel is visualized. Electrical cautery should be left to the otolaryngologist due to the risk of septal perforation.

After visualizing the (anterior) bleeding site, silver nitrate sticks may be judiciously placed just proximal to the bleeding source on the anterior nasal septum. Silver nitrate requires a relatively bloodless field, as the chemical reaction leading to precipitation of silver metal and tissue coagulation cannot proceed in the setting of active hemorrhage due to washout of substrate. Once a relatively bloodless field is achieved, gently and briefly (a few seconds) apply silver nitrate directly to the bleeding site. Chemical cautery should never be attempted on both sides of the nasal septum. Subsequent attempts on the same side of the nasal septum should be separated by 4 to 6 weeks to avoid perforation.[9]

THROMBOGENIC FOAMS AND GELS

Thrombogenic foams and gels are a good option, and they may be considered after attempts at chemical cautery have failed and before insertion of nasal tampons. Gelfoam® and Surgicel® (oxidized cellulose) are effective hemostatic agents that can be placed simultaneously on visualized bleeding mucosa, and they are bioabsorbable, so removal is not needed. FloSeal®, a hemostatic gelatin matrix that is mixed in a syringe with thrombin and injected into the nasal cavity, may decrease episodes of rebleeding and the need for specialty follow-up compared to other agents.[10] A 2013 randomized controlled trial involving 216 patients demonstrated that 5 mL of the injectable form of tranexamic acid, equal to 500 milligrams, applied topically to the nasal mucosa using a 15-cm piece of cotton pledget, stopped anterior epistaxis in 70% of patients, compared to a 31% success rate in those who received anterior packing alone.[11] There were no adverse events. Topical use of injectable tranexamic acid may prove to be a valuable procoagulant.

ANTERIOR NASAL PACKING

Anterior nasal packing can be placed if direct pressure, vasoconstrictors, or chemical cautery are unsuccessful in controlling epistaxis and if thrombotic foams and gels are not available. A variety of nasal balloons or sponges are available, or an anterior pack created by layering ribbon gauze in the nasal cavity can be used.

ANTERIOR EPISTAXIS BALLOONS

Anterior epistaxis balloons (Rapid Rhino®) are easy to use and more comfortable for the patient than layered strip gauze or nasal sponges. Anterior epistaxis balloons are available in different lengths and are coated with cellulose or other materials that promote platelet aggregation. Soak the balloon with water, insert it gently along the floor of the nasal cavity, and inflate slowly with air until the bleeding stops. Stop inflation if the patient develops discomfort. Do not inflate with saline; if a saline-filled balloon ruptures, aspiration could result. Read specific insertion instructions for each product before use. If there is a drawstring at the distal end, tape the drawstring to the face to secure the balloon in place.

PREFORMED NASAL TAMPONS OR SPONGES

Preformed nasal tampons or sponges are made of synthetic material that expands after hydration (**Figure 244-3**). These devices are commercially available in 5- and 10-cm lengths, for anterior and posterior packing, respectively. One product is Merocel®, a compressed dehydrated polyvinyl acetate sponge. Coat the sponge with water-soluble antibiotic ointment and insert it gently along the floor of the nasal cavity. If the tampon has not expanded within 30 seconds of placement, gently irrigate it (while in place) with 5 mL of normal saline to promote expansion. An alternative method is to cut the Merocel® pack lengthwise in two equal halves, and coat each half with lubricating ointment. Insert the two halves parallel to each other and parallel with the nasal septum; irrigate each half with about 2 mL of normal saline. This method may provide better compression of septal bleeding.[12] Whichever method is used, tape the drawstring to the face (Figure 244-3) to secure the tampon in place and prevent inadvertent aspiration. Merocel® nasal packs work effectively but sometimes cause more pain than balloons with removal.[13]

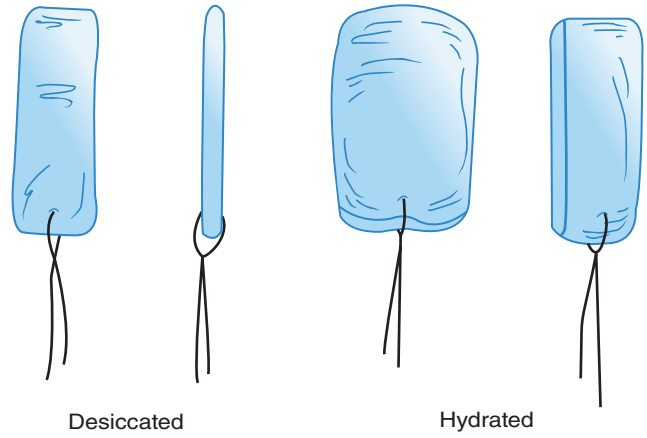

FIGURE 244-3. The Merocel® nasal sponge in its desiccated (*left*) and hydrated (*right*) forms.

RIBBON GAUZE PACKING

If the preceding devices are unavailable, ribbon gauze packing can be placed to control epistaxis (**Figure 244-4**).

POSTERIOR NASAL PACKING

Failure to control hemorrhage after direct pressure, optimal use of vasoconstrictors, cautery, and anterior packing suggests (but is not diagnostic of) posterior bleeding. Bilateral anterior packing may help augment tamponade of the nasal septum. If that is not successful, the previously mentioned devices are usually available in longer lengths to provide posterior packing. If longer posterior-length packs do not work, ear, nose, and throat (ENT) consultation and assistance are needed. Posterior packing is associated with higher complication rates, including pressure necrosis, infection, hypoxia, and cardiac dysrhythmias, especially in patients with underlying cardiopulmonary disease, and thus, posterior packing is generally applied as a temporizing measure while awaiting ENT support. A formal nasal block may be required for analgesia, as posterior packing is often quite uncomfortable for the patient, but topical anesthesia may be sufficient if applied properly. The Rapid Rhino® has both an anterior (5.5 cm) and posterior (7.5 cm) balloon that can be inflated as required to tamponade bleeding. **Figure 244-5** shows the placement of a dual balloon catheter. All posterior packing should be accompanied by an anterior pack.

If resources are limited, a satisfactory posterior pack can be achieved using a 14-French Foley catheter. The procedure is as follows. Place the patient in "sniffing position," and anesthetize the nasal mucosa by placing three cotton pledgets soaked in a 1:1 mixture of 4% lidocaine solution and 0.05% oxymetazoline intranasally for 5 minutes. Consider cutting off the Foley tip beyond the balloon as the tip may stimulate the gag reflex. Lubricate the distal third of the catheter with lidocaine gel, and advance the Foley catheter along the floor of the nasal cavity until the end is visualized in the posterior oropharynx. Inflate the balloon with 7 mL of air, and gently retract the catheter approximately 2 to 3 cm until it is lodged in the choanal arch of the posterior nasopharynx. Do not use saline for balloon insufflation because rupture could result in aspiration. If the balloon slides back into the nasal cavity, deflate the balloon, and advance the catheter as before. Inflate with 10 mL of air in total, and retract to secure the balloon. Avoid using more than 10 mL

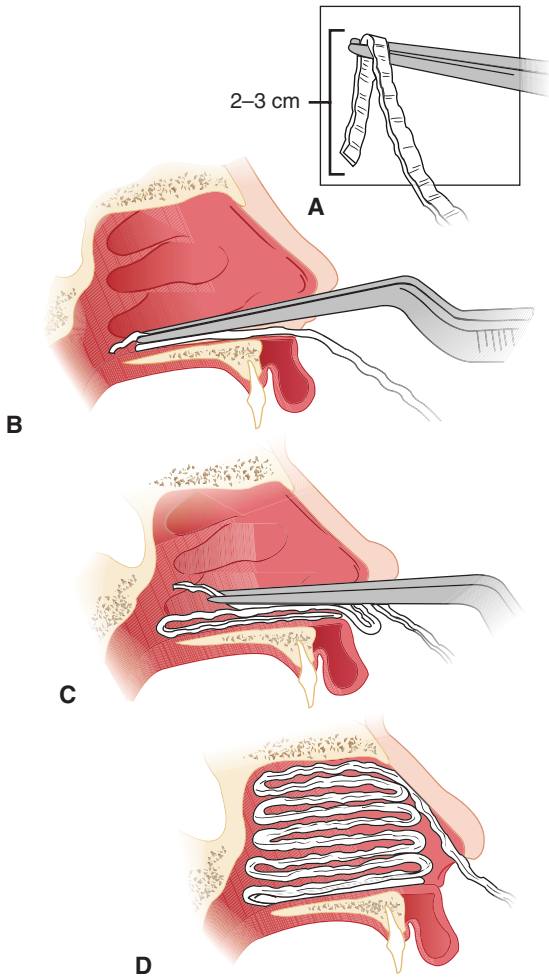

FIGURE 244-4. The key to placement of an anterior nasal pack that will control epistaxis adequately and stay in place is to lay the packing into the nasal cavity in an accordion-like manner so that part of each layer of packing lies anteriorly, preventing the gauze from falling posteriorly into the nasopharynx. **A.** The first layer of $^1/_4$-inch petrolatum-impregnated gauze strip is grasped approximately 2 to 3 cm from its end. **B.** The first layer is then placed on the floor of the nose through the nasal speculum (not pictured here). The bayonet forceps and nasal speculum are then withdrawn. **C.** The nasal speculum is reintroduced on top of the first layer of packing, and a second layer is placed in an identical manner. After several layers have been placed, it is often useful to reintroduce the bayonet forceps to push the previously placed packing down onto the floor of the nose, making it tighter and more secure. **D.** A complete anterior nasal pack can tamponade a bleeding point anywhere in the anterior nasal cavities and will stay in place until removed by the provider or patient.

of air to prevent risk of pressure necrosis. Secure the pack by taping the catheter to the patient's cheek.

In patients requiring posterior packing or in cases of uncontrolled anterior epistaxis, early ENT intervention reduces charges and length of stay.[14] Approximately 10% of patients admitted for epistaxis require invasive therapy; success is similar for arterial ligation or embolization, but cost and risk of stroke are higher for patients receiving embolization.[15]

DISPOSITION AND FOLLOW-UP

If hemorrhage is controlled and hemodynamic stability is ensured over a period of observation (1 hour or more in the ED), patients with anterior epistaxis can be discharged home with ENT follow-up within 48 hours ideally. Provide patients with instructions for simple techniques to control repeat hemorrhage, and consider prescription of inhaled vasoconstrictors such as oxymetazoline for rebleeding. Patients

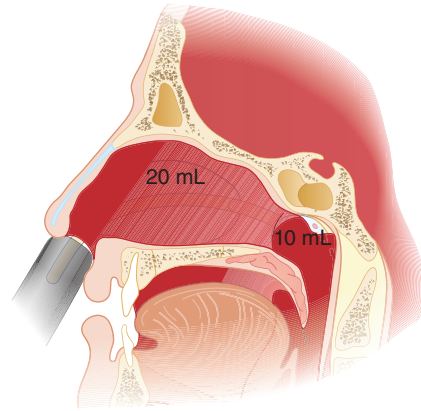

FIGURE 244-5. A dual balloon epistaxis catheter providing anterior and posterior compression. Overinflation of the posterior balloon may cause pressure necrosis; avoid using more than 10 mL.

on warfarin with INR levels in the desired range may continue medication. Discontinue nonsteroidal anti-inflammatory drugs for 3 to 4 days. If anterior packing with either absorbable or nonabsorbable material is going to be in place for more than 48 hours, an antibiotic with staphylococcal coverage such as amoxicillin-clavulanic acid has been traditionally recommended to prevent infection with *Staphylococcus aureus* and possible associated toxic shock syndrome.[16] However, benefit is not clear.[17,18] If the packing will be removed in 24 to 36 hours, prophylactic antibiotics may not be needed.[16] Consider potential drug interactions that may increase bleeding.[19] Instruct the patient to follow-up with ENT or return to the ED in 2 to 3 days for removal of nonbiodegradable packing. If the patient requires posterior packing, admission is strongly advised to monitor for complications.

NASAL FRACTURES AND SEPTAL HEMATOMA

ANATOMY

The nasal pyramid is formed by two rectangular-shaped bones that articulate with the frontal bone, the frontal process of the maxilla, and the perpendicular plate of the ethmoid to form a "tent-like" configuration (**Figures 244-6 and 244-7**). A large proportion of the structural integrity is maintained by a cartilaginous framework of the nasal septum, lateral processes, and medial and lateral crura of the alar cartilages (**Figure 244-8**).

CLINICAL FEATURES

Determine the mechanism of injury to evaluate the potential location of displaced bony fragments and to assess other associated pathology, especially head and neck injury. Assess the midface, zygomatic arch, orbits, sinuses, teeth, and cervical spine. Naso-orbital-ethmoid injuries are characterized by a broad, flattened nasal bridge with increased intercanthal distance (**Figure 244-9**). Malocclusion and palatal instability suggest Le Fort's fracture (see chapter 255, "Trauma to the Face").

NASAL EXAMINATION

After a general exam, perform an examination of the nose to include an external assessment for bony crepitus, deformity, and edema (**Figure 244-10**). Periorbital ecchymosis in the absence of other findings of orbital injury is suggestive of nasal fracture.[6] Profuse epistaxis may also suggest nasal fracture. Nasal bone mobility, which is virtually diagnostic of fracture, is appreciated by grasping the dorsum of the nose between the thumb and index finger and attempting to rock the nasal

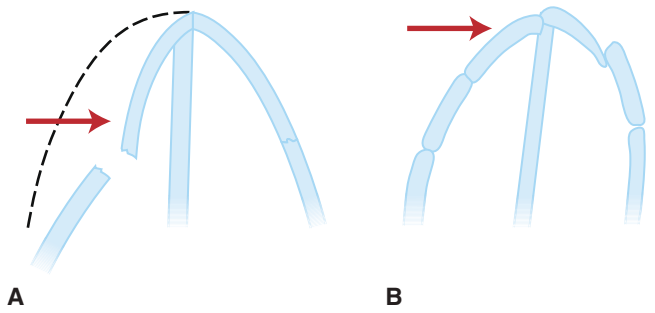

FIGURE 244-6. A and B. Lateral impact nasal injury. [Reproduced with permission from Reichman EF, Simon RR: *Emergency Medicine Procedures*. © 2004, Eric F. Reichman, PhD, MD, and Robert R. Simon, MD.]

pyramid back and forth.[6] Perform anterior rhinoscopy after obtaining a relatively bloodless field with topical vasoconstrictors and evacuation of clots. Key components of the internal examination should include assessment for mucosal lacerations, septal fractures or deviation, and septal hematoma.

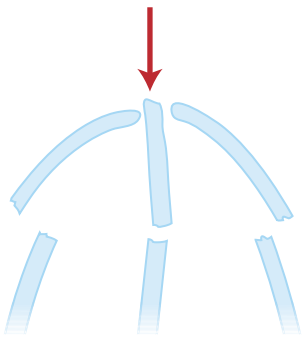

FIGURE 244-7. Frontal impact nasal injury. [Reproduced with permission from Reichman EF, Simon RR: *Emergency Medicine Procedures*. © 2004, Eric F. Reichman, PhD, MD, and Robert R. Simon, MD.]

DIAGNOSIS AND IMAGING

The diagnosis of nasal fracture is clinical, and radiologic confirmation of isolated nasal fracture is not required. The results of plain films rarely change management.[20,21] The indications for closed reduction are limited to alleviation of nasal obstruction and correcting deformity to improve cosmesis. These indications are best evaluated clinically at the bedside and usually are not emergency procedures.[20] Ultrasonography is an alternative to plain radiographs for the diagnosis of nasal fractures and has sensitivities and specificities similar to plain radiography[22-24] (**Figures 244-11 and 244-12**). CT scanning is not needed for isolated nasal fractures and is best reserved when there is concern for intracranial injury or other facial fractures.[25]

TREATMENT

The main priority is the exclusion of other associated traumatic injuries (see chapter 255) and nasal septal hematoma (see septal hematoma section below). Nasal fractures with overlying lacerations should be treated similarly to other open fractures. Concern for cerebrospinal fluid rhinorrhea or otorrhea requires further imaging and otolaryngologic or neurosurgical consultation. Nasal fractures in children should be referred to an ENT specialist within 2 to 4 days to account for rapid healing in children.[6]

Once serious injury is excluded, the management of uncomplicated nasal fractures is dictated by the timing of the examination in relation to the injury and ability to evaluate for significant displacement of the nasal pyramid. Early in the course, significant soft tissue swelling may obscure an adequate physical examination. If the patient presents immediately after the injury event, there may be opportunity to reduce a displaced nasal fracture before edema distorts the landmarks. Otherwise, it is prudent to recommend ENT consultation for an elective closed reduction within 6 to 10 days of the initial insult. Because of the development of fibrous connective tissue along the fracture line, failure to perform an adequate reduction within this time frame may result in an unacceptable cosmetic outcome and may ultimately require rhinoseptoplasty.[26] Most nasal fractures do not require immediate intervention and can be managed at ENT follow-up within the specified time frame of 6 to 10 days. Closed reduction is best left to the ENT specialist.

NASAL SEPTAL HEMATOMA

Vascular supply to the septal cartilage is provided through the perichondrium. A hematoma lifts the perichondrium, disrupting blood

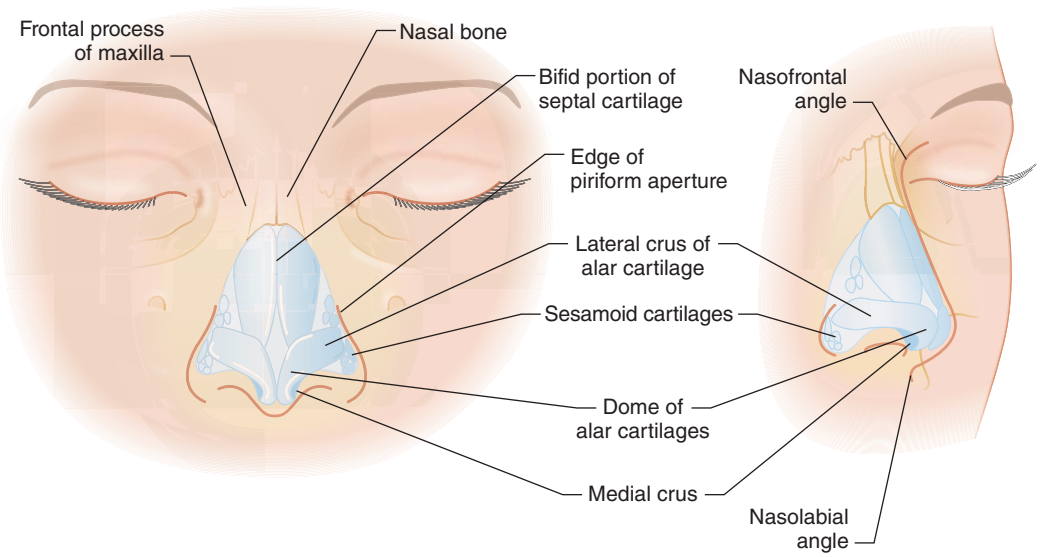

FIGURE 244-8. The nasal cartilages and the keystone area where they articulate with the nasal bones. [Reproduced with permission from Reichman EF, Simon RR: *Emergency Medicine Procedures*. © 2004, Eric F. Reichman, PhD, MD, and Robert R. Simon, MD.]

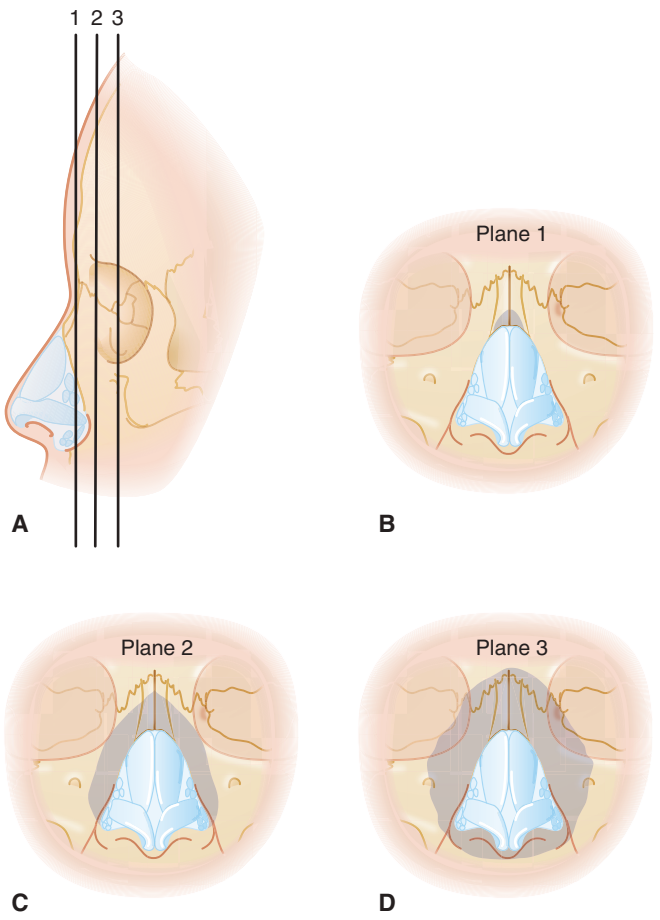

FIGURE 244-9. A through D. Stranc and Robertson classification of frontal impact injury. Plane 3 injury results in naso-orbital-ethmoid disruption.

supply to the cartilage. If a septal hematoma is identified, incise and drain the hematoma urgently to avoid ischemic necrosis of the nasal septum (**Figures 13 and 14**). Necrosis can lead to saddle deformity and nasal obstruction, ultimately requiring rhinoseptoplasty. Because pooled, clotted blood is a nidus for infection, unidentified septal hematomas can develop into abscesses. Systemic symptoms developing after facial trauma should prompt investigation for nasal septal abscess, and any suspicion should prompt ENT referral, urgent surgical drainage, and IV antibiotics to avoid serious complications. Untreated infected hematomas not only increase risk for saddle deformity and a poor functional outcome but can also spread contiguously, leading to osteomyelitis, cavernous sinus thrombosis, meningitis, and intracranial abscesses.[27]

DRAINAGE OF NASAL SEPTAL HEMATOMA

The procedure for incision and drainage of a nasal septal hematoma is as follows:

1. Place patient in "sniffing position," and be prepared to perform adequate anterior rhinoscopy with a nasal speculum, light source, suction, irrigation, and packing materials.
2. Properly anesthetize the nasal mucosa by placing three cotton pledgets soaked in a 1:1 mixture of 4% lidocaine solution for 5 minutes, followed by infiltrative anesthesia if required.
3. Although sterile technique cannot be fully achieved in the nasal cavity, use sterile instruments, and keep the operative area as clean as possible with irrigation of foreign debris.

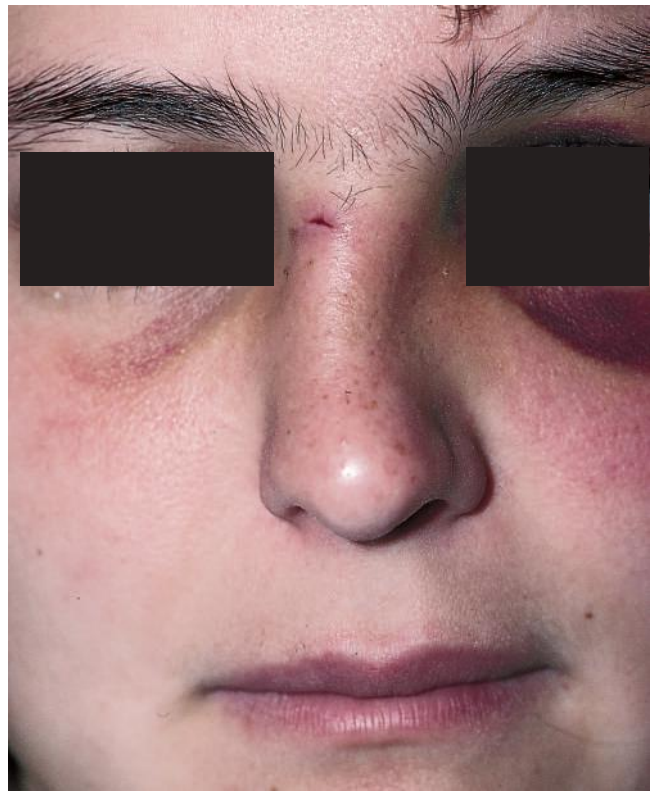

FIGURE 244-10. Nasal fracture clearly identifiable on physical examination with deformity and periorbital ecchymosis. [Photo contributed by David W. Munter. Reproduced with permission from Knoop K, Stack L, Storrow A, Thurman RJ: *Atlas of Emergency Medicine,* 3rd ed. © 2010, McGraw-Hill, New York.]

4. While obtaining adequate visualization of the hematoma with the nasal speculum, make a small horizontal incision superficially through the mucosa, making sure you do not incise the cartilaginous septum.
5. Evacuate the clot with Frazier suction or with forceps.
6. Perform bilateral anterior nasal packing with nasal tampons coated in topical antibiotic ointment to prevent reaccumulation of the clot and keep the septum midline.
7. Discharge with 24-hour ENT of ED follow-up.[28] Some recommend the use of prophylactic antibiotics for patients with packing in place, but this is not necessary if the packing will be removed in 24 to 36 hours.

NASAL FOREIGN BODIES

Although nasal foreign bodies are most common in children (see chapter 117, "Nose and Sinus Disorders in Infants and Children"), they should also be considered in psychiatric and mentally retarded adults.[29,30] Morbidity of undiagnosed nasal foreign bodies includes aspiration, infection, pressure necrosis, or perforation. Consider a nasal foreign body in patients with purulent unilateral nasal discharge or recurrent unilateral epistaxis. It is important to recognize button battery impaction because it may cause liquefaction necrosis and septal perforation.[31] Plain radiography is a potential tool for foreign body identification, but many objects are not radiopaque.[32] Nasal foreign body removal is discussed in the Pediatric Section, "The Nose and Sinuses."

SINUSITIS AND RHINOSINUSITIS

Sinusitis is inflammation of the mucosal lining of the paranasal sinuses. There are six nasal sinuses: two maxillary and two frontal sinuses, and a single ethmoid and frontal sinus. Rhinosinusitis is defined as an inflammation of the paranasal sinuses and the nasal cavity. The term *rhinosinusitis* is preferred because sinusitis is almost always accompanied by rhinitis.[33] Depending on the duration of the disease, rhinosinusitis is classified into acute (<4 weeks), subacute (4 to 12 weeks), or chronic (>12 weeks).[34-36]

PATHOPHYSIOLOGY

All six paranasal sinuses are coated by respiratory mucociliary epithelium, and the sinuses drain through the ostia into the nose. Any type of acute inflammation of the mucosa leads to obstruction of the ostia, accumulation of secretions within the sinuses, and reabsorption of air, resulting in negative pressure in the sinuses and clinical symptoms. Acute rhinosinusitis, like otitis media, is usually viral. *Haemophilus influenzae* and *Streptococcus pneumoniae* are the usual organisms in acute bacterial rhinosinusitis.[37] Chronic infections are usually due to anaerobes, gram-negative bacteria, *Staphylococcus aureus*, and, occasionally, fungi, especially in the immunocompromised.[35]

CLINICAL FEATURES

Acute rhinosinusitis is defined by two or more of the following symptoms: blockage or congestion of the nose, facial pain or pressure, diminished ability to smell or detect odors, and either anterior or posterior nasal discharge, for 7 days to 4 weeks. Additional symptoms can include tooth pain, fever, or sinus pressure while bending forward or changing head position.[35] On physical examination, the patient may have pain and tenderness over the sinuses with percussion. Inspect the face for swelling and redness, and inspect the nose for mucosal swelling, anatomic abnormality, and foreign bodies. Also perform a neurologic examination, and examine the ears, eyes, and

teeth to evaluate for extension of disease. Subacute and chronic sinusitis persist for 4 weeks or more.

DIAGNOSIS

The diagnosis of uncomplicated **acute rhinosinusitis** is clinical.[37] Plain sinus radiographs or CT scans are not needed. The symptoms of acute rhinosinusitis are similar to a common cold or viral upper respiratory infection, but symptom duration ranges from 7 days to up to 12 weeks.[37] CT scans are helpful to diagnose complications in a toxic patient or to evaluate for intracranial extension. The differential diagnosis of rhinosinusitis includes migraine headache, craniofacial neoplasm, foreign body retention, and dental caries.

TREATMENT

The treatment for **acute uncomplicated rhinosinusitis** is generally supportive. Nasal saline irrigation alone, or in conjunction with other adjunctive measures like nasal decongestants, may decrease symptom severity.[34] Restrict the use of topical decongestants like oxymetazoline to approximately 3 days to avoid rebound mucosal congestion or edema (rhinitis medicamentosa). Topical (intranasal spray) corticosteroids may shorten the duration of illness.[38]

In a 2014 Cochrane database systematic review analyzing the efficacy of antibiotic therapy, the authors concluded that antibiotics may provide a small treatment effect in patients with symptoms of rhinosinusitis lasting >7 days.[33] However, because 80% of patients treated with placebo also improved within 2 weeks, it is unclear whether the treatment effect is clinically significant. In general, **antibiotics should be reserved for patients with purulent nasal secretions and severe symptoms for ≥7 days.** If antibiotics are prescribed, amoxicillin is recommended as first-line therapy for most adults,[37] at a dose of 500 milligrams PO three times per day. Patients with penicillin allergies may receive macrolide antibiotics or trimethoprim-sulfamethoxazole.[37] For patients who have received antibiotics within the past 4 to 6 weeks, consider a fluoroquinolone or high-dose amoxicillin-clavulanate.[34] Use caution in selection of antibiotics in patients who are on oral anticoagulation.[19] In the aforementioned Cochrane review, comparisons between different classes of antibiotics showed no significant difference.[33] Follow-up with a primary care provider is advised.

Patients with **subacute, chronic or recurrent rhinosinusitis** should be evaluated for conditions that modify management, such as allergy, cystic fibrosis, or immunocompromise. Outpatient noncontrasted CT of the sinuses can evaluate for invasion of neighboring tissues and neoplasms.[34] Bacterial cultures may be helpful to tailor therapy in outpatients who are at risk for multidrug-resistant organisms. ENT follow-up is advised.[37,39]

COMPLICATIONS

Complications of rhinosinusitis are mostly related to extension of the infection beyond usual anatomic boundaries. Meningitis, cavernous sinus thrombosis, and intracranial abscesses are rare but important complications associated with contiguous spread of sinus disease. Up to 75% of cases of orbital cellulitis, which can lead to blindness through venous congestion and ischemia of the optic nerve, are attributable to disease of the sinuses.[37] Frontal sinusitis can lead to osteomyelitis of the frontal bone with a doughy swelling of the forehead called *Pott's puffy tumor*, and can also be associated with an extradural or subdural empyema. In general, patients with these deeper infections usually appear systemically ill or have focal neurologic signs and require admission and IV antibiotics.

CHAPTER 245

Oral and Dental Emergencies

Ronald W. Beaudreau

ORAL AND DENTAL ANATOMY

The normal adult dentition consists of 32 permanent teeth. The adult dentition has four types of teeth: 8 incisors, 4 canines, 8 premolars, and 12 molars. The primary or deciduous dentition consists of 20 teeth of three types: 8 incisors, 4 canines, and 8 molars. **Figure 245-1** shows the

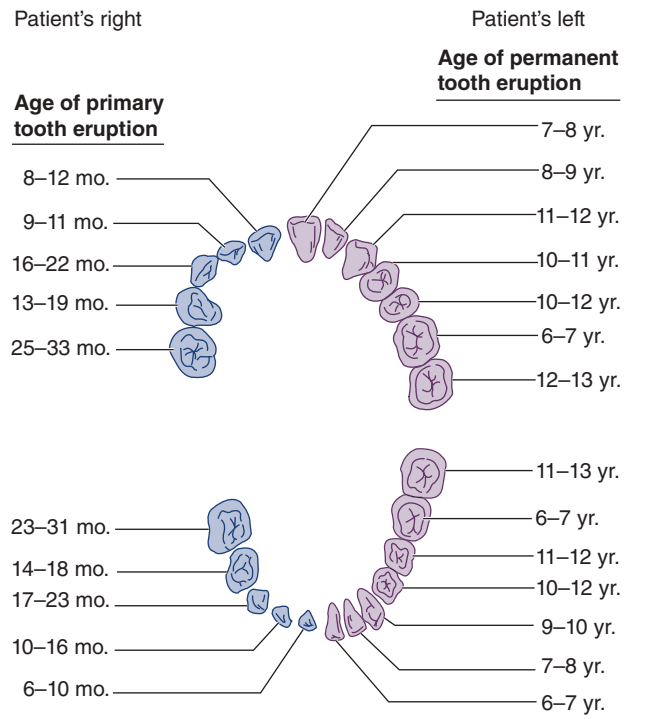

FIGURE 245-1. Normal eruptive patterns of the primary and permanent dentition. mo. = month; yr. = years.

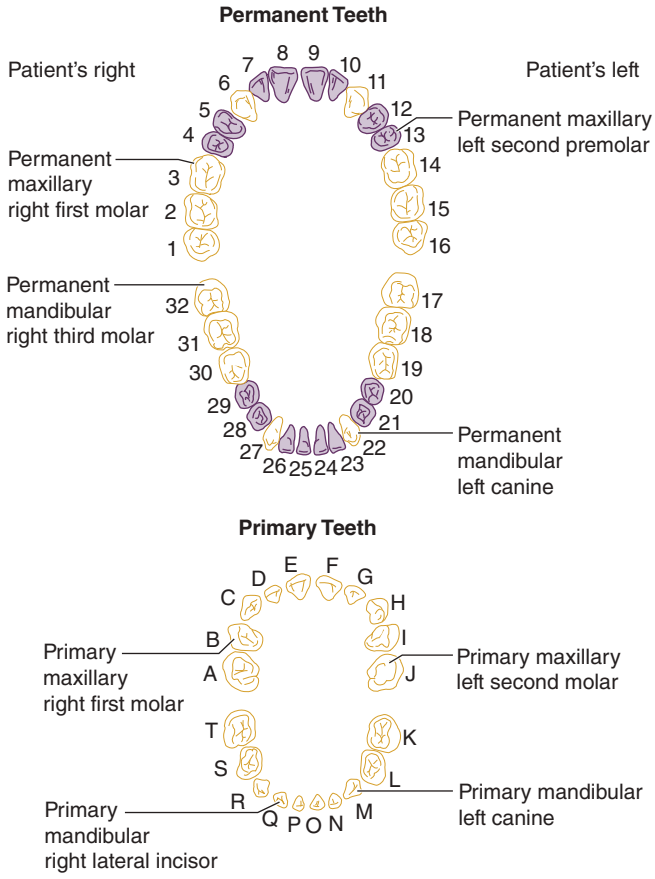

FIGURE 245-2. Identification of teeth.

eruptive pattern of both the primary and permanent dentition. **Figure 245-2** illustrates the most commonly used tooth numbering system; however, description of the tooth type and location is also appropriate.

ANATOMY OF THE TEETH

A tooth consists largely of *dentin,* which surrounds the *pulp*, the tooth's neurovascular supply (**Figure 245-3**). Dentin is a homogeneous material produced by pulpal odontoblasts throughout life. Dentin is deposited as a system of microtubules filled with odontoblastic processes and extracellular fluid. The *crown*, or the visible portion of tooth, consists of a thick *enamel* layer overlying the dentin. Enamel, the hardest substance in the human body, consists largely of hydroxyapatite and is produced by ameloblasts before eruption of the tooth into the mouth. The *root* portion of the tooth extends into the alveolar bone and is covered with a thin layer of *cementum.*

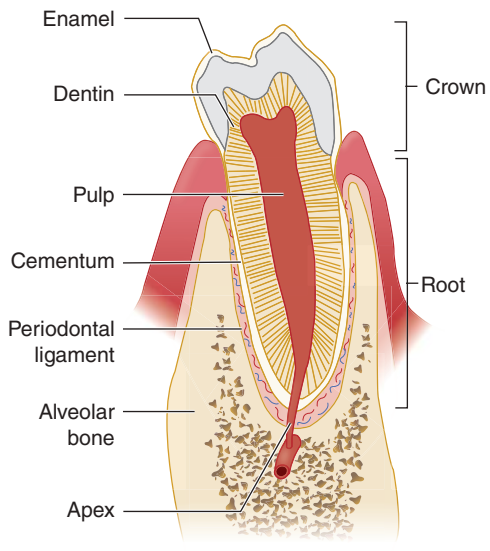

FIGURE 245-3. The dental anatomic unit and attachment apparatus.

THE NORMAL PERIODONTIUM

The periodontium, or attachment apparatus, is essential for maintaining the integrity of the dentoalveolar unit. The attachment apparatus consists of a gingival component and a periodontal component. The gingival component includes the junctional epithelium, gingival tissue, and gingival fibers and primarily functions to maintain the integrity of the periodontal component. The periodontal component includes the periodontal ligament, alveolar bone, and cementum of the root of the tooth and forms the majority of the attachment apparatus. Disease states such as gingivitis and periodontal disease weaken and destroy the attachment apparatus, resulting in tooth mobility and tooth loss.[1]

Gingival tissue is keratinized stratified squamous epithelium. It can be divided into the free gingival margin and the attached gingiva. The free gingiva is the portion that forms the 2- to 3-mm-deep *gingival sulcus* in the disease-free state. The attached gingiva adheres firmly to the underlying alveolar bone. The nonkeratinized alveolar mucosa extends from the attached gingiva to the vestibule and floor of the mouth. The mucosal tissue of the cheeks, lips, and floor of the mouth is also comprised of nonkeratinized squamous epithelium.

OROFACIAL PAIN

Table 245-1 lists common causes of orofacial pain. Pain of dental origin may be diffuse in nature, presenting as a headache, sinus pain, eye pain, or jaw or neck pain, or may be localized to a single tooth. Remember to consider myocardial infarction as a cause of jaw pain.

Examine the soft tissue using a tongue depressor to expand your view looking specifically at the inner lips, the buccal and labial mucosa, the hard and soft palate, and the tongue and floor of the mouth. Ask the patient to extend the tongue, and gently grasp it with a piece of dry gauze, further extending it to the right and to the left, to expose each base. The floor of the mouth should be palpated with a finger in the mouth and one externally under the chin to check for a mass or lesion. Examine the teeth visually, and then gently percuss the suspected teeth with a firm clean object to determine if a specific tooth is the source of pain. After trauma, test for mobility and tenderness with gentle pressure and percussion. Assure that all the teeth occlude as normal for the patient. The degree of opening of the mouth should be evaluated. Palpate for potential fractures of the mandible of maxilla. Finally, the temporomandibular joint should be evaluated by placing your index fingers in the ears and feeling for crepitance or popping while the mandible is fully opened and closed.

PAIN OF ODONTOGENIC ORIGIN

Tooth Eruption and Pericoronitis Discomfort is commonly associated with the eruption of primary or deciduous teeth in infants. Irritability, drooling, and decreased intake are commonly associated findings. Approximately 11% to 12% of teething infants will have a mildly elevated temperature when examined in a doctor's office, but a cause-and-effect relationship between teething and fever has never been demonstrated.[2] Eruption of permanent teeth, especially third molars, or *wisdom teeth,* may cause pain. Gingival irritation and inflammation associated with tooth eruption are common and must be distinguished from *pericoronitis.* Pericoronitis is inflammation of the *operculum*, or the gingival tissue, overlying the occlusal surface of an erupting tooth. Impaction of food and debris beneath the operculum results in a severe inflammatory response. Without intervention, this progressive inflammatory process

TABLE 245-1 Differential Diagnosis of Orofacial Pain

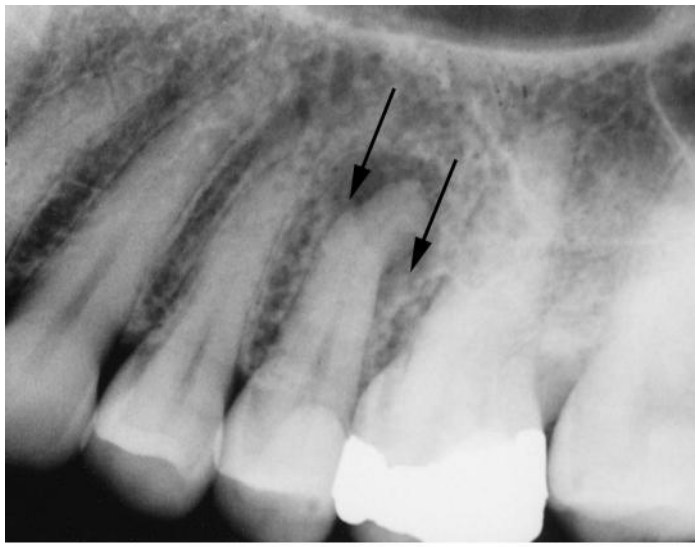
Nontraumatic Causes of Potential Dental Pain	
Odontogenic origin	
Tooth eruption	Cracked tooth syndrome
Pericoronitis	Periradicular periodontitis
Dental caries	Periapical abscess/facial space infection
Dentinal sensitivity/cervical erosion	Postextraction discomfort
Reversible pulpitis	Postextraction alveolar osteitis
Irreversible pulpitis	Post-restorative pain
Periodontal pathology	
Gingivitis	Periodontal abscess
Periodontal disease	Acute necrotizing gingivostomatitis
Gingival abscess	Peri-implantitis
Neurogenic/neurophysiologic syndromes	
Trigeminal neuralgia	Bell's palsy
Other cranial neuralgias	Temporomandibular disorder
Nondental infections	
Oral candidiasis	Hand-foot-and-mouth disease
Herpes simplex types 1 and 2	Sexually transmitted infections
Varicella-zoster, primary and secondary	Herpangina
Mumps	Sinusitis
Sialadenitis	Parotitis
Malignancies	
Squamous cell carcinoma	Leukemia
Kaposi's sarcoma	Melanoma
Lymphoma	Graft-versus-host disease
Other etiologies	
Aphthous ulcers	Pyogenic granuloma
Traumatic ulcers	Lichen planus
Stomatitis and mucositis	Cicatricial pemphigoid
Uremia	Pemphigus vulgaris
Vitamin deficiency	Erythema multiforme
Radiation/chemotherapy related	Crohn's disease
Benign migratory glossitis	Behçet's syndrome
Orofacial Trauma	
Dental fractures	Alveolar ridge fractures
Subtle enamel cracks/infractions	Facial bone fractures
Dental crown and/or root fractures	Oral soft tissue lacerations
Dental luxations and avulsions	

will result in localized infection. Because of the close proximity of the masticator space (comprised of the masseteric space, pterygomandibular space, and the superficial and deep temporalis space) to third molars, this infection can cause trismus. If the infection spreads into the connecting parapharyngeal spaces, it can be life threatening. Treatment of mild to moderate pericoronitis without associated systemic symptoms consists of appropriate antibiotic therapy such as penicillin VK, 500 milligrams PO four times a day, or clindamycin, 300 milligrams PO four times a day; local irrigation of food and debris from underneath the operculum; saline mouth rinses; and analgesia with nonsteroidal anti-inflammatory drugs (NSAIDs) and opiates as appropriate. More severe cases may require IV antibiotics and admission. If pericoronitis is related to trauma from an opposing tooth during mastication, as is frequently the case with third molars, antibiotics and extraction of the opposing tooth will bring marked relief within 24 hours. For outpatient management, referral to a general dentist or an oral and maxillofacial surgeon within 24 to 48 hours is appropriate.[3]

Dental Caries and Pulpitis *Dental caries* is the loss of integrity of the tooth enamel from hydroxyapatite dissolution by prolonged exposure to the acidic metabolic by-products of plaque bacteria. Caries most commonly occurs in areas where plaque accumulates such as pits and fissures of the occlusal surface, interproximally, and along the gingival margins. When a sufficient breach of enamel integrity occurs and the dentin is involved, caries spreads along dentinal microtubules. Direct communication between the oral environment and the vital dental pulp is established, and sensitivity to cold or sweet stimulus may result.

The pulpal inflammatory process is initially reversible, but with continued stimuli, the pulp's ability to respond and repair is compromised. *Irreversible pulpitis* can be distinguished from *reversible pulpitis* by the duration of symptoms. In reversible pulpitis, the duration of pain is short, lasting seconds, as compared with irreversible pulpitis, in which the pain may last for minutes to hours. The most common stimulus is heat or cold, although sweet or sour stimuli also can elicit pain. Spontaneous tooth pain usually represents *pulpal necrosis* and is treated with analgesia; penicillin VK, 500 milligrams PO four times a day, or clindamycin in penicillin-allergic patients; and referral to a general dentist. Antibiotics for dental pain are controversial; two systematic reviews have concluded there is there is insufficient evidence to determine whether antibiotics for irreversible pulpitis reduce pain[4,5] if there is no obvious infection. The use of local anesthetics as discussed in this chapter's section on dental local anesthesia techniques can greatly reduce symptoms and should be considered for short-term pain management. The definitive treatment for irreversible pulpitis and pulpal necrosis is root canal therapy or dental extraction.

Cracked Tooth Syndrome *Cracked tooth syndrome* is an incomplete fracture of a tooth that may extend into the vital pulp. Molars are most commonly affected. The patient experiences sharp pain on chewing that resolves when chewing ceases. Cold and sweet stimuli may also evoke pain. NSAIDs are frequently effective at temporarily controlling pain.[3] The patient should avoid chewing on the affected side and see a dentist for definitive treatment.



Periradicular Periodontitis Acute *periradicular periodontitis* is the extension of pulp disease, inflammation, or necrosis into the tissues surrounding the root and apex of the tooth (deepest portion of the tooth socket). Occasionally it can be due to occlusal trauma. Periradicular lesions appear as a slight widening of the periodontal ligament space, a thinning of the lamina dura, or a radiolucent area associated with the root apex on a periapical dental radiograph. A Panorex is rarely useful for identification of all but the most extensive periradicular lesions, but can be important in identifying other painful osseous pathology (**Figure 245-4**).

Pain on percussion of the suspected tooth with a light metal instrument, such as a handle of a dental mirror, helps to identify the offending tooth. Radiographically and clinically indistinguishable from periradicular periodontitis, a *periapical abscess* by definition contains a collection of pus. A small swelling of the gingiva with a draining fistula adjacent to the affected tooth is known as a *parulis*, and can help identify the involved tooth (**Figure 245-5**). If a dental abscess erodes through the cortical bone but does not drain spontaneously, then subperiosteal extension results in intraoral or facial swelling and fluctuance that should be incised and drained. Treat dental abscesses or other periapical lesions with penicillin VK, 500 milligrams PO four times a day, or clindamycin, 300 milligrams PO four times a day, and analgesia with an NSAID or opiate. Refer to a dentist for definitive treatment.

Facial Space Infections Spread of odontogenic infections into the various facial spaces is relatively common. Buccal extension of a periapical infection of the mandibular teeth will involve the buccinator space. Maxillary labial extension of infection primarily will involve the infraorbital space. Perforation through the lingual cortical bone of mandibular molars, particularly the second and third molars, usually occurs below the mylohyoid ridge and involves the submandibular space. Lingual spread of periapical infections associated with mandibular anterior teeth will affect the lingual space. The submandibular space and lingual space communicate with each other at the posterior border of the mylohyoid muscle. Cellulitis of bilateral submandibular spaces and the lingual space is called **Ludwig's angina** and is potentially life threatening. As

A

B

FIGURE 245-4. The radiographic appearance of a healthy tooth with a normal periodontal ligament space and distinct lamina dura (**A**) compared with the radiographic appearance of periapical radiolucency (*arrows*) consistent with periradicular periodontitis, a periapical abscess, or periradicular cyst (**B**). [Image used with permission of Gary M. Beaudreau.]

FIGURE 245-5. A parulis (*arrow*) superior to the maxillary molar. [Image used with permission of David E. Beaudreau.]

these spaces and the masticator space communicate directly with the parapharyngeal space, airway compromise is the immediate concern. For detailed discussion, see chapters 243, "Face and Jaw Emergencies" and 246, "Neck and Upper Airway."

Infection of the infraorbital space may have a potentially devastating outcome if retrograde spread through the ophthalmic veins occurs and the cavernous sinus becomes involved. **Cavernous sinus thrombosis** presents as an infraorbital or periorbital cellulitis with rapidly developing meningeal signs, sepsis, and coma. Early recognition and treatment with a high-dose IV antibiotic, as above, are essential in decreasing morbidity and mortality.

Postextraction Pain Immediate postoperative pain is most commonly related to the trauma of surgery. Postoperative edema, such as with extraction of third molars, peaks within the first 24 to 48 hours and is best managed with ice packs, elevation of the head of the bed to 30 degrees, NSAIDs, and oral narcotics. Trismus, common immediately after extraction, can result from direct injury to the temporomandibular joint, injury to the muscles of mastication during administration of the inferior alveolar nerve block or during the surgery, and, most commonly, normal perioperative inflammation. Trismus peaks in the first 24 hours and usually decreases thereafter unless infection develops. Progressively worsening trismus is concerning for a postoperative infection.

Postextraction Alveolar Osteitis (Dry Socket) *Postextraction alveolar osteitis*, or **dry socket**, usually occurs on the second or third postoperative day and is associated with exquisite oral pain. Total or partial displacement of the clot from the socket or fibrinolytic dissolution of the clot results in exposure of the alveolar bone and initiates a localized osteomyelitis of the exposed bone. Risk factors for developing postextraction alveolar osteitis include smoking, preexisting pericoronitis or periodontal disease, a traumatic extraction, a prior history of alveolar osteitis, and hormone replacement therapy.[6] The incidence of postextraction alveolar osteitis is 1% to 5% of all extractions but is considerably higher (up to 30%) among impacted third molar extractions.[6,7]

Treatment is gentle irrigation of the socket with warmed normal saline or chlorhexidine 0.12% oral rinse.[6-9] Local dental anesthesia (see the section on dental local anesthesia techniques) or topical anesthesia may be needed. Management of pain with NSAIDs or opiate medication is necessary. Antibiotic therapy with penicillin VK, 500 milligrams PO four times a day, or clindamycin, 300 milligrams PO four times a day, is reserved for the most severe cases. Refer for dental follow-up.[6-9]

Postextraction Bleeding Postextraction bleeding is not uncommon. Displacement of the clot may result in recurrent or continued bleeding. Generally, firm pressure applied to the extraction site is adequate to control bleeding. This is best accomplished by folding a 2 × 2-inch gauze pad and placing it over the extraction site and applying firm pressure by clenching with the opposing teeth. Pressure must be held firmly, not a chewing action, for 20 minutes or until hemostasis is complete. If direct pressure is not successful, then apply an absorbable gelatin sponge (Gelfoam®, Pfizer Inc., New York, NY), microfibrillar collagen (Avitene®, Davol, Inc., Warwick, RI), or regenerated cellulose (Surgicel®, Ethicon, Inc., Somerville, NJ) into the socket to provide a matrix for clot formation. Sutures can be used for holding such agents in place or to loosely close the gingiva over the socket. **Do not suture the gingiva tightly because this may cause necrosis of the gingival flap.** If this is not successful, careful injection of the soft tissue surrounding the extraction with lidocaine with epinephrine may control the bleeding. Careful cautery with silver nitrate can also be useful. If these methods are unsuccessful, then oral and maxillofacial surgical consultation is necessary.

Postrestorative Pain Postrestorative pain can result from normal trauma from mechanical instrumentation of the tooth or direct exposure of the pulpal tissue during instrumentation. Pain associated primarily with mastication may be the result of improper occlusion of the new dental restoration or filling. After endodontic therapy, buildup of pressure in the pulpal chamber can cause severe pain. Provide NSAIDs or narcotic analgesia and refer to the patient's dentist. Temporary prolonged pain relief can also be obtained using 0.5% bupivacaine with epinephrine and the appropriate dental anesthetic block as discussed in the dental local anesthesia technique section of this chapter. Follow-up with the dentist the next day then should be possible.

Orthodontic Appliances The most common emergency is a broken or bent wire that is irritating or lacerating the cheek or lip. This wire needs to be bent back away from soft tissue. This can easily be accomplished with dental instruments, or something soft like a pencil eraser can be used to gently bend the wire. Cutting the wire is generally not indicated as it makes the end sharper. The broken portion of the wire can be removed in its entirety by removing the rubber ligatures from each orthodontic bracket, but this generally is not necessary. The patient should follow up as soon as possible with the orthodontist.

PERIODONTAL PATHOLOGY

Periodontal Disease Periodontal disease is a continuum of disease that begins with gingival inflammation and bleeding, or gingivitis, and can progress to destruction of the periodontal attachment apparatus, deepening of the normal gingival sulcus, periodontal pocket formation, bone loss, tooth mobility, and ultimately loss of teeth.[1] Besides oral hygiene, many factors including hormonal variations, medications, and systemic disease can also influence periodontal health.

Periodontal disease usually progresses painlessly but may present as swollen gingival tissue or gingival bleeding. Treatment is directed at slowing or arresting the progression of disease primarily by the removal of plaque and its by-products.[1] Antibiotics may play a role in treatment. Referral to a dentist for definitive treatment is indicated because the treatment involves extensive dental cleaning, instruction and improvement in oral hygiene, and in some cases, periodontal surgery.

Gingival and Periodontal Abscess A *gingival abscess* is an acutely painful swelling confined to the margin of the gingiva or interdental papilla. It usually rapidly enlarges over 24 to 48 hours, and purulent exudate can frequently be expressed from the orifice. The most common etiology is the entrapment of foreign matter such as a popcorn kernel, piece of meat, toothbrush bristle, or piece of food in the gingiva. Treatment includes identifying and removing the embedded foreign body and irrigating with normal saline. Continued home irrigation is beneficial, and symptoms resolve quickly.[3]

When plaque and debris are entrapped in the periodontal pocket, a *periodontal abscess* may form, resulting in severe pain. Small periodontal abscesses respond to local therapy with warm saline rinses and antibiotics such as penicillin VK, 500 milligrams PO four times a day, or clindamycin, 300 milligrams PO four times a day. Larger periodontal abscesses require incision and drainage. Chlorhexidine 0.12% mouth rinses twice daily are useful in the short term. Provide analgesia with NSAIDs or narcotics as indicated.[3]

Acute Necrotizing Ulcerative Gingivitis *Acute necrotizing ulcerative gingivitis* is an aggressively destructive process (**Figure 245-6**). Also known as *Vincent's disease* or *trench mouth*, it is part of a spectrum of disease ranging from localized ulceration of the gingiva to often fatal noma, in which localized ulceration and necrosis spread to the adjacent tissues of the cheeks, lips, and underlying facial bones.[10] The diagnostic triad includes pain, ulcerated or "punched out" interdental papillae, and gingival bleeding. Secondary signs include fetid breath, pseudomembrane formation, "wooden teeth" feeling, foul metallic taste, tooth mobility, lymphadenopathy, fever, and malaise.[3,10]

The differential diagnosis for acute necrotizing ulcerative gingivitis is quite extensive, but herpes gingivostomatitis is the most difficult to differentiate. Herpes gingivostomatitis usually has smaller vesicular eruptions, less bleeding, more systemic signs, and lack of interdental papilla involvement.[10]

The cause is still poorly understood. Acute necrotizing ulcerative gingivitis appears to be an opportunistic infection in a host with lowered resistance. Anaerobic bacteria such as *Treponema*, *Selenomonas*, *Fusobacterium*, and *Prevotella* invade otherwise healthy tissue, resulting in an aggressively destructive disease process.[10,11] The most important predisposing factor is human immunodeficiency virus infection. A previous episode of necrotizing gingivitis is the second most important predisposing factor. Other contributing factors include poor oral hygiene, unusual emotional stress, poor diet and malnutrition, inadequate sleep, Caucasian descent, age <21 years old, poor socioeconomic status, recent illness, alcohol use, tobacco use, acatalasia, and various infections such as malaria, measles, and intestinal parasites.[10,11]

Treatment consists primarily of bacterial control. Chlorhexidine 0.12% oral rinses twice a day, professional debridement and scaling, and adjunctive antibiotic therapy with metronidazole, 500 milligrams PO three times a day, are the mainstay of treatment. Reduction in pain can be expected within 24 hours of institution of this regimen. Identification and resolution of the predisposing factors and supportive therapy with a soft diet rich in protein, vitamins, and fluids are important in establishing and maintaining a disease-free state.[10,11]

Peri-Implantitis Osseointegrated dental implants have become common over the last 30 years, allowing for a dental implant to replace a tooth. However, as with any procedure, complications do occur, and problems related to implants may present to the ED. Pathologic changes around an implant are all given the general term of *peri-implant disease*. Patients who present with *peri-implantitis* present with a similar presentation to that of a periodontal abscess and require similar treatment. Gentle removal of the plaque and debris from around the implant and irrigation with normal saline or 0.12% chlorhexidine solution should be done. Antibiotic treatment with metronidazole, 500 milligrams PO three times a day for 10 days, or amoxicillin, 500 milligrams PO three times a day for 10 days, is indicated. Give analgesia as needed, and refer to a dentist for definitive care.[3]

FIGURE 245-6. Acute necrotizing ulcerative gingivitis. [Image used with permission of Philip J. Hanes.]

NEUROGENIC AND NEUROPHYSIOLOGIC SYNDROMES

Craniofacial Neuralgias *Trigeminal neuralgia* is the most common of the craniofacial neuralgias. Other significantly less common neuralgias of the craniofacial region include *glossopharyngeal neuralgia*, *vagal neuralgia*, and *superior laryngeal neuralgia* involving the respective nerve distributions. Post–herpes zoster–related neuralgia is also a cause of acute facial pain and may become chronic in nature. See chapter 165, "Headache" for further discussion.

Bell's Palsy (Idiopathic Facial Nerve Palsy) *Bell's palsy* is a peripheral unilateral weakness of the facial nerve of unknown etiology. As part of the differential diagnosis for orofacial pain, patients with a facial nerve palsy related to herpes zoster may present with nonspecific facial pain prior to the onset of weakness or the onset of any visible vesicles. In such cases, this diagnosis must be considered. See chapter 243 for a more extensive discussion on facial nerve palsy.

Temporomandibular Disorder *Temporomandibular disorder* is a common cause of facial pain and headache representing a group of signs and symptoms that involve the muscles of mastication or the temporomandibular joint. See chapter 243 for a more extensive discussion.

SOFT TISSUE LESIONS OF THE ORAL CAVITY

APHTHOUS STOMATITIS

Aphthous stomatitis, or ulceration, is one of the most common oral lesions, affecting 20% of the normal population (**Figure 245-7**). The cause appears to be a cell-mediated immune response to a yet unidentified triggering agent. Multiple factors predispose to aphthous ulcer formation: local trauma, stress, poor sleep, a hormonal imbalance, smoking, and certain foods such as chocolate, coffee, peanuts, cereals, almonds, strawberries, cheese, tomatoes, and gluten. Aphthous ulceration involves the nonkeratinized epithelium, especially the labial and buccal mucosa, and begins as an erythematous macule that ulcerates and forms a central fibropurulent eschar. Aphthous stomatitis occurs in a major and minor form. *Minor aphthae* usually measure from 2 to 3 mm to several centimeters in diameter, are painful, and frequently are multiple. They usually resolve spontaneously in 10 to 14 days. *Major aphthae* have larger, deeper ulcers that take significantly longer to heal. A third form, called *herpetiform aphthae*, has up to 100 ulcers, each 1 to 2 mm in diameter. They tend to coalesce, creating much larger ulcers that require 10 to 14 days to heal. Treatment is symptomatic but, in severe cases, may consist of topical corticosteroids such as Orobase® (Colgate Oral Pharmaceuticals, Canton, MA) or 0.01% dexamethasone elixir as a mouth rinse. Resolution typically occurs quickly after onset of therapy. Major aphthae are more resistant to therapy and may require intralesional steroid injection or systemic steroid therapy.[12,13]

HERPES ZOSTER AND OTHER INFECTIONS

Herpes zoster (see chapter 153, "Serious Viral Infections") frequently occurs along the distribution of the trigeminal nerve. Herpes zoster typically begins as a 1- to 4-day prodrome of exquisite pain in the area innervated by the affected nerve and may be mistaken for a simple headache or toothache. Vesicular eruptions characteristically occur unilaterally, do not cross the midline, and last 7 to 10 days. Isolated intraoral lesions can occur but are not common. Involvement of the ophthalmic branch of the trigeminal nerve requires urgent ophthalmologic consultation.

Other common infections such herpes simplex type 1 and 2, herpangina, hand-foot-and-mouth disease, and varicella-zoster cause painful ulcerative lesions of the oral cavity and perioral region. These conditions are adequately discussed in chapter 121, "Mouth and Throat Disorders in Infants and Children." Many sexually transmitted infections can affect the oral cavity. In general, the appearance of oral lesions is similar in appearance to that of their genital counterpart. Treatment of sexually transmitted diseases of the oral cavity is the same as for genital involvement. See chapter 149, "Sexually Transmitted Infections," for detailed discussion.

TRAUMATIC ULCERS

Traumatic ulcers are a result of direct trauma to epithelial tissue. Common sources of trauma include rough or jagged edges on teeth or restorations, ill-fitting dentures, oral hygiene mishaps, and burns to the hard or soft palate secondary to hot foods. Removal of persistent sources of trauma is essential; otherwise, treatment is palliative.

MEDICATION-RELATED SOFT TISSUE ABNORMALITIES

Gingival hyperplasia is associated with many commonly used medications (**Figure 245-8**). Approximately 50% of patients on phenytoin will develop significant gingival hyperplasia. Many other medications, such as cyclosporine and calcium channel blockers, especially nifedipine, cause gingival hyperplasia. Concomitant use of two such medications results in accelerated gingival proliferation. Enlargement begins in the interdental papillae. The clinical and histologic characteristics of gingival hyperplasia related to phenytoin, cyclosporine, and calcium channel blockers appear to be identical. The clinical appearance of the gingival tissue depends on oral hygiene and secondary inflammation. In the absence of inflammation, gingival proliferation results in dense tissue, normal in coloration, with a smooth, stippled, or granular texture. Inflammation causes edematous changes and an erythematous coloration. Inflamed tissue bleeds readily. Histologically, an increase in collagen fibers, fibroblasts, and glycosaminoglycans is seen. Epithelial acanthosis also occurs. Although the cause of drug-related gingival hyperplasia is unclear, poor oral hygiene clearly increases its likelihood and severity. Treatment includes fastidious oral hygiene to slow the hyperplasia and gingivectomy in advanced cases.

Many other medications are known to cause abnormalities of the oral mucosa or dental structures. Allergic mucositis, erythema multiforme, and fixed drug-type reactions are examples. Xerostomia and associated mucosal alterations are a side effect of many medications such as anticholinergics, antidepressants, and antihistamines.[1] Stomatitis and mucosal ulcerations from chemotherapeutic agents are also common.

LESIONS OF THE TONGUE

Many systemic conditions and local stimuli affect the appearance of the tongue. Many systemic conditions, various vitamins deficiencies, and iron-deficiency anemia cause atrophy of the filiform papillae, resulting in a smooth erythematous appearance. Occurrence of ectopic thyroid tissue on the midline posterior portion of the tongue is called a *lingual thyroid* and is a common finding. Some common conditions affecting the tongue are discussed below.

Benign Migratory Glossitis Geographic tongue, or benign migratory glossitis, is a common benign finding on oral examination, occurring in

FIGURE 245-7. Aphthous stomatitis. [Image used with permission of Baldev Singh.]

FIGURE 245-8. Gingival hyperplasia (overgrowth) secondary to phenytoin (Dilantin). [Used with permission of Philip J. Hanes.]

1% to 3% of the population. Females are affected twice as often as males. The typically multiple, well-demarcated zones of erythema on the tongue are caused by atrophy of the filiform papillae. The lesions concentrate on the tip and lateral borders of the tongue and heal in several days, only to quickly reappear in other areas. These lesions usually are asymptomatic; however, a burning sensation or sensitivity to hot or spicy foods has been described. The cause is unknown, but fluctuations with stress and menstrual cycle occur. Generally, treatment is not indicated because this entity is benign. Reassurance of patients is usually sufficient. In patients in whom discomfort is a major factor, oral topical steroids such as fluocinonide gel applied several times daily may provide relief.[14]

Strawberry Tongue Strawberry tongue is associated with erythrogenic, toxin-producing *Streptococcus pyogenes*. Clinically, the tongue has prominent red spots on a white-coated background. Microscopically, the fungiform papillae are hyperemic with a smooth glossy surface. Treatment is with antibiotics directed at group A streptococci.

LEUKOPLAKIA AND ERYTHROPLAKIA

Leukoplakia is a white patch or plaque that cannot be scraped off and cannot be classified as any other disease. Leukoplakia is the most common oral precancer; however, only 2% to 4% of leukoplakic lesions show dysplastic changes. The cause is unknown, but tobacco, alcohol, ultraviolet radiation, candidiasis, human papillomavirus, tertiary syphilis, and trauma have all been implicated. The most common intraoral site involved is the buccal mucosa. Other sites of involvement include the hard and soft palates, maxillary gingiva, and lip mucosa. Biopsy is mandatory for all persistent leukoplakic lesions. Leukoplakic lesions of the floor of the mouth, tongue, and vermilion border are most likely associated with malignancy. Lesions demonstrating dysplastic changes warrant removal.[15]

Erythroplakia is defined as a red patch that similarly cannot be clinically or pathologically characterized as any other disease. Although erythroplakia is far less common than leukoplakia, it has a greater potential for dysplastic changes.

ORAL CANCER

Oral cancer accounts for 2% to 4% of the cancers in the United States. More than 90% of all oral malignancies are squamous cell carcinoma (**Figure 245-9**).[15] Lymphomas, Kaposi's sarcoma, and melanoma comprise most of the remainder. Several intrinsic and extrinsic etiologic factors for oral squamous cell carcinoma have been identified. Extrinsic factors include tobacco use, especially chewing tobacco or snuff; excessive alcohol consumption; and sunlight exposure. Intrinsic factors include general malnutrition and chronic iron-deficiency anemia. Oral candidiasis, especially the hyperplastic form, immunosuppressive states such as human immunodeficiency virus infection, and oncogenic viruses such as human papillomavirus, herpes simplex virus, and various adenoviruses and retroviruses may play some role in the etiology of oral cancer.

Oral squamous cell carcinoma has four common morphologic presentations. It can be exophytic, with an irregular surface, or ulcerative, with irregular depressions and rolled borders. Malignant leukoplakic and erythroplakic lesions are believed to represent squamous cell carcinomas that have yet to form a mass or ulcerate.

The most common site involved in oral cancer is the tongue, particularly the posterolateral border, accounting for 50% of the oral cancers in the United States.[15] Cancer of the floor of the mouth accounts for nearly 35%. Cancer of the lips is common and usually secondary to sunlight exposure. Oral cancer is generally painless, and patients are often unaware of the presence of a mass until it is advanced. Oral cancer is usually firm, may bleed from ulceration, and have a history of poor healing. There may be associated firm lymphadenopathy. Early diagnosis is the key to successful treatment of oral squamous cell carcinoma. All ulcers, erythroplakic lesions, and leukoplakic lesions of the oral cavity that do not respond to palliative treatment in 10 to 14 days warrant biopsy. Treatment depends on site of involvement and staging of disease.

DENTOALVEOLAR TRAUMA

Management of dentoalveolar trauma depends on the extent of tooth and alveolar involvement, the degree of development of the apex of the tooth, and the age of the patient. In injuries in younger patients, especially those who are <12 years of age, the pulp of anterior teeth is quite large, and dental fractures involving the pulp are common. Fortunately, in this age group, the apex of the root also is usually incompletely formed, allowing for a greater pulpal regenerative capability. As one ages, more dentin is formed. Thus, in older patients, the pulp chamber may be very small and pulpal exposure highly unlikely. Involvement of the root of the tooth compromises the attachment apparatus and makes it difficult to restore the tooth to function.

DENTAL FRACTURES

The International Association of Dental Traumatology system divides dental trauma into eight categories: enamel infraction, enamel fracture, enamel-dentin fracture, enamel-dentin-pulp fracture, crown-root fracture without pulp exposure, crown-root fracture with pulp exposure, root fracture, and alveolar bone fracture (**Figure 245-10**). The International Association of Dental Traumatology has developed guidelines to aid dentists and other healthcare professionals in the management of each these categories.[16]

FIGURE 245-9. Oral squamous cell carcinoma of the hard palate. [Image used with permission of H. Anthony Neal.]

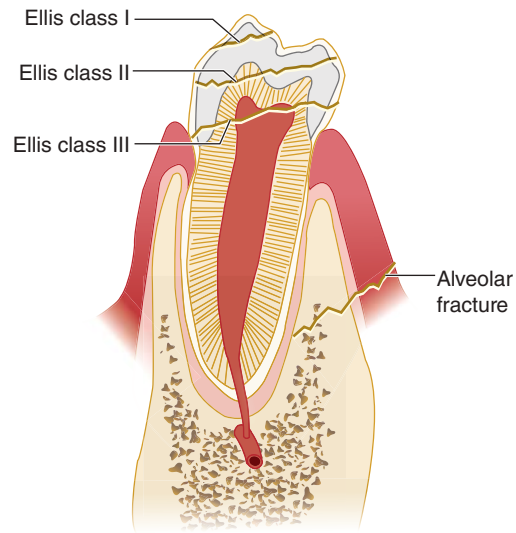


FIGURE 245-10. The International Association of Dental Traumatology classification of dental fractures.

The goal of the emergency treatment of a fractured tooth is maintaining pulpal vitality and completion of the formation of the root and apex of the tooth. The proximity of the fracture to the pulp and the length of time before treatment, as well as other associated injuries, are most important in determining outcome. Treatment is aimed at sealing the dentinal tubules and creating a barrier between the dental pulp and the oral environment. In properly treated uncomplicated dental fractures, 1% to 3% of the affected pulps undergo necrosis. Because pulpal necrosis is a process, it can occur at any time after trauma, and serial follow-up with a dentist is recommended.[16]

A fracture of the crown of the tooth can involve any part of the enamel, dentin, and pulp of the tooth. *Infraction* is the least serious type dental injury and essentially is a crack in the enamel of the tooth without loss of structure. This can be obvious or quite subtle. No emergency treatment is needed.

Enamel fractures do not extend into the dentin of the tooth (**Figure 245-11**). Generally, no emergency treatment is indicated, except to smooth sharp corners that may irritate the tongue or mucosa. If the enamel fragment is recovered and kept moist, the patient's dentist can bond it back in place. If the fragment was not recovered, soft tissue radiographs of any oral lacerations are necessary to rule out foreign bodies. Referral to a general dentist for aesthetic repair depends on the degree of cosmetic concern of the patient.[16]

A

B

FIGURE 245-11. International Association of Dental Traumatology classification for fractures of teeth (clinical). **A.** Enamel fracture. **B.** Enamel-dentin fracture of the central incisor on the left in the photograph (notice the pink blush of the pulp through the thin layer of dentin), and an enamel-dentin-pulp fracture of the central incisor on the right in the photograph. [Image used with permission of Felicity K. Hardwick.]

Enamel-dentin fractures involve the dentin of the tooth and require intervention (Figure 245-11). These fractures account for 70% of tooth fractures. Generally, patients experience sensitivity to hot or cold stimuli as well as air passing over the exposed surface during breathing. The enamel-dentin fracture can be identified both by the patient's symptoms and visualization of exposed dentin, which is a creamy yellow color compared with the whiter enamel. Because dentin is microtubular in structure, communication with the oral environment or desiccation from mouth breathing initiates an inflammatory response in the dental pulp. The thickness of remaining dentin determines the rate of pulpal contamination. Greater than 2 mm of remaining dentin is felt to offer some protection to the pulpal tissue. A delay in treatment of more than 24 to 48 hours increases the likelihood of pulpal necrosis. The ED goal is the identification of a fracture. If definitive treatment cannot be assured in 1 to 2 days, then cover the exposed dentin to decrease likelihood of pulpal injury. This is best achieved using glass ionomer dental cement that is easily mixed according to the manufacturer's instructions and carefully applied to the dried exposed dentin (DenTemp®, Majestic Drug Co., South Fallsburg, NY; and others). If the dentin layer is less than 0.5 mm and the pulp can be seen as a pink area without bleeding, then first place a thin layer of calcium hydroxide base (Dycal®, Dentsply International, York, PA) followed by glass ionomer, as described above, to further protect the dental pulp. Referral to a dentist for definitive treatment is important.[16]

In *enamel-dentin-pulp* fractures, exposure of the pulp has occurred (Figure 245-11). On wiping the fractured surface dry with sterile gauze, blood originating from the pulp of the tooth is easily identified. After carefully controlling pulpal bleeding with sterile gauze or a cotton pellet, cover the exposed pulp with a calcium hydroxide base (Dycal®, Dentsply International, York, PA), and then cover this and the remaining exposed dentin with glass ionomer cement as in enamel-dentin fractures until urgent dental evaluation can occur. If the pulpal exposure is extremely small, placing a calcium hydroxide base and glass ionomer is adequate until dental evaluation. For all but the smallest pulpal exposures, definitive treatment is some kind of endodontic or root canal therapy. Oral analgesics should be prescribed and topical analgesics avoided.[16]

Crown-root fractures and *root fractures* are an uncommon consequence of dental trauma. The coronal segment of the tooth may be displaced or simply mobile. Tenderness to percussion is usual. With any dental trauma, careful attention must be paid to identifying fractures of the root, as they can be clinically obscure and dental radiographs from several angles may be necessary to identify these fractures. This, however, is beyond the scope of most EDs. Crown-root fractures may or may not involve the pulp. Emergency treatment consists of stabilizing the coronal segment until definitive treatment can be arranged. In isolated root fracture, the pulp is always involved. Healing of stabilized root fractures has been reported; thus, current recommendations are to reposition the coronal segment to its original position, confirm that position by radiograph, if available, and then stabilize with a flexible splint as described below for luxation injuries. Dental follow-up within 24 to 48 is important, as splinting for a minimum of 4 weeks is required. In the ED, where oral surgical or dental consultation may not be readily available, extraction of an extremely mobile coronal segment of the tooth may be required to prevent possible aspiration. If less than one third of the root is involved, a dentist can perform root canal therapy, and restoration of the tooth may be possible.[16,17]

LUXATION INJURIES

The same forces that cause dental fractures may result in loosening of a tooth from the attachment apparatus. Careful evaluation of the teeth for tenderness, malpositioning, or mobility must be performed. Luxations account for nearly 50% of injuries to teeth. There are six types of luxations: concussion, subluxation, extrusive luxation, lateral luxation, intrusive luxation, and avulsion.[16]

Concussion is injury to the supporting structures of a tooth with clinical tenderness to percussion but no mobility. *Subluxation* is injury resulting in mobility without clinical or radiographic evidence of dislodgment of the tooth. *Extrusive luxation* is partial or total disruption

of the periodontal ligament resulting in a partial dislodgment of a tooth from the alveolar bone. *Lateral luxation* is displacement of a tooth labially (toward the lip) or lingually (toward the tongue) with concomitant fracture of the alveolar bone. *Intrusive luxation* is displacement of a tooth into its socket with associated periodontal ligament damage and alveolar bone contusion and fracture. Treatment of luxations depends on the tooth involved, the severity of injury, and the presence of associated root fracture and/or significant associated alveolar fracture.[16]

Concussions A concussive injury to a tooth is minor. The degree of tenderness to percussion determines the treatment. Stabilizing the tooth by splinting it to adjacent teeth is not indicated. Management of pain with NSAIDs, soft diet, and referral to a dentist to confirm the diagnosis and exclude more severe injury is the most appropriate course of action for the emergency physician.[16]

Luxations *Subluxation* represents a more significant injury and is associated with a higher incidence of subsequent pulpal necrosis. Clinically, tooth mobility and some bleeding along the gingiva may be noted. A subluxed tooth generally does not require splinting.[16]

An *extrusive luxation* requires repositioning the tooth to its original position and splinting to stabilize the tooth during healing. Ideally, dental radiographs should be obtained prior to repositioning the tooth to ensure that there is not a fracture of the root of the tooth, but in most EDs, this may not be possible, and repositioning and stabilizing should be attempted regardless. Repositioning the tooth may require local anesthesia. Firm, gentle pressure usually will reposition the tooth. If a clot has formed apical to the tooth, then more aggressive manipulation may be required. A flexible wire splint placed by a dentist provides ideal stabilization.[16] In the ED, a temporary splint with a noneugenol zinc oxide periodontal dressing (Coe-Pak™, GC America Inc., Alsip, IL; or ZONE Periopak®, DUX Dental, Oxnard, CA) (**Figure 245-12**) is acceptable. Avoid excess material placement, especially on the occlusal surface, because interference in occlusion will place stress on the tooth during mastication. Other treatment options include wire splinting, bondable reinforcement ribbon, calcium hydroxide paste, and light cured composite.[18] The patient should see a dentist or oral and maxillofacial surgeon within 24 hours.

A *lateral luxation* represents a more extensive injury and is associated with fracture of the surrounding alveolar bone. Repositioning of the tooth is generally more difficult. It usually can be accomplished by manipulating the displaced tooth with the thumb and forefinger. Once the apex has been dislodged from its locked-in position labially, apically directed axial pressure will reposition the tooth. Intra-arch stabilization is necessary for a minimum of 4 weeks. Temporary splinting with a periodontal dressing is acceptable if a minimal associated alveolar fracture occurred. Otherwise, splinting by an oral and maxillofacial surgeon or general dentist in the ED is mandatory.[16]

Intrusive luxations are the most serious because significant damage to the alveolar socket and periodontal ligament occurs. Root resorption is common as a result of damage to the periodontal ligament. Recommended treatment is allowing the tooth to erupt on its own or to orthodontically extrude the tooth if no eruption is noted by 3 weeks.[16]

All patients who sustain luxation injuries should be instructed to maintain a soft diet for at least 2 weeks. Meticulous oral hygiene is essential. Twice daily rinsing with chlorhexidine 0.12% mouth rinse is helpful. Referral to a dentist for close follow-up is indicated.

Avulsions

Tooth Replantation and Care at the Scene **Total displacement of a tooth from its socket, or *avulsion*, represents up to 16% of all dental injuries and is a true dental emergency.[19]** Replantation at the scene is the treatment of choice because the long-term prognosis for the replanted tooth is highly time dependent. Ideally, the patient or a healthcare provider at the scene should perform this procedure. Handling only the crown portion

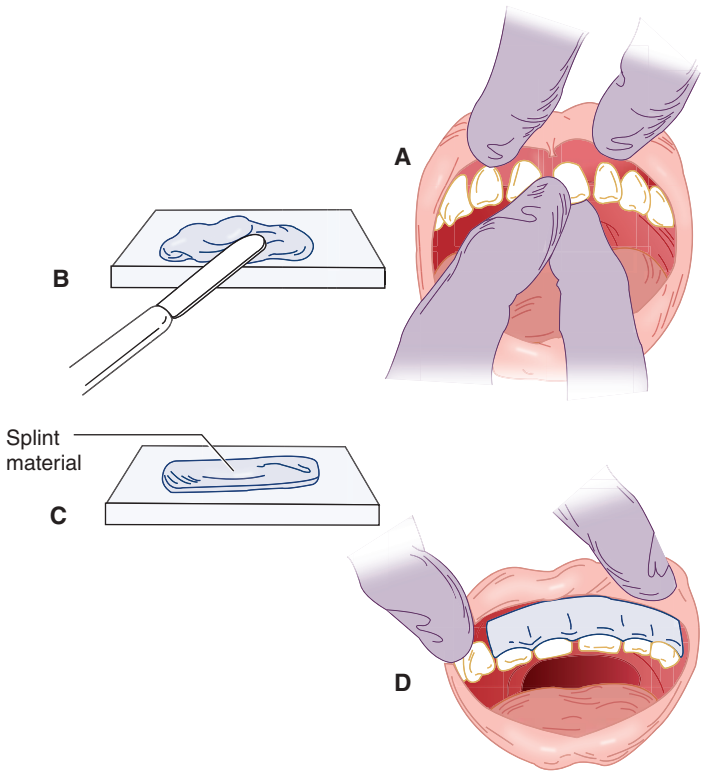

FIGURE 245-12. Temporary stabilization of a replanted or repositioned tooth. **A.** Tooth is repositioned back into its original position in the socket. **B.** Splint material is mixed thoroughly. **C.** Splint material is shaped and made ready for application. **D.** Packing is molded over repositioned tooth and two adjacent teeth to each side.

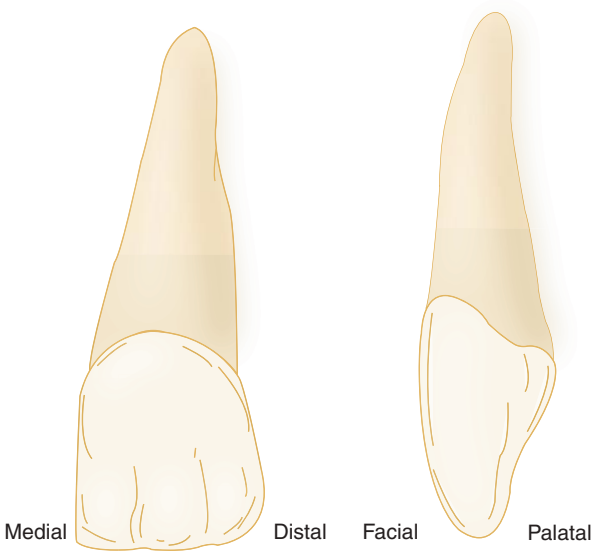

FIGURE 245-13. Illustration of a maxillary left central incisor. Note that the part of the tooth facing medially comes to more of a right angle at the incisal edge (biting edge) than occurs distally. The facial portion of the tooth is more convex.

of the tooth, gently rinse the tooth for a maximum of 10 seconds with sterile normal saline or tap water to remove debris. Then replace it immediately into the socket. Anterior teeth are most commonly affected, and **Figure 245-13** illustrates the morphology of the maxillary central incisor to assist replantation in the proper orientation. Early improper replantation holds a higher success rate for tooth salvage than delayed replantation resulting from waiting for arrival at the ED or for an oral and maxillofacial surgeon.[19]

If immediate replantation is not possible, or if the risk of aspiration is high, such as in a child or a patient with a decreased level of consciousness, then transport the tooth with the patient to the ED. Acceptable transport media include isotonic solutions such as Hank's balanced salt solution, sterile saline, milk, and saliva. Commercial preparations of Hank's balanced salt solution such as Save-A-Tooth® (Phoenix-Lazerus, Inc., Pottstown, PA) and EMT Tooth Saver™ (Smart Practice, Phoenix, AZ) are available and come with a useful transport container as part of the system. If the avulsed tooth was not recovered, obtain radiographs to ensure that the tooth was not aspirated.[19]

Survival of the periodontal ligament fibers that remain attached to the root of an avulsed tooth is key to successful replantation. Milk is an acceptable storage medium because of its osmolarity and essential concentration of calcium and magnesium ions. Hank's balanced salt solution, a pH-balanced cell culture medium, is the best transport medium and maintains periodontal ligament cell viability for up to 4 to 6 hours. Hank's solution can help to restore cell viability in a tooth that has been avulsed longer than 20 minutes.[19]

Tooth Replantation in the ED In the ED, before replantation, rinse the tooth root clean of dirt and debris with sterile saline or, preferably, Hank's balanced salt solution. Do not scrub the root of the tooth, and do not disrupt existing periodontal fibers. Handle only the crown of the tooth. If an avulsed tooth with an open apex has been dry for <20 minutes, then the prognosis for reestablishing a vital pulp is good. If the apex is completely closed and cannot be opened with saline irrigation, then revitalization is not possible. If the tooth has been dry from 20 to 60 minutes regardless of apices, soak the tooth in a physiologic solution while preparing to replant the tooth. Physiologic solution decreases the chance of ankylosis (fixation of the tooth to the underlying bone). For an avulsed tooth that has been dry for >60 minutes, the periodontal cells are dead, and the goal is to maintain alveolar bone contour and aesthetics; however, ankylosis, root resorption, and eventual tooth loss are the expected outcome. **Table 245-2** provides specific recommendations.[19]

Preparation of the dental socket plays little role in the success or failure of the replanted tooth. Prepare the socket by carefully removing the clot and gently irrigating with sterile normal saline. Avoid socket manipulation if possible. However, any fracture of the socket wall should be carefully repositioned with an appropriate instrument. Local anesthesia is usually required. Replantation is accomplished with firm pressure.

TABLE 245-2 Specific Recommendations for Replantation of Avulsed Teeth

Clinical Scenario	Treatment
Open apex	1. Gently irrigate the tooth root clean with sterile saline.
Moist tooth stored in acceptable media, and/or <60 min extra oral dry time	2. If available, cover root with minocycline hydrochloride microspheres (Arestin™, OraPharma, Inc.) or soak for 5 min in doxycycline solution (doxycycline, 1 milligram/20 mL saline). 3. Administer local anesthesia. 4. Remove coagulum from the socket with a stream of saline. Examine the socket. If there is a fracture of the socket wall, reposition it with an appropriate instrument. 5. Firmly replant tooth and verify the tooth position clinically and radiographically, if possible. 6. Flexible splint for up to 2 wk.
Open apex	1. Remove from tooth attached necrotic soft tissue carefully with gauze.
Extra oral dry time >60 min or other reason suggesting nonviable cells	2. If available, immerse tooth in 2% stannous fluoride solution for 20 min. 3. Administer local anesthesia. 4. Remove coagulum from the socket with a stream of saline. Examine the socket. If there is a fracture of the socket wall, reposition it with an appropriate instrument. 5. Firmly replant tooth and verify the tooth's position clinically and radiographically, if possible. 6. Flexible splint for up to 4 wk.
Closed apex	1. Gently irrigate the tooth root clean with sterile saline.
Moist tooth stored in acceptable media, and/or <60 min extra oral dry time	2. Administer local anesthesia. 3. Remove coagulum from the socket with a stream of saline. Examine the socket. If there is a fracture of the socket wall, reposition it with an appropriate instrument. 4. Firmly replant tooth and verify the tooth's position clinically and radiographically, if possible 5. Flexible splint for up to 2 wk.
Closed apex	1. Remove from tooth attached necrotic soft tissue carefully with gauze.
Extra oral dry time >60 min or other reason suggesting nonviable cells	2. If available, immerse tooth in 2% stannous fluoride solution for 20 min. 3. Administer local anesthesia. 4. Remove coagulum from the socket with a stream of saline. Examine the socket. If there is a fracture of the socket wall, reposition it with an appropriate instrument. 5. Firmly replant tooth and verify the tooth's position clinically and radiographically, if possible. 6. Flexible splint for up to 4 wk.

Having the patient bite on gauze until more permanent stabilization can be arranged is acceptable. Some form of stabilization of the tooth in the ED such as a periodontal dressing (Figure 245-12) is necessary until follow-up with an oral and maxillofacial surgeon.[18,19]

All patients need antibiotics. Doxycycline, 100 milligrams PO twice a day, is the preferred antibiotic choice. For children <12 years old, penicillin VK PO four times a day (12.5 milligrams/kg/dose) is acceptable. Tetanus prophylaxis is necessary if the tooth has been contaminated by soil and the tetanus status is uncertain. Posttreatment instructions for most dental trauma are essentially the same. Patient should be instructed to maintain a soft diet for 2 weeks, brush carefully with a soft toothbrush after each meal, and use chlorhexidine 0.12% mouth rinse twice a day.[19]

Sequelae of Luxation Injuries Posttraumatic sequelae are variable. Pulp canal obliteration, pulpal necrosis, internal and external resorption of the root, and ankylosis may occur. The severity of luxation or avulsion is the most important determining factor in sequela occurrence. Transient apical breakdown occurs with all type of luxations but is especially common with extrusive and lateral luxations and avulsions. More than 50% of extrusively luxated teeth undergo pulpal necrosis within 1.5 years of the traumatic event. Close dental follow-up is essential for early identification of these sequelae.

Significant force must occur to dislodge or fracture teeth; consequently, associated **alveolar ridge fracture** is common. Care to ensure the integrity of the maxilla and mandible is also important. Stabilization of repositioned alveolar segments and associated teeth is essential for optimal results. This is best accomplished with flexible fixation placed by a general dentist or oral surgeon. Stabilization is maintained for up to 4 weeks depending on the severity of the involvement of alveolar bone. With significant alveolar ridge fracture, segments may require intermaxillary stabilization for up to 6 weeks in order to ensure adequate healing.[19]

Luxation Injuries of Primary Teeth Avulsion or luxation injuries of primary teeth are treated differently from those of permanent teeth. In patients age 6 to 12 years old, dentition is mixed, so it is very important to distinguish primary from permanent teeth. Avulsed primary teeth are never replanted. Most luxation injuries in children require no treatment and heal spontaneously. However, severe luxations of primary teeth generally require extraction of the tooth. Repositioning or replanting primary teeth risks injuring the underlying permanent teeth and thus is avoided. Intruded primary teeth are generally left alone to re-erupt into normal position. Because of the risk of damage to the permanent dentition, unless there is occlusal interference or the risk of aspiration, a dentist should manage most complicated luxation injuries of primary teeth. Referral to a general dentist for follow-up is essential to ensure optimal long-term outcome.[20]

SOFT TISSUE TRAUMA

ORAL CAVITY MUCOSAL LACERATIONS

Traumatic injuries to the soft tissue of the oral cavity are common and can involve any of the soft tissues of the mouth. Appropriate treatment remains an area of controversy. Generally, because of the vascularity of the oral tissue, lacerations of the mouth heal quickly. See the "Intraoral Mucosal Laceration" section of chapter 42, "Face and Scalp Lacerations" for management recommendations. Lacerations involving the cheek or buccal mucosa must be examined carefully for involvement of Stensen's duct, which drains the parotid salivary gland (the duct opens into the mouth opposite the upper second molar). If Stensen's duct is compromised, repair by an oral and maxillofacial surgeon or otorhinolaryngologist is indicated. Likewise, lacerations to the floor of the mouth require careful evaluation for involvement of Wharton's duct of the submandibular salivary glands.

LIP LACERATIONS

Lip lacerations are a potential cosmetic problem, so careful closure is essential. (see chapter 42 for management recommendations).[21]

FRENULUM LACERATIONS

Laceration of the maxillary labial frenulum, unless unusually large, does not require repair. These lacerations can be very painful, so provide adequate analgesia. Because of the vascularity of adjacent tissue, lacerations to the lingual frenulum of the tongue usually do need to be repaired. An absorbable suture such as 4-0 chromic gut or Vicryl® is appropriate.

TONGUE LACERATIONS

Lacerations of the tongue require special consideration because bleeding and delayed swelling can compromise the airway. **Simple linear lacerations less than 1 cm involving the central portion of dorsal surface of the tongue and that do not gape open heal well without repair.** Except for the most extensive tongue lacerations, suturing does not necessarily improve outcome or reduce morbidity. All lacerations that bisect the tongue require repair. Partial amputations can be successfully replanted with the appropriate microsurgical techniques.[21]

Local anesthesia can be obtained by local infiltration or topically by placing 4% lidocaine-soaked gauze for 5 minutes on the laceration. Bilateral lingual nerve blocks can be used for lacerations of the anterior two thirds of the tongue that cross the midline. Repair of the tongue, especially in children, presents a special challenge, and many adjuncts such as a dental bite block or a Molt mouth prop can be helpful in keeping the mouth open. A piece of 4 × 4 gauze can be used to grasp the tongue, or a surgical towel clamps or a large caliber suture such as 0-silk or nylon placed through the anterior portion of the anesthetized tongue can facilitate retraction and control the tongue.[21]

When laceration repair is warranted, absorbable sutures such as 4-0 chromic gut or Vicryl should be used. Sutures should be placed so as to include the muscular layer and the superficial mucosal layers of the tongue. Wound edges should be approximated and closed very loosely to allow for swelling of the tongue, which can be significant. Placing a closed hemostat between the suture and the tongue while tying can help prevent overtightening of the suture. The constant motion of the tongue quickly unties sutures in the mouth so sutures should be tied with at least four square knots. If feasible, the sutures can also be placed so that the knots are buried into the wound. All patients should be instructed rinse several times daily with a saline or chlorhexidine 0.12% mouth rinse.[21]

DENTAL LOCAL ANESTHESIA TECHNIQUES

Competence in dental local anesthesia is a useful skill for the emergency provider. The maxillary teeth can be anesthetized using local infiltrative or supraperiosteal techniques, which are easily learned by reading.

ANATOMY

The trigeminal nerve is the largest cranial nerve, and although it has important motor function, it is primarily a sensory nerve (**Figure 245-14**). It divides into three main braches: the ophthalmic nerve, maxillary nerve, and mandibular nerve. The maxillary nerve provides sensory innervation to the maxilla and associated structures including the maxillary teeth and gingiva and oral mucous membranes. The third division, or mandibular nerve, is the largest of the three branches. The mandibular nerve has three main divisions. The first is the long buccal nerve that provides sensory innervation to the mucosa of cheek and buccal gingiva of the mandibular molars. The second is the lingual nerve that runs superficial to the internal pterygoid muscle and innervates the anterior two thirds of the tongue, lingual gingiva, and floor of the mouth. Finally, the largest branch is the inferior alveolar nerve, which accompanies the inferior alveolar vein and artery in a neurovascular bundle passing between the ramus of the mandible and the sphenomandibular ligament to enter the mandibular canal. It divides at the region of the premolars with the mental nerve exiting the mental foramen to innervate the soft tissue of the lip and chin, and the incisal nerve continuing within the mandibular canal to innervate the teeth and gingiva.

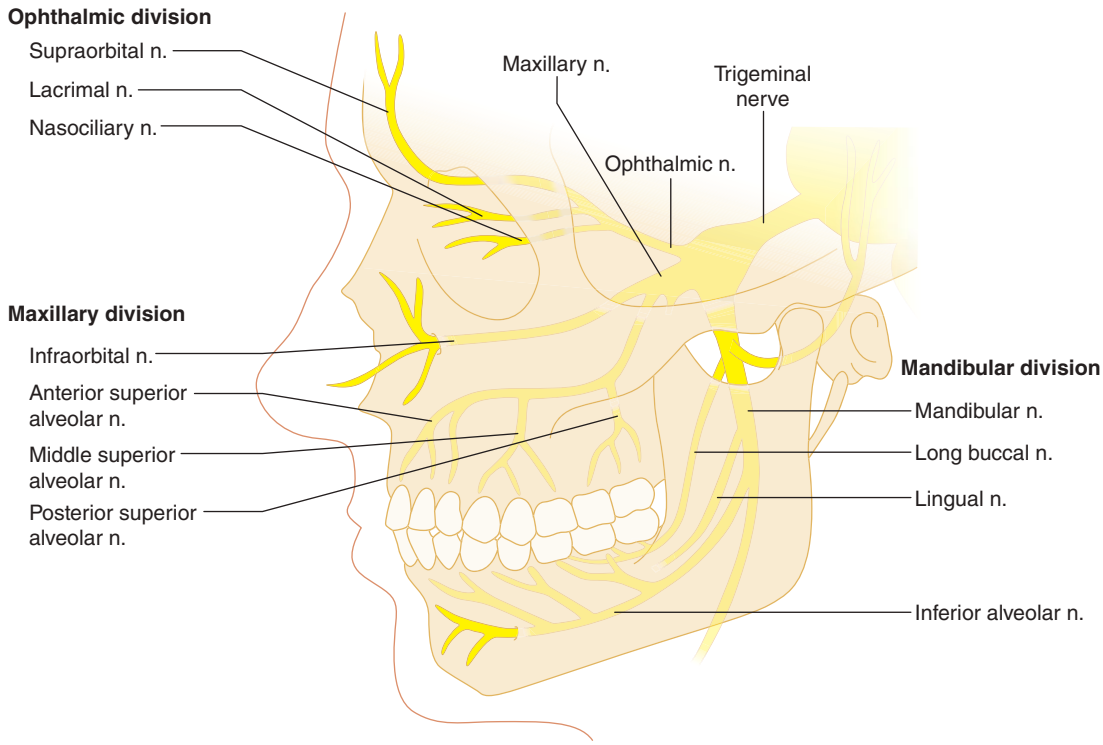

FIGURE 245-14. The trigeminal nerve and its three main divisions.

EQUIPMENT

Specialized equipment is useful when giving dental injections, especially the inferior alveolar nerve block. Equipment includes:

1. A monojet aspirating dental syringe
2. Dental cartridges of anesthetic solution
3. Disposable 27-gauge, 32-mm needle
4. Topical anesthetic, if possible

If an aspirating dental syringe is not available any 3-mm aspirating syringe can be used. With larger syringes, the inferior alveolar nerve block is difficult because the syringe barrel interferes with the proper positioning of the needle.

Position the patient in a dental chair or stretcher in a semi-reclined position with the head firmly against the headrest. Anticipate sudden movement of the patient. An overhead light is essential because dental injections require good visibility and control at all times to ensure safety of both the patient and the physician.

MAXILLARY INJECTIONS

Supraperiosteal Infiltration Maxillary cortical bone is thin and porous enough to allow the diffusion of anesthetic solution to reach the apex of the root and effectively anesthetize the tooth. **Figure 245-15** illustrates the supraperiosteal infiltration technique. The upper lip or cheek, depending on which tooth you are anesthetizing, is pulled up and taut. With the bevel facing toward the bone, the needle is inserted at the height of the buccal fold adjacent to the tooth. The needle should be directed along the long axis of the tooth and inserted to height of or slightly above the apex of the tooth. In most cases, the needle only needs to be inserted a few millimeters. Aspirate, and if negative, then slowly inject 0.5 to 1 mL of anesthetic solution. It is important to remember that the root of the canine is significantly longer than that of other teeth and that, in general, the roots of teeth are inclined in a distal direction. The goal is to deposit the anesthesia at or above the apex of the desired tooth.[22-24]

Palatal Injection
Supraperiosteal infiltration of the maxillary teeth provides adequate anesthesia for pain control for a toothache, but not for procedures such as management of a dry socket or avulsed tooth. This may also require anesthesia of the palatal tissue, which can simply be accomplished by local infiltrative anesthesia. With a fine-gauge needle, puncture the palatal mucosa about half way up the palate adjacent to the target tooth (**Figure 245-16**). Inject 0.1 mL of anesthetic solution. Blanching of the surrounding tissue is common, and this injection is usually quite uncomfortable. If a larger area of anesthesia is required, anesthesia of the anterior portion of the palate can be obtained by injecting anesthesia over the incisive foramen. The landmark is the incisive papilla. Anesthesia to the unilateral posterior portion of the palate can be obtained by injecting a small amount of anesthesia over the greater palatine foramen.[22-24]

MANDIBULAR INJECTIONS

In contrast to the maxilla where the cortex of overlying bone is relatively thin and infiltrative anesthesia is usually effective, the mandibular boney cortex is relatively thick and the inferior alveolar nerve block is usually required to gain adequate anesthesia of the mandibular molars and premolars. A mental nerve block, as described in chapter 36, "Local and Regional Anesthesia," can provide anesthesia for the premolars, canines, and incisors, as well as soft tissue of the lip and chin, when properly administered. The bone adjacent to the canines and incisors is thinner and more amenable to infiltrative anesthesia. Also, soft tissue anesthesia of the tongue can be obtained using the basics of the inferior alveolar nerve block. Injection of the long buccal nerve may be necessary for incision and drainage of dental abscesses in the mandibular molar region, and this technique will be described.

Inferior Alveolar Nerve Block (Direct Technique) The patient should be instructed to open the mouth widely to ensure good visualization of anatomic landmarks (**Figure 245-17**). First, the physician needs to palpate the greatest depth of the anterior border of the ramus or coronoid notch with the index finger or thumb. Then with that

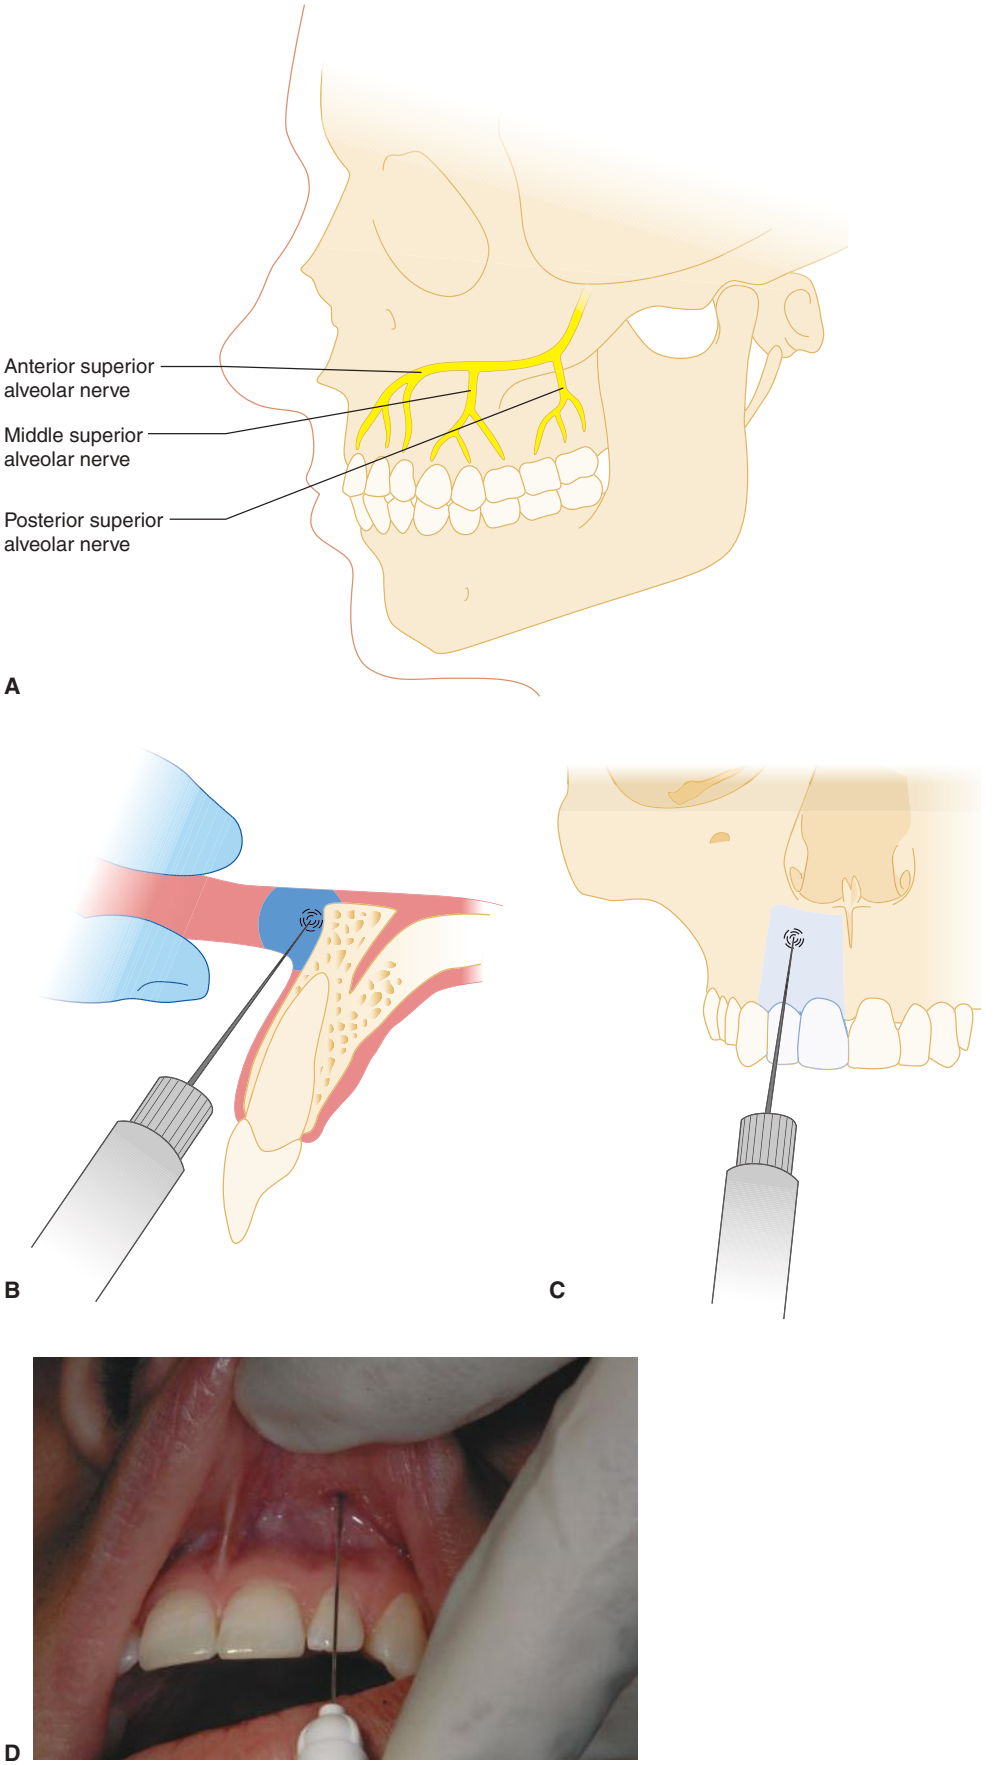

FIGURE 245-15. The supraperiosteal infiltration. **A.** The maxillary nerve and innervation of the maxillary teeth by the posterior superior alveolar nerve, the middle superior alveolar nerve, and the anterior superior alveolar nerve. **B.** With the lip or cheek pulled taught, the needle is inserted at the height of the buccal fold. Note: the 2-3 concentric circles of dotted lines around the needle tip indicate the area where the anesthesia is deposited. **C.** The needle is directed along the long axis of the tooth, and anesthesia is deposited just superior to the area of the root apex. **D.** Clinical photograph depicting a supraperiosteal infiltration of the maxillary lateral incisor.

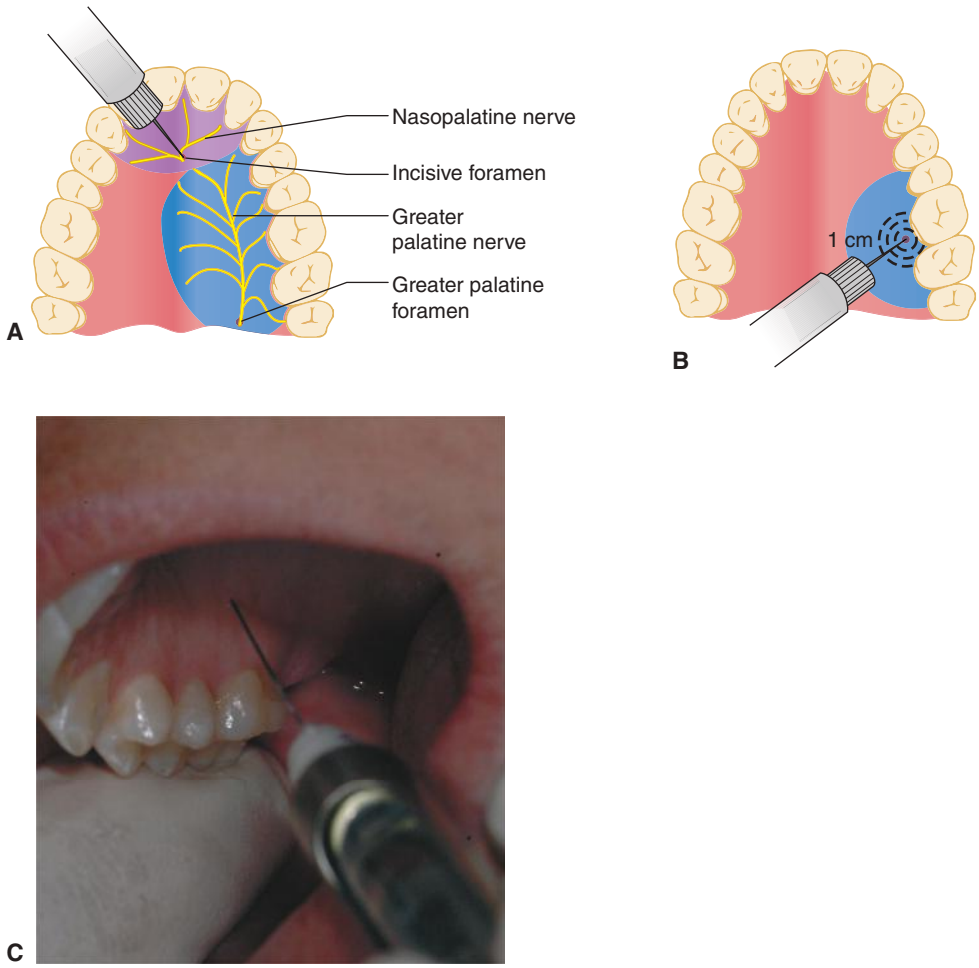

FIGURE 245-16. Palatal Infiltration. **A.** The innervation to the soft tissue of the hard palate. The posterior portion of the palate is innervated by bilateral greater palatine nerves after they each exit their respective greater palatine foramens (see blue shaded area). The anterior portion of the hard palate is innervated by the nasopalatine nerve after exiting the incisive foramen. Injection over the incisive foramen (shown) will result in anesthesia to the purple shaded area. **B.** A fine-gauge needle is inserted into the palatal tissue about 1 cm below the gingival margin, and a small amount of anesthesia is injected. Blanching of the palatal tissue surrounding the injection site is noted. This will provide anesthesia to the tissue adjacent to area injected as shown. A similar injection over the area of the greater palatine foramen or the incisive foramen will provide anesthesia to their respective zones. **C.** Clinical photograph depicting a palatal infiltration.

finger or thumb, the tissue is retracted toward the cheek revealing the pterygotemporal depression that is between the raised ridge of mucosa (pterygomandibular raphe) medially and coronoid notch laterally. With the syringe directed from the opposite premolar area, the needle is inserted into the pterygomandibular depression at a point 1 to 1.5 cm above the occlusal plane. This is approximately at the level of index finger or thumb. The needle is then slowly advanced until bone is contacted (about 20 to 25 mm). Once bone has been contacted, the needle should be withdrawn about 1 to 2 mm and then aspirated. If no blood is aspirated, then about 1.5 mL of anesthetic solution should be slowly injected. The needle then should be withdrawn about half of the distance, and the remainder of the dental carpule injected. This will ensure the anesthesia of the lingual nerve.[22-24] With experienced operators, the direct technique has about a 20% to 25% failure rate. Most commonly, failure is due to using too low of a point of injection. This places the anesthesia below the sphenomandibular ligament, which impedes its flow toward the inferior alveolar nerve. Repositioning the syringe higher above the occlusal plane will usually result in a successful injection.

Lingual Nerve Block If only lingual nerve anesthesia is desired, then the above technique can be followed except the needle need only be initially inserted about 10 mm, aspirated, and then the anesthetic agent instilled. This will provide anesthesia to the ipsilateral half of the anterior two thirds of the tongue (**Figure 245-18**).[22-24]

Long Buccal Injection If buccal soft tissue anesthesia is required, then this injection should be used. The needle is inserted into the mucosa in the buccal vestibule adjacent to the second or third mandibular molars (Figure 245-18). [22-24]

Injection Complications The normal vasovagal symptoms including syncope that can occur with any injection may occur during or after a dental injection. Flushing and elevation of the heart rate can also occur. Mild to severe allergic reactions are possible. Due to the close proximity of the inferior alveolar artery and vein and the pterygoid plexus, a potential complication of inferior alveolar nerve block is traumatic hematoma formation. These are usually self-limiting and treated with ice to the face but can be quite uncomfortable and an aesthetic issue for more than a week. Due to the superficial nature of the lingual nerve relative to the inferior alveolar nerve, inadvertent injury to the lingual nerve with subsequent temporary or permanent paresthesia can occur. This not only can affect sensation to the anterior two thirds of the affected side but also may affect taste because taste fibers run with the lingual nerve. Postinjection trismus, due to local trauma to the muscles of mastication, can occasionally occur. Needle breakage, although uncommon, has been reported, especially with improper technique such as bending the needle prior to use or redirecting the needle while injecting. Finally, unintentional injection too posteriorly may result in injection into the parotid region and can cause temporary facial nerve palsy.[24]

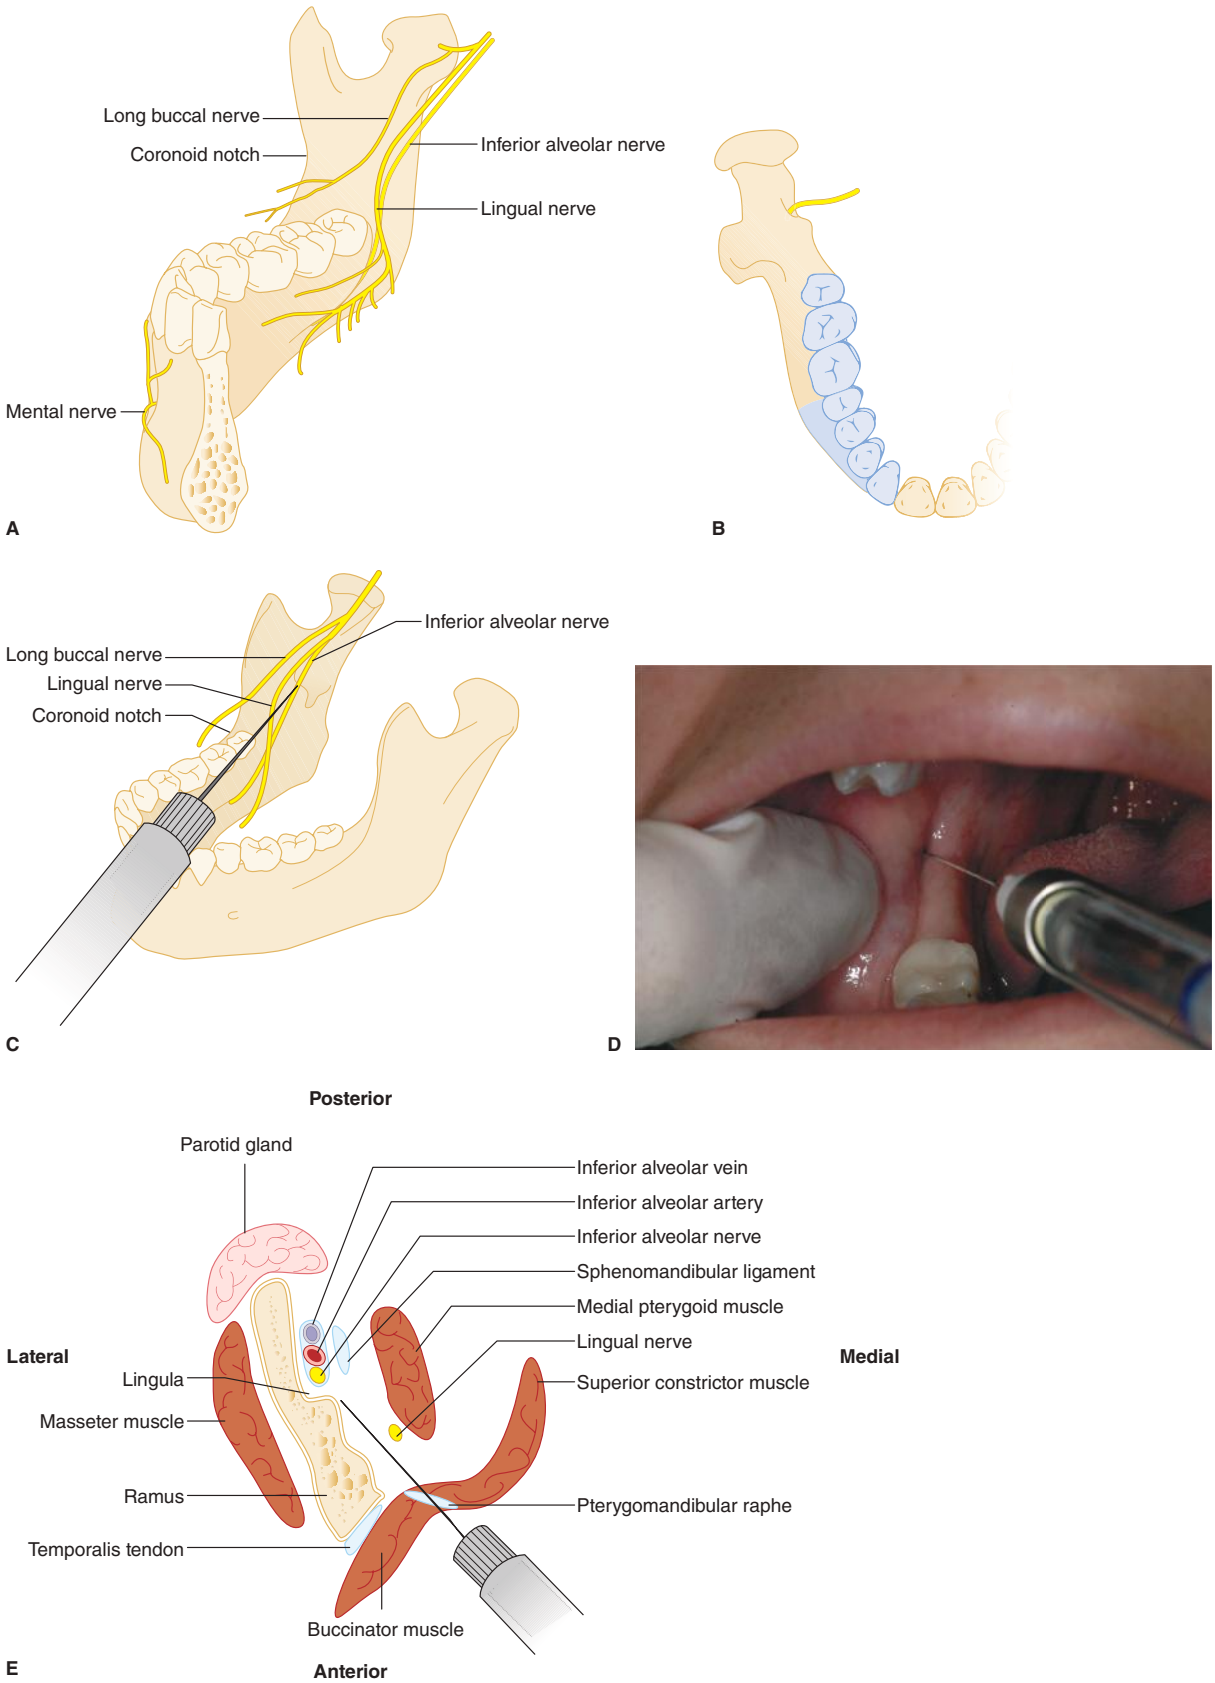

FIGURE 245-17. Inferior alveolar nerve block (direct technique). **A.** Shows the anatomy of the inferior alveolar nerve as it enters the mandibular foramen in the pterygomandibular space. The lingual nerve lies superficial and medial to the inferior alveolar nerve. The coronoid notch is noted. **B.** The area of anesthesia obtained with a successful inferior alveolar nerve block. Usually the lingual nerve is also blocked, which provides anesthesia to the floor of the mouth, lingual gingiva, and the anterior two thirds of the tongue. **C.** The syringe should be directed from the contralateral premolar area about 1 to 1.5 cm above the mandibular plane. It is inserted about 20 to 25 mm until bone is touched in an area above the lingula. The needle should then be withdrawn 1 to 2 mm and aspirated for blood before injecting anesthesia. The sphenomandibular ligament attaches to the lingula and prevents the anesthesia from reaching the inferior alveolar nerve if the injection is too low. **D.** Clinical photograph of the direct technique. Note the point of injection in the pterygomandibular depression just lateral to the pterygomandibular raphe. **E.** A diagram of a transverse section of the pterygomandibular fossa at the level of an inferior alveolar nerve injection. Note that the needle passes through the buccinator muscle to an area just superior to the lingula.

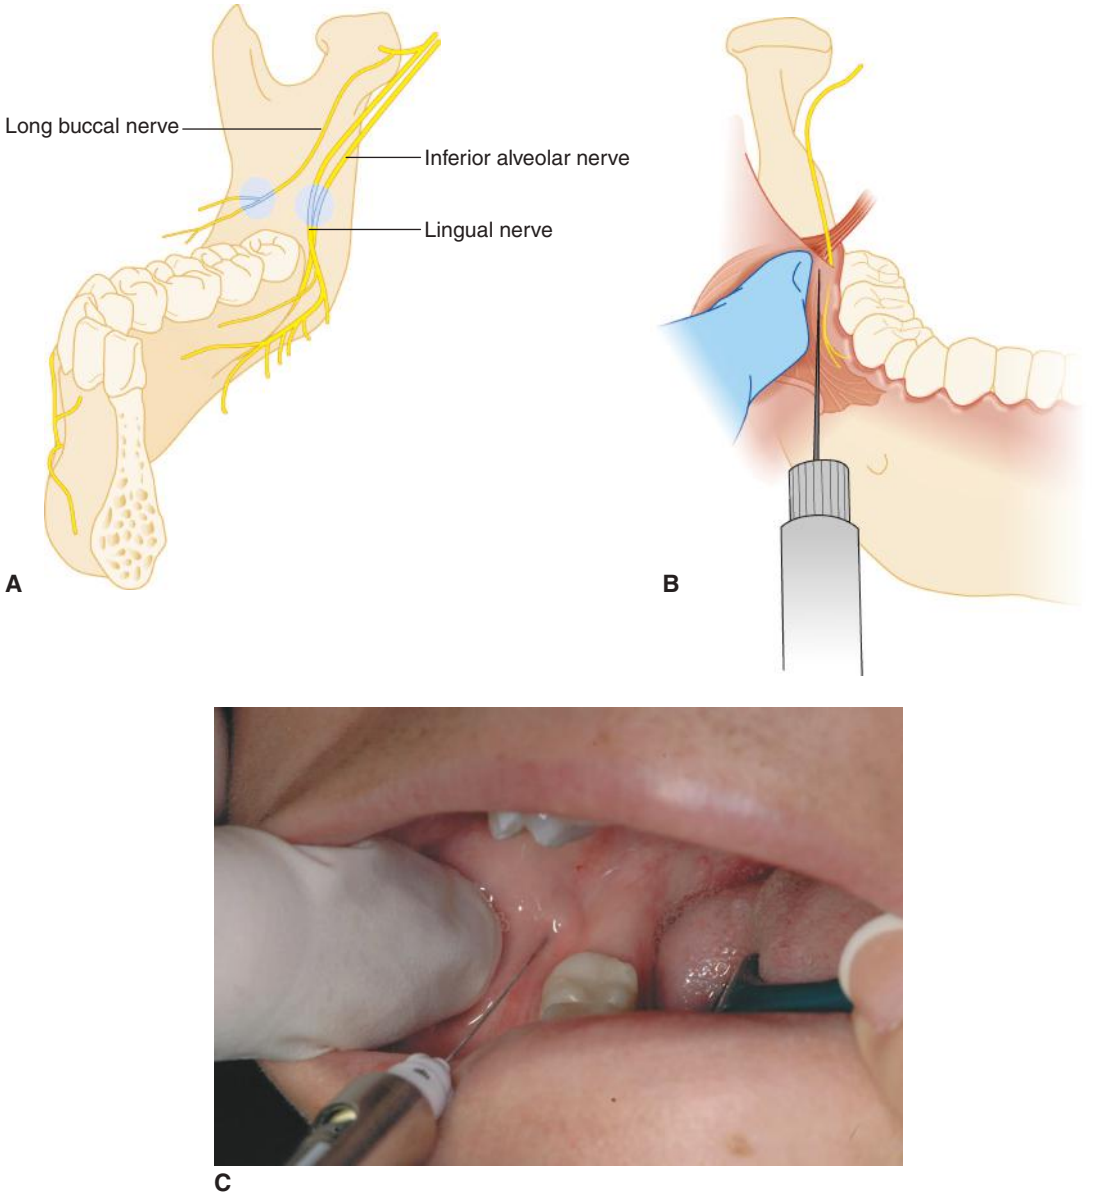

FIGURE 245-18. The lingual nerve block and the long buccal nerve block. **A.** The shaded areas represent the area in which anesthesia should be deposited for their respective blocks. The lingual nerve runs superficial and medial to the inferior alveolar nerve and can be easily anesthetized as part of the inferior alveolar nerve block. The lingual nerve block can be performed by depositing anesthesia about half the depth of the inferior alveolar nerve block. **B.** A diagrammatic representation of the long buccal nerve block. The long buccal nerve requires a separate injection of a small quantity of anesthetic just lateral to the molars in the buccal mucosa. **C.** Clinical photograph of the long buccal nerve block.

CHAPTER 246

Neck and Upper Airway

Nicholas D. Hartman

This chapter reviews infectious and noninfectious conditions that can obstruct the upper airway. These disorders must be recognized quickly because early airway management may be lifesaving. Neck trauma is discussed in the chapter 260, "Trauma to the Neck," and angioedema is discussed in the chapter 14, "Anaphylaxis, Allergies, and Angioedema."

NECK AND UPPER AIRWAY INFECTIONS

PHARYNGITIS/TONSILLITIS

Viruses account for the majority of cases of pharyngitis or tonsillitis. Acute viral pharyngitis is most commonly caused by rhinovirus but can be caused by multiple other viral agents (**Table 246-1**).[1]

VIRAL PHARYNGITIS

Viral pharyngitis generally displays a vesicular or petechial pattern on the soft palate and tonsils and is associated with rhinorrhea. However, in

TABLE 246-1 Microbial Causes of Acute Pharyngitis

Pathogen	Syndrome/Disease	Estimated % of Cases*
Viral		
Rhinovirus (100 types, 1 subtype)	Common cold	15–20
Coronavirus (3+ types)	Common cold	>5
Adenovirus (types 3, 4, 7, 14, 21)	Pharyngoconjunctival fever, acute respiratory disease	6
Herpes simplex virus (type 1, 2)	Gingivitis, stomatitis, pharyngitis	4
Parainfluenza virus (types 1–4)	Common cold, croup	2
Influenza virus (types A, B)	Influenza	2
Respiratory syncytial virus	Bronchiolitis, pharyngitis	1–2
Coxsackievirus A (types 2, 4, 5, 6, 8, 10)	Herpangina	<1
Epstein-Barr virus	Infectious mononucleosis	<1
Cytomegalovirus	Infectious mononucleosis	<1
Human immunodeficiency virus type 1	Acute retroviral syndrome	<1
Bacterial		
Streptococcus pyogenes (GABHS)	Pharyngitis, tonsillitis, scarlet fever	10–22
Fusobacterium necrophorum	Pharyngitis, tonsillitis, Lemierre's syndrome	5–10
Streptococcus dysgalactiae subspecies *equisimilis* (formerly group C β-hemolytic streptococci)	Pharyngitis, tonsillitis	3–5
Neisseria gonorrhoeae	Pharyngitis	<1
Corynebacterium diphtheriae	Diphtheria	<1
Arcanobacterium haemolyticum	Pharyngitis	<1
Chlamydial		
Chlamydia pneumonia	Pneumonia, bronchitis, pharyngitis	<1
Mycoplasmal		
Mycoplasma pneumonia	Pneumonia, bronchitis, pharyngitis	<1

Abbreviation: GABHS = group A β-hemolytic *Streptococcus*.
*Estimates of percentage of all cases of pharyngitis due to the indicated organism.

patients with nonstreptococcal pharyngitis (mostly viral), 16% have tonsillar exudate, 55% have cervical adenopathy, and 64% lack cough.[2] Most cases of viral pharyngitis require no specific diagnostic testing. There are three notable exceptions where testing may be indicated: suspected influenza, infectious mononucleosis, and acute retroviral syndrome. See Centers for Disease Control and Prevention influenza Web site for testing and treatment recommendations (http://www.cdc.gov/flu/). Infectious mononucleosis, influenza herpesvirus, and cytomegalovirus infections are discussed in the chapter 153, "Serious Viral Infections." The acute retroviral syndrome of early human immunodeficiency virus infection can also mimic mononucleosis. Symptoms of pharyngitis develop 2 to 4 weeks after exposure and resolve within 2 weeks. See the chapter 154, "Human Immunodeficiency Virus Infection" for recommendations on testing and treatment. Non–human immunodeficiency virus, noninfluenza viral pharyngitis should be treated symptomatically with oral hydration, antipyretics, analgesics, and rest. Patients unable to tolerate oral fluids or who become dehydrated should be given IV fluids.

BACTERIAL PHARYNGITIS

Group A β-Hemolytic *Streptococcus* **Group A β-hemolytic *Streptococcus* (GABHS) pharyngitis,** Lancefield group A species of *Streptococcus pyogenes*, is responsible for 5% to 15% of pharyngitis in adults.[1,2] After an incubation period of 2 to 5 days, patients develop the sudden onset of sore throat, painful swallowing, chills, and fever. Headache, nausea, and vomiting are common. Signs and symptoms of GABHS pharyngitis include marked erythema of the tonsils and tonsillar pillars (found in 62% of cases); tonsillar exudate (32%); and enlarged, tender cervical lymph nodes (76%).[2] A 2012 epidemiologic study found that only 6% of GABHS cases had fever and 28% had cough.[2] Patients may have uvular edema, myalgias, and malaise but are less likely to have rhinorrhea or conjunctivitis compared to viral pharyngitis.

Uvula edema, sometimes referred to as *Quincke's edema*, can be associated with upper airway infections such as GABHS pharyngitis, peritonsillar abscess, or epiglottitis. It can also be idiopathic. If it is an isolated finding and symptoms are uncomfortable to the patient, dexamethasone, 4 milligrams IV or PO, can be given as a single dose in the ED.

The original Centor criteria listed four clinical indicators of GABHS pharyngitis: (1) tonsillar exudates, (2) tender anterior cervical adenopathy, (3) absence of cough, and (4) history of fever.[2] The Centers for Disease Control and Prevention reversed its prior recommendation for empiric treatment based on clinical findings in 2012 in concert with the Infectious Diseases Society of America.[3] The Centers for Disease Control and Prevention and Infectious Diseases Society of America recommend using two or more Centor criteria as a threshold for selecting patients for rapid strep testing and treating only those with positive tests.[3,4] Guidelines do not recommend throat cultures in adult patients with one or fewer Centor criteria or routine throat culture for those with negative rapid strep tests, unless considering other bacterial pathogens[3]

Untreated, GABHS infection lasts 7 to 10 days. Antibiotic therapy of GABHS hastens resolution by 1 to 2 days if initiated within 2 to 3 days of symptom onset and prevents suppurative complications and rheumatic fever, although not glomerulonephritis.[3] **GABHS has never been resistant to penicillin, so penicillin remains the recommended first-line drug for GABHS.**[5,6] Adults should receive a single IM dose of 1.2 million units of benzathine penicillin G, 500 milligrams of penicillin VK PO two times daily for 10 days, or amoxicillin 500 milligrams PO two times daily or 1000 milligrams one time daily. A first-generation cephalosporin antibiotic or clindamycin may be used for penicillin-allergic patients.[5] A single dose of PO or IM dexamethasone in immunocompetent adults with moderate to severe pharyngitis can achieve an earlier onset of pain relief and a shorter duration of pain.[7]

Other Causes of Bacterial Pharyngitis Several other bacteria can cause pharyngitis, although these infections are less common (Table 246-1). ***S. dysgalactiae* subspecies *equisimilis***, previously known as β-hemolytic groups C and G streptococci, are important pathogens causing pharyngitis, skin infections, and more serious infections such as meningitis or toxic shock syndrome in the elderly or immunocompromised.[8] *S. dysgalactiae* subspecies *equisimilis* frequently colonizes the upper respiratory tract (60% who are culture positive are asymptomatic),[8] so distinguishing acute infection from a carrier state may be difficult;[9] treatment is recommend for patients with acute symptoms.[8] *S. dysgalactiae* subspecies *equisimilis* pharyngitis is almost uniformly susceptible to penicillin.[8] Clindamycin and fluoroquinolones are alternatives.[8]

Fusobacterium necrophorum, a gram-negative anaerobe,[10] is the causative agent in **Lemierre's syndrome**, a complication of pharyngitis causing suppurative thrombophlebitis of the internal jugular vein, with or without bacteremia and septic emboli. Suspect *F. necrophorum* in adolescents or young adults with worsening symptoms and neck swelling.[11] Treatment is with penicillin, clindamycin, or third-generation cephalosporins; *F. necrophorum* resistance to macrolides is high.[11]

Gonococcal pharyngitis is usually associated with genital infection and is treated by the same antibiotics. **Diphtheria** is caused by *Corynebacterium diphtheriae* and is rare in well-immunized populations. It is characterized by a slow onset of mild to moderate pharyngeal discomfort and low-grade fever. On physical examination, a gray membrane is

seen adherent to the tonsillar or pharyngeal surface and may extend to the uvula, soft palate, pharynx, and larynx. Treatment is with diphtheria antitoxin and metronidazole to prevent transmission to others.

PERITONSILLAR ABSCESS

A peritonsillar abscess is a collection of purulent material between the tonsillar capsule, the superior constrictor, and palatopharyngeus muscles. Risk factors include periodontal disease, smoking, chronic tonsillitis, multiple trials of antibiotics, and previous peritonsillar abscess.[12] Peritonsillar abscess develops primarily in adolescents and young adults without seasonal variation as previously thought.[12,13] Although peritonsillar abscesses are typically polymicrobial infections, in patients 15 to 24 years of age, *Fusobacterium necrophorum* has been the most common organism in many communities.[13,14]

CLINICAL FEATURES AND DIAGNOSIS

Patients with peritonsillar abscess (adolescents and adults) appear ill and present with sore throat (99%), fever (54%), malaise, odynophagia, dysphagia, and/or otalgia.[15] Physical signs include inferior and medial displacement of the infected tonsil(s) (46%), contralateral deflection of the swollen uvula (43%), tender cervical lymphadenopathy (41%), trismus (32%), muffled voice ("hot potato voice"), palatal edema, and dehydration[15] (**Figure 246-1**). The differential diagnosis of a peritonsillar abscess includes peritonsillar cellulitis, mononucleosis, lymphoma, herpes simplex tonsillitis, retropharyngeal abscess, neoplasm, and internal carotid artery aneurysm. In peritonsillar cellulitis, erythema and edema of the tonsillar pillar and soft palate are evident, but pus has not yet formed. Diagnosis of a peritonsillar abscess is often made by history and physical examination alone. When the diagnosis is in question, intraoral US has a sensitivity of 89% to 95% with a specificity of 79% to 100% for peritonsillar abscess.[16] CT scan with contrast is indicated if there is concern for spread beyond the peritonsillar space or lateral neck space complications.[16]

TREATMENT

Treatment options include drainage of the abscess by needle aspiration, incision and drainage, or, rarely, immediate tonsillectomy. Choice of treatment depends on clinical symptoms, degree of patient cooperation, history of previous tonsil disease, and healthcare personnel experience. There is no difference in outcome when comparing needle aspiration with incision and drainage.[16] Abscess tonsillectomy ("quinsy tonsillectomy") should only be considered when patients have strong indication for tonsillectomy, such as sleep apnea, recurrent tonsillitis, or recurrent peritonsillar abscess.[16] Needle aspiration is minimally invasive, less painful than incision and drainage, and may be performed by general or specialized medical personnel. Approximately 90% of patients will be treated effectively after a single needle aspiration.[16]

Needle aspiration should be performed by an individual trained in the technique. First, apply lidocaine spray or gel or benzocaine-tetracaine spray to the overlying mucosa. Then inject 1 to 2 mL of lidocaine with epinephrine into the mucosa of the anterior tonsillar pillar using a 25-gauge needle **The drainage needle should penetrate no more than 1 cm because the internal carotid artery usually lies laterally and posterior to the posterior edge of the tonsil.** The plastic sheath of the needle can be cut 1 cm from its tip to serve as a guard. If the internal carotid artery lies more medial and anterior, it can usually be palpated in this area. Once adequate anesthesia is achieved, introduce an 18-gauge needle just lateral to the tonsil, approximately halfway between the base of the uvula and the maxillary alveolar ridge, until the abscess cavity is encountered and pus is aspirated. Often, multiple aspirations may be required to find the abscess. If not done previously, a contrast CT scan of the neck is recommended when the results of needle aspiration are negative and a parapharyngeal or retropharyngeal space process is suspected.

Initial therapy should include a 10-day course of antimicrobials effective against group A *Streptococcus* and oral anaerobes (including *F. necrophorum*). Proven agents are penicillin VK plus metronidazole[15] or clindamycin for penicillin-allergic patients. Toxic patients or patients unable to take medicine PO should receive piperacillin-tazobactam, 3.375 grams IV, or similar agent. Single IV use of high-dose steroid (methylprednisolone, 125 milligrams, or dexamethasone, 10 milligrams) in addition to antibiotics and drainage improves severity and duration of pain.[15,17] Provide follow-up within 24 to 36 hours of aspiration, with instructions to return to the ED if worse. If the patient is not improving, consider repeating the aspiration, otolaryngologic consultation for incision and drainage or tonsillectomy, or obtaining a CT scan to confirm or reject the diagnosis. Complications of a peritonsillar abscess include airway obstruction, rupture of the abscess with aspiration of the contents, hemorrhage secondary to erosion of carotid sheath, retropharyngeal abscess, mediastinitis, and poststreptococcal sequelae.

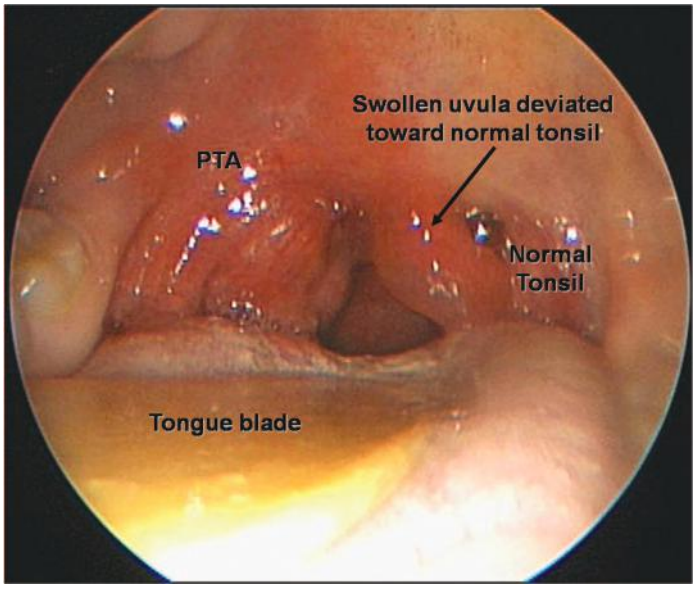

FIGURE 246-1. Right peritonsillar abscess (PTA) displacing right tonsil medially and the uvula toward the normal left tonsil. Abscess is between the right tonsil and the superior constrictor muscles.

ADULT EPIGLOTTITIS (SUPRAGLOTTITIS)

Epiglottitis is an inflammatory condition, usually infectious, primarily of the epiglottis but often including the entire supraglottic region (many prefer the term *supraglottitis*). It can lead to rapid airway obstruction. Prior to the introduction of a conjugate vaccine for *Haemophilus influenzae* type b in the 1980s, most cases of epiglottitis affected children age 1 to 5 years. In the postvaccine era, the dramatic decline in pediatric cases has confined the disease primarily to adults, with an estimated mean age of 45 years.[18,19] Most cases in adults are caused by *Streptococcus* species, *Staphylococcus* species, viruses, and fungi, although most frequently, no organism can be isolated.[19] Risk factors for mortality in patients with epiglottitis are advanced age and male sex.[20]

CLINICAL FEATURES AND DIAGNOSIS

Symptoms are typically a 1- to 2-day history of worsening dysphagia, odynophagia, and dyspnea, particularly in the supine position. The clinical triad of the "three Ds" (drooling, dysphagia, and distress) is a classic but infrequent presentation. Other symptoms are fever, tachycardia, cervical adenopathy, and anterior neck tenderness with pain on gentle palpation of the larynx and upper trachea. Stridor is primarily inspiratory. Patients often position themselves sitting up, leaning forward, mouth open, head extended, and panting.

Diagnosis is clinical and confirmed by radiographs or transnasal fiberoptic laryngoscopy. Lateral cervical soft tissue radiographs demonstrate obliteration of the vallecula, swelling of the aryepiglottic folds,

FIGURE 246-2. Acute epiglottitis. *Arrow* points to thickened epiglottis resembling a thumb print on a soft tissue lateral radiograph.

edema of the prevertebral and retropharyngeal soft tissues, and ballooning of the hypopharynx (**Figure 246-2**). The epiglottis appears enlarged and thumb-shaped. Direct laryngoscopy examination can confirm the diagnosis in adults if necessary but should be done carefully to avoid sudden, unpredictable airway obstruction. **Patients with worsening dyspnea in the supine position should *not* be sent to the CT scanner; CT of the neck is not needed to make the diagnosis.**

TREATMENT

Obtain immediate otolaryngologic consultation for suspected epiglottitis. Be prepared to establish a definitive airway. Patients should not be left unattended, and they should remain sitting up. Initial treatment consists of supplemental humidified oxygen, IV hydration, cardiac monitoring, pulse oximetry, and IV antibiotics. Humidification and hydration can help decrease the risk for sudden airway blockage. Steroids are often given to decrease airway inflammation and edema (methylprednisolone, 125 milligrams IV).

In adults, the need for intubation usually can be determined by transnasal fiberoptic examination of the supraglottis. Intubation is generally accomplished by "awake" fiberoptic intubation in the operating room, with preparations for immediate awake tracheostomy or cricothyrotomy. In cases of airway obstruction in the ED, be prepared for a very difficult intubation secondary to the swollen, distorted anatomy. In the case of intubation failure, the last resorts for preserving the airway are cricothyrotomy and needle cricothyrotomy.

Current antibiotic recommendations are cefotaxime 50 milligrams/kg IV every 8 hours plus vancomycin 15 milligrams/kg every 12 hours.[21] Alternative antibiotics include ampicillin-sulbactam, ceftriaxone, or piperacillin-tazobactam.[21] Respiratory fluoroquinolones are an option for patients with severe penicillin allergies.

RETROPHARYNGEAL ABSCESS

The retropharyngeal space is a potential space anterior to the prevertebral fascia that extends from the base of the skull to the tracheal bifurcation. In adults, a retropharyngeal abscess is usually due to intraoral procedures, trauma, foreign bodies such as a fishbone, or extension from odontogenic infection.[22] Cultures from retropharyngeal abscesses are usually polymicrobial: group A β-hemolytic streptococci, *Staphylococcus aureus* (including methicillin-resistant *S. aureus*), *H. influenzae*, and *Bacteroides*, *Peptostreptococcus*, and *Fusobacterium* species.

CLINICAL FEATURES AND DIAGNOSIS

The most common symptoms in adults are sore throat, dysphagia, neck pain, and less commonly, stridor. In addition, patients may also have complaints of cervical lymphadenopathy, poor oral intake, muffled voice, and respiratory distress. Visible neck swelling is not common.

A lateral soft tissue radiograph of the neck taken during inspiration with moderate cervical extension can demonstrate thickening and protrusion of the retropharyngeal wall, classically with 5 to 7 cm of prevertebral widening at the second cervical vertebra.[23] However, contrast-enhanced CT scan of the neck is the test of choice for diagnosis of a retropharyngeal abscess.[24] Early CT findings may reflect reactive, nonsuppurative edema, mild fat stranding with discernible tissue planes, linear fluid, minimal mass effect, and no associated enhancement. Necrotic nodes with central low attenuation and ring enhancement reflect an abscess (**Figure 246-3**). A patient with airway distress should not be sent unobserved for CT scanning.

TREATMENT

Obtain immediate otolaryngologic consultation. Provide IV hydration and antibiotic treatment with either clindamycin or cefoxitin IV; alternatively, piperacillin-tazobactam or ampicillin-sulbactam may be used.[21] Although a few patients with small abscess cavities may be managed with IV antibiotics alone, most patients will require surgical intervention. Catastrophic complications from retropharyngeal abscess include extension of

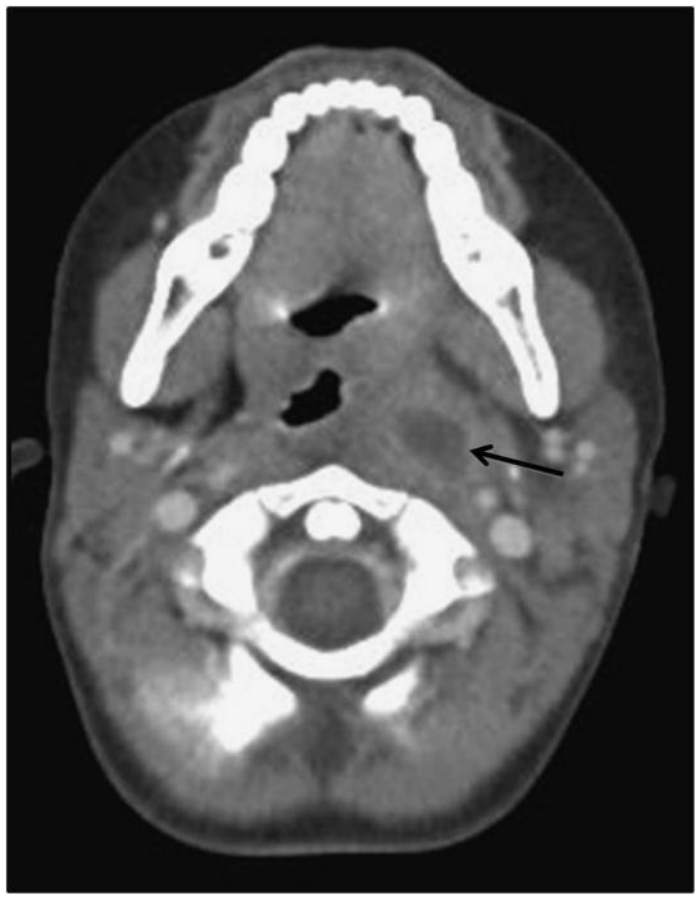

FIGURE 246-3. Contrasted CT of a left retropharyngeal abscess (*arrow*).

the infection into the mediastinum and upper airway asphyxia from direct pressure or aspiration after sudden rupture of the abscess.[25]

ODONTOGENIC ABSCESS

Odontogenic infections can arise from an infected tooth or after a tooth extraction. Development of the infection varies from <1 day to up to 1 to 3 weeks after the onset of tooth pain and may occur despite oral antibiotics. Odontogenic infections are polymicrobial; the most common bacteria are *Streptococci viridians*, *Peptostreptococcus*, *Prevotella*, and staphylococci.[26] **Most deep neck infections originate from an odontogenic source, usually the mandibular teeth.** Dental abscesses may spread into the parapharyngeal and retropharyngeal spaces. Presenting features include neck mass, trismus, fever, leukocytosis, dysphagia, and dyspnea. Potential complications include necrotizing fasciitis, descending necrotizing mediastinitis, orbital infections, and hematogenous dissemination to distant organs.

CLINICAL FEATURES

See chapter 245,"Oral and Dental Emergencies" for management of dental infections isolated to the mandible or maxilla. Soft tissue extension from odontogenic infection ranges from diffuse cellulitis to abscess formation in labial or buccal gingiva. In some cases, intraoral or dentocutaneous fistula formation may occur. Fascial layers of the head and neck produce planes or potential spaces for infectious spread. Infections associated with maxillary teeth tend to spread into potential spaces in the face. Infections of maxillary molars tend to involve the masticator space, which can extend into the parapharyngeal space and downward into the neck and mediastinum. Infections of anterior mandibular teeth tend to spread into the neck. Infections of anterior teeth, bicuspids, and first molars of the mandible tend to enter the sublingual space, with edema of the floor of the mouth with little extraoral swelling. Involvement of the submandibular space is typically the result of second and third mandibular molar infections.

DIAGNOSIS AND TREATMENT

Superficial odontogenic abscesses can be diagnosed with US at the bedside.[27] For diagnosis of suspected deep space infections, contrast-enhanced CT scan is recommended to identify the need for surgical management.[27] Treatment of odontogenic infections includes appropriate antibiotic therapy (aerobic and anaerobic coverage) and surgical drainage of abscesses. Penicillin VK and amoxicillin remain appropriate options for outpatient treatment; amoxicillin-clavulanate, clindamycin, cefuroxime, and levofloxacin are second-line choices.[28,29] Patients with deep-neck infections require IV antibiotics; ampicillin-sulbactam with clindamycin and ciprofloxacin is one recommended regimen. Other useful agents include piperacillin-tazobactam, imipenem-cilastatin, and ertapenem.

COMPLICATIONS

Ludwig's angina is infection of the submental, sublingual, and submandibular spaces. Patients usually present with poor dental hygiene, dysphagia, and odynophagia. Clinical examination reveals trismus and edema of the entire upper neck and floor of mouth. Infection progresses rapidly and can posteriorly displace the tongue, causing airway compromise. Definitive airway management should be considered early in the course, including awake fiberoptic intubation or awake tracheostomy.[30] Stridor, difficulty managing secretions, and cyanosis are late signs and require emergent airway management. Systemic antibiotics are not a substitute for definitive airway management because it may take >1 week for edema resolution with antibiotic therapy.

Patients with **necrotizing infections** are critically ill, with overlying skin discoloration, crepitus of the subcutaneous tissue, and systemic signs, including fever, tachycardia, hypotension, and confusion. CT reveals subcutaneous emphysema, deep tissue gas, and pockets of suppuration (**Figure 246-4**). Aerobic and anaerobic cultures are necessary for identification of causative organisms. Therapy of necrotizing fasciitis is immediate surgery with fasciotomy with wide local debridement and broad-spectrum IV antibiotics. Mediastinal extension places the patient at risk for great vessel erosion, retroperitoneal extension, pleural abscess, pericardial effusion, and sepsis; mortality ranges from 10% to 40%.[31] Tracheostomy should be performed if airway obstruction develops. Surgery can be lifesaving, and immediate surgical consultation is required for this rapidly progressing disease.[31]

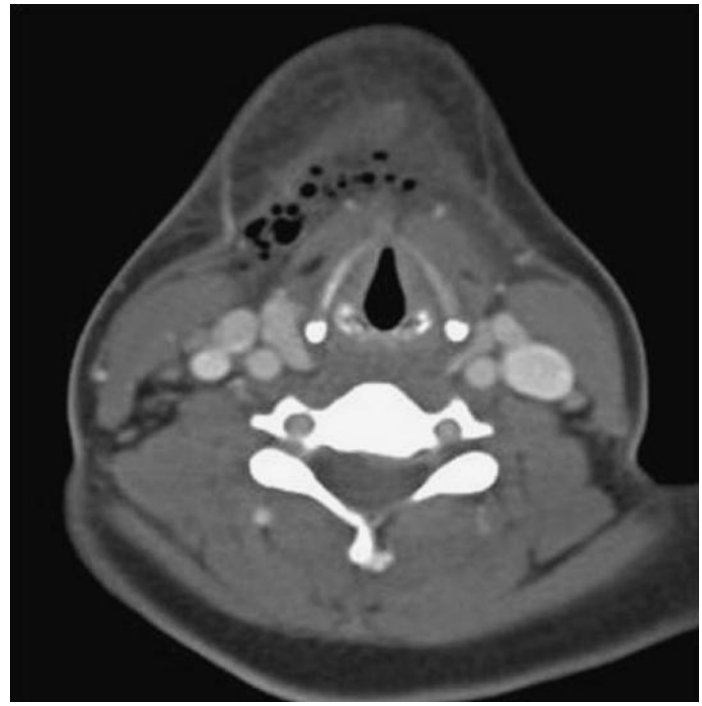

FIGURE 246-4. CT demonstrating necrotizing fasciitis with gas in the deep tissue of the anterior neck.

NECK AND UPPER AIRWAY MASSES

CLINICAL FEATURES

Neck masses (**Figures 246-5 and 246-6**) can result from congenital, infectious, glandular, or neoplastic disorders. Enlargement may lead to airway compromise, dehydration secondary to dysphagia and odynophagia, or secondary infected. Age of the patient and characteristics including location of the mass may aid in the diagnosis (**Tables 246-2 and 246-3**).[32] Neck masses in children are discussed in the chapter 122, "Neck Masses in Infants and Children," in the Pediatrics section. **In adults >40 years old, up to 80% of lateral neck masses persistent for >6 weeks are malignant.[33]**

DIAGNOSIS AND MANAGEMENT

The urgency for evaluation of a neck mass depends on patient acuity.[33] Patients with airway compromise or significant dysphagia and odynophagia should be evaluated by flexible nasopharyngolaryngoscopy **before** CT scan. CT scan will delineate the extent of the mass and likely will be required for surgical intervention. If no airway compromise or dehydration is present, the patient should follow up with primary care for outpatient imaging and further evaluation. The final diagnosis for a neck or upper airway mass will not be made in the ED. All neck masses should have follow-up for diagnosis and treatment.

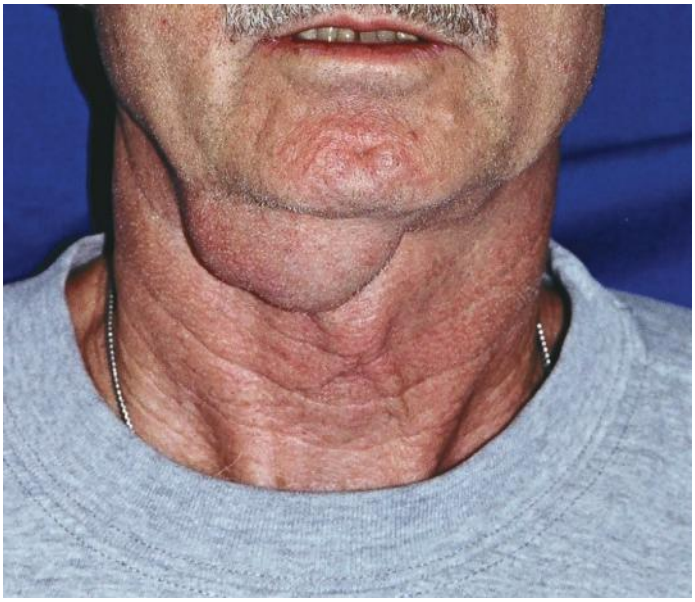

FIGURE 246-5. Right plunging ranula presenting as a painless ballotable submandibular mass.

Empiric antibiotic therapy should be initiated for inflammatory lymph nodes, usually with cephalexin, 250 to 500 milligrams PO three to four times daily; amoxicillin, 250 to 500 milligrams PO three times daily; or clindamycin, 300 milligrams three to four times daily. Resolution is expected in 2 weeks for those lesions that are due to infection alone. Empiric therapy of sialoadenitis should include staphylococcal coverage most commonly, clindamycin[34] (see chapter 118, "Neck Masses in Children").

TABLE 246-2 Neck Masses in Young and Older Adults

Young Adult	Adult
Reactive lymphadenopathy	Metastatic aerodigestive tract carcinoma
Mononucleosis	Salivary gland infection or neoplasm
Lymphoma	
Branchial cleft cyst	Lymphoma
Thyroglossal duct cyst	Thyroid disorder
	Tuberculosis

POSTTONSILLECTOMY BLEEDING

Tonsillectomy is the second most common reason for care in pediatric hospitals in the United States.[35] Postoperative bleeding is a well-known complication of tonsillectomy that can, rarely, lead to death from airway obstruction or hemorrhagic shock. Rate of secondary hemorrhage varies according to the method used for the procedure. The incidence of posttonsillectomy bleeding ranges from 1% to 8.8%, with approximately half requiring surgical intervention for control of bleeding.[36]

Although bleeding can be seen within 24 hours of surgery, most significant hemorrhage occurs between postoperative days 5 and 10. There is a significantly higher incidence of bleeding in patients between 21 and 30 years of age, as well as those over age 70.[36] Posttonsillectomy bleeding can be fatal and requires prompt intervention with control of the airway. An otolaryngologist should be consulted early.

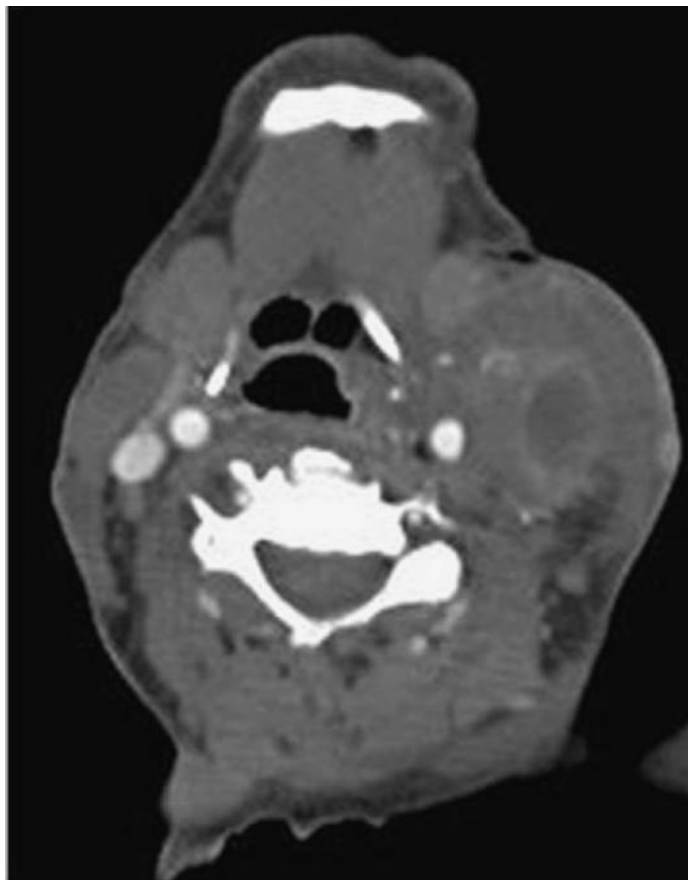

FIGURE 246-6. Hypopharyngeal squamous cell carcinoma metastatic to left cervical lymph nodes. Note the thrombosis of the left jugular vein with displacement of the airway to the right.

TABLE 246-3 Common Causes of Neck Masses in Adults

Disorder	Physical Finding	Pathology	Management
Ranula	Sublingual area swelling	Mucus retention cyst due to ductal obstruction of the sublingual gland	Surgical excision
Laryngeal papillomas	Sessile, warty-appearing lesions on the soft palate or tonsillar pillars	Human papillomavirus type 6 or 11 infection	Surgical excision
Palatine torus	Boney smooth painless mass of the hard palate	Exostoses of the palate	No treatment needed in most cases
Mandibular torus	Boney smooth painless growth of the mandible under the tongue	Exostoses of the mandible	No treatment needed in most cases
Branchial cleft cysts	Painless, fluctuant masses close to the angle of the mandible	Incomplete obliteration of the branchial apparatus during development	Antibiotics if infected, surgical excision
Thyroglossal duct cysts	Soft, mobile, subhyoid bone midline mass	Remnant of the thyroid anlage	Antibiotics if infected, surgical excision
Lymphoma	Multiple, rubbery low-neck masses, night sweats, fever, malaise	Malignant process	Biopsy, referral to ENT and oncology
Acute retroviral syndrome	Generalized adenopathy, unprotected sex by history	Human immunodeficiency virus infection	Antiretroviral medication
Squamous cell carcinoma	Firm, possibly fixed cervical lymph node	Oral lesion metastatic to cervical node	Biopsy, referral to ENT and oncology
Parotid tumors	Nonpainful masses under or anterior to the ear	Benign or malignant process	Biopsy, referral to ENT and oncology as needed
Sialoadenitis	Tender swelling in area of parotid, submandibular, or sublingual salivary gland	Salivary gland infection	Antibiotics, salivary stimulants, also see chapter 122, "Neck Masses in Children"
Thyroid enlargement	Diffuse nodular thyroid enlargement or solitary nodular thyroid	Benign or malignant process	See chapters 228, "Hypothyroidism," and 229, "Hyperthyroidism"

Abbreviation: ENT = otolaryngology.

TREATMENT

Keep the patient NPO (nothing by mouth) and sitting upright, monitor with pulse oximetry, and maintain IV access. Obtain a CBC and coagulation studies, and type and cross-match blood. Examine the oropharynx to see if bleeding can be visualized. A grayish-white eschar is normal following a tonsillectomy. **Apply direct pressure to the bleeding tonsillar bed using a tonsillar pack or a 4×4 gauze on a long clamp, moistened with either thrombin or lidocaine and epinephrine.** To prevent loss of the pack into the airway, place a suture through the pack and tape the suture to the face. Place pressure on the lateral pharyngeal wall, avoiding midline manipulation, to decrease stimulation of the gag reflex. Massive bleeding is rare, but when it occurs, intubation may be the only means of protecting the airway. This is always difficult, with oropharyngeal edema from recent surgery and blood obscuring visualization of the cords. Plans should be made for an emergent cricothyrotomy prior to attempting intubation.

Pressure alone can be adequate for control of posttonsillectomy hemorrhage until the otolaryngologist arrives. Alternatively, if a bleeding site can be visualized, bleeding may be cauterized with silver nitrate after local infiltration with 1% lidocaine with epinephrine. Otolaryngologic consultation in the ED is always needed because patients may have a second or even third posttonsillectomy hemorrhage,[37] and surgery or endovascular embolization may be necessary for definitive control.[38]

CHAPTER 247

Complications of Airway Devices

John P. Gaillard

TRACHEOSTOMY TUBES AND CANNULAS

A tracheostomy is an opening between cartilaginous rings in the trachea and the skin, with a tracheostomy tube placed into the stoma to facilitate ventilation. Tracheostomy is usually performed by an otolaryngologist as an elective or semi-elective procedure and is not an emergency procedure. Most tracheostomies are performed on chronically ill patients requiring prolonged mechanical ventilation.

There are many types of tracheostomy tubes available, including those made of plastic, silicone, nylon, and metal. Most hospitals stock only a few types of tracheostomy tubes, and one must be familiar with the types available. Tracheostomy tubes vary in diameter, total length, the length before and after the curve, and the presence or absence of a cuff (**Figure 247-1**). The size of the tracheostomy tube is usually defined by the inner diameter, ranging in adults from 5 to 10 mm and in pediatric patients from 2.5 to 6.5 mm. Most pediatric and adult tracheostomy tubes have a 15-mm standard respiratory connection that may be used with ventilator tubing or a bag-valve device.

Fenestrated tracheostomy tubes have an opening along the dorsal surface of the body of the tube. The fenestration allows the passage of air through the tracheostomy tube to the vocal cords so the patient can speak. Irritation from the fenestration may promote growth of granulation tissue, which may extend into the fenestration, leading to bleeding, obstruction, and difficulty removing the tracheostomy tube. If any difficulty is encountered removing a fenestrated tracheostomy tube, obtain surgical or ear, nose, and throat consultation.

Most adult tracheostomy tubes have a removable inner cannula, which allows secretions to be cleared from the lumen without removing the entire tube from the trachea. In assessing an adult tracheostomy patient, remove and examine the inner cannula for crusting or obstruction. Both disposable and reusable inner cannulas may be cleaned by using a small brush dipped in a solution of hydrogen peroxide and then

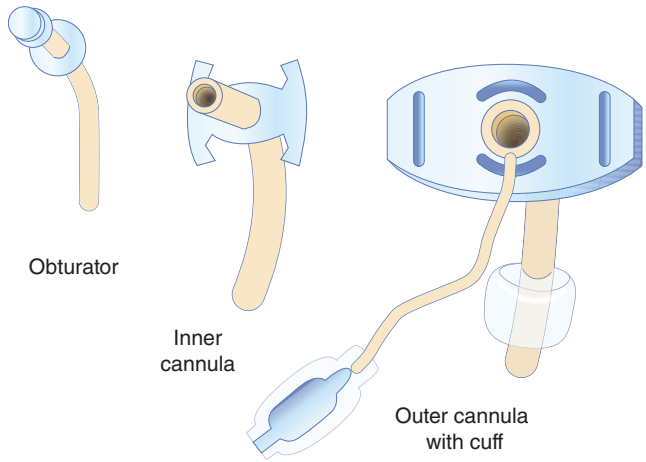

FIGURE 247-1. Common components of most tracheostomy tube sets.

rinsing the cannula with warm tap water. If the correct size of disposable inner cannula is not available in the ED, use the existing inner cannula temporarily, or change the entire tracheostomy tube. **Pediatric tracheostomy tubes never have an inner cannula because of the small inner diameter, so the entire tube must be removed for cleaning.**

COMPLICATIONS OF TRACHEOSTOMIES

Complications due to the surgery are grouped according to the timing since the tracheostomy and the technique. Summed complication rates from randomized controlled trials show 10.0% for percutaneous technique and 8.7% for open tracheostomy.[1] Bleeding, obstruction, dislodgement, and infection are all potential early complications, occurring within the first week. Late complications are those that occur after 1 week. Granulation, tracheal stenosis, a fistula (tracheocutaneous, tracheoesophageal, or tracheoinnominate) plus any of the early complications may be late complications.[1-4] Risk factors for tracheal stenosis are intubation duration of more than 1 week and having an endotracheal tube larger than 7.5 mm.[4]

Patients with tracheostomy tubes can develop respiratory distress. **Figure 247-2** is a step-by-step approach to assess and treat respiratory distress. In the ED, the provider must be proficient in the following skills (as outlined in the sections that follow): replacement of an uncuffed with a cuffed tracheostomy tube for mechanical ventilation, replacement of a tracheostomy tube after accidental decannulation, correction of a tube obstruction, and control of bleeding or infection at the tracheostomy site. It is important to determine a few key elements about the tracheostomy: when and why was the procedure performed, what type of tracheostomy tube is the patient using currently, and can the patient be orally intubated if needed? **Patients who have undergone a laryngectomy or who have tumors or scarring that occlude the upper airway cannot be orally intubated.**

Tracheostomy Tube Obstruction Consider mucus plugging of the trachea or mainstem bronchi distal to the tube. If the tracheostomy is patent and is in the airway, leave it in place. If the tracheostomy tube is obstructed, mucous plugging is commonly the cause. Secretions may act as a ball-valve mechanism, allowing air in but restricting exhalation. Suctioning may relieve the obstruction. Preoxygenation and placement of sterile saline solution into the trachea will aid in suctioning. Prolonged use of large suction catheters without preoxygenation will cause hypoxemia. If mucous plugging cannot be relieved by suctioning, the inner cannula of the tracheostomy tube and, occasionally, the entire tracheostomy tube may need to be removed and cleaned.

Tracheostomy Dislodgement It is possible for the tracheostomy tube to become dislodged from the trachea but still be in the neck. In this case, a suction catheter cannot be passed through the tube, and on x-ray, the tracheostomy tube may be seen to extrinsically compress the trachea (**Figure 247-3**). In this circumstance, remove the entire tracheostomy tube. It may be difficult to accurately identify the actual tracheal stoma when replacing the tube (see "Changing a Tracheostomy Tube" section below). A nasopharyngoscope or flexible bronchoscope should be inserted into the visible stoma in an attempt to identify the tracheal opening. If the opening still cannot be identified, obtain ear, nose, and throat or surgical consultation. If the patient cannot maintain the airway, oral intubation will be necessary.

Tracheostomy Site Infection Indwelling tracheostomy tubes are contaminated with normal or pathogenic flora. Surgical site infection is more common in patient post open tracheostomy (7%) than percutaneous insertion (3.4%).[5] Stomal skin infection, tracheitis, and bronchitis can be a recurring problem. Infection may be polymicrobial, including *Staphylococcus aureus*, *Pseudomonas*, and *Candida*. Antibiotics are indicated in the setting of clinical disease. Stable patients can be treated with amoxicillin-clavulanate, 875 milligrams PO twice daily.[6] Unstable patient should receive piperacillin-tazobactam, 3.375 grams IV, plus vancomycin, 1000 milligrams IV. Use a fluoroquinolone for *Pseudomonas*. Dressing changes with gauze soaked in 0.25% acetic acid are effective for local wound infections.

Tracheostomy Site Bleeding Bleeding can occur at any time after a tracheostomy. Granulation tissue in the stoma, trachea, or thyroid or erosion of the thyroid vessels, the tracheal wall (frequently from suction trauma), or the innominate artery are all sources of hemorrhage. Slow bleeding originating from the stoma may be controlled by packing the site with saline-soaked gauze. If this is ineffective, remove the tube and examine the stoma and tracheal wall. Local bleeding can be controlled with silver nitrate. Electrocautery should be done by a surgeon. If bleeding is brisk, replace the tracheostomy tube with a cuffed endotracheal tube with the cuff below the bleeding site.

Tracheoinnominate artery fistula is a rare but life-threatening complication of tracheostomy. Cuff pressure >25 mm Hg, tracheostomy below the third tracheal ring, and deformed neck or chest are all risk factors.[7] Bleeding results from vessel erosion caused by either direct pressure of the tip of the tracheal cannula against the innominate artery or from a cuff with inappropriately high pressures due to overinflation. Most patients with a tracheoinnominate artery fistula present within the first 3 weeks after tracheostomy, with the peak incidence between the first and second week. Some patients may have a sentinel arterial bleed or hemoptysis. Bleeding may be mild or severe and should be thoroughly investigated because of the potential for sudden massive hemorrhage.[8] Immediate otolaryngologic and thoracic surgery consultation is required, and operative repair is lifesaving.

If patients present with massive bleeding, the first maneuver is to hyperinflate the cuff to control brisk bleeding while planning operative intervention. If bleeding persists, slowly withdraw the tube while exerting pressure against the anterior trachea. If these interventional maneuvers do not control the bleeding, then place a cuffed endotracheal tube from above to prevent pulmonary aspiration of blood. Passing the endotracheal tube past the tracheoinnominate fistula will require direct visualization with a flexible nasopharyngoscope or bronchoscope through the tube and an assistant to withdraw the tracheostomy tube as the endotracheal tube passes.[5] **Stomal hemorrhage is then controlled with digital pressure of the innominate artery against the manubrium.** This is known as the Utley maneuver.[9] Tamponade of the hemorrhage should be maintained during transport to the operating room, as the patient will need emergent surgery with rigid bronchoscopy.

Tracheal Stenosis Tracheal stenosis may present weeks to months after decannulation and results from mucosal necrosis and subsequent scarring. Signs and symptoms include dyspnea, wheezing, stridor, and the inability to clear secretions. A chest radiograph may demonstrate the narrowed tracheal airway. Medical treatment includes humidified oxygen, nebulized racemic epinephrine, and steroids. Operative treatment involves rigid bronchoscopy with laser excision of the scar bands, and stenting or tracheal reconstruction in more severe cases.

MECHANICAL VENTILATION WITH A TRACHEOSTOMY TUBE

If the patient requires mechanical ventilation, an uncuffed tracheostomy tube will result in a large air leak, and it will be difficult to ventilate the patient. In this case, the uncuffed tube should be exchanged for a cuffed tube. If a tracheostomy tube is not readily available, an endotracheal tube may be inserted into the stoma to maintain airway security. If the

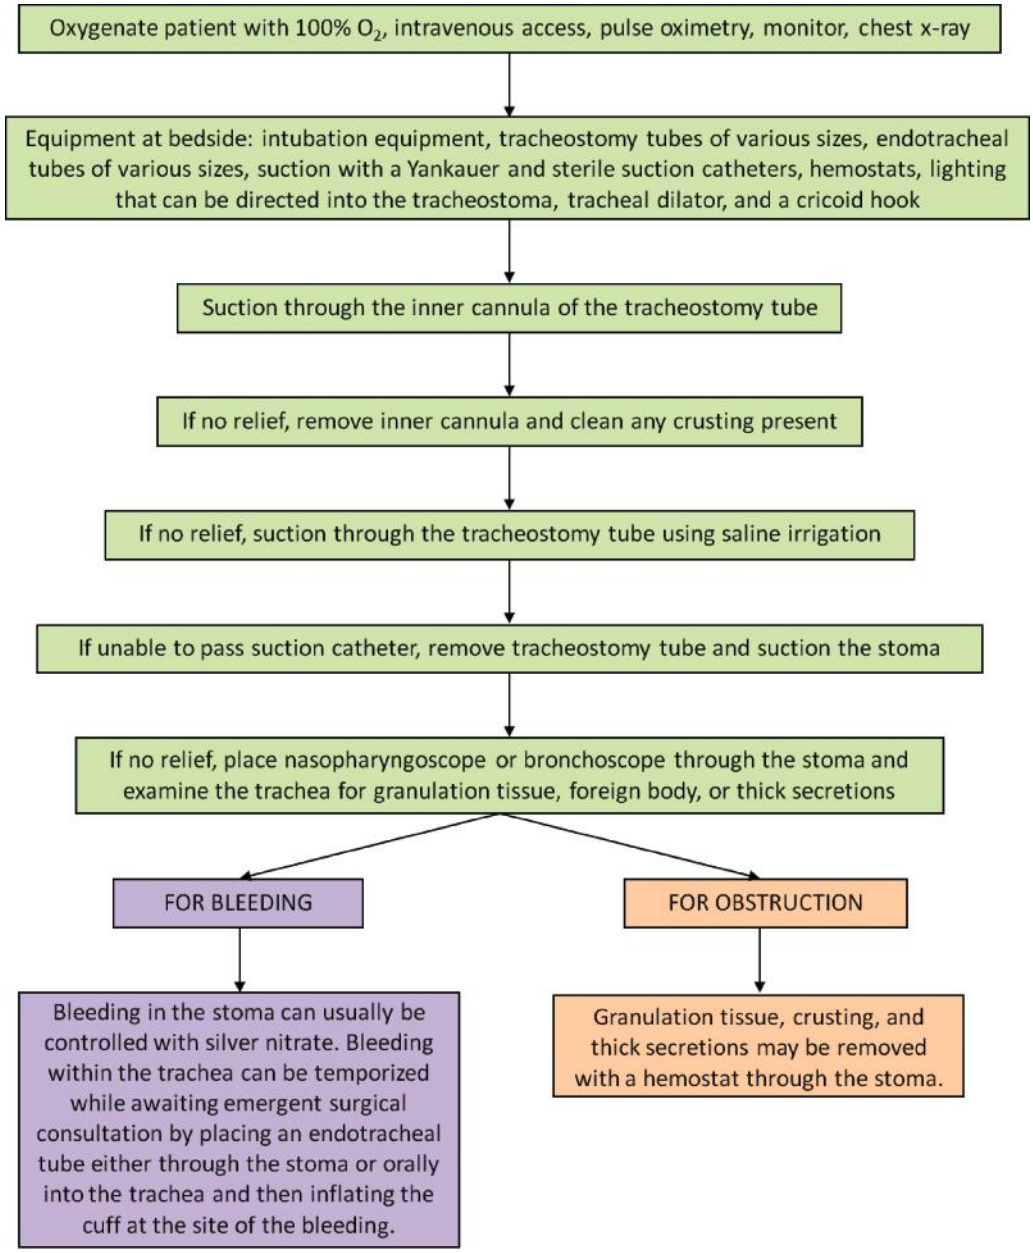

FIGURE 247-2. Steps in assessing a tracheostomy patient with respiratory distress.

stoma cannot be cannulated, the patient may be orotracheally intubated to secure the airway—unless the patient has a laryngectomy (see the following "Larnygectomy Patients" section).

CHANGING A TRACHEOSTOMY TUBE

The amount of difficulty encountered when changing a tracheostomy tube depends on when the procedure was performed and on patient anatomy. **If the tracheostomy is <7 days old, the tract will not be mature and manipulation may easily create a false passage within the soft tissue of the neck. In addition, a tract may easily collapse at any time in patients with obese necks or neck masses. If the situation is not emergent and the tracheostomy is <7 days old, tracheostomy tubes should be changed by a surgeon familiar with the procedure.**

An uneventful tracheostomy change depends on adequate preparation and is best accomplished with an assistant. The spontaneously breathing, stable patient can easily breathe through a patent stoma without the tube in place, so there is no reason to rush through this procedure. The needed equipment is listed in **Table 247-1**. If a cuffed tube is used, test the balloon before use and make sure the balloon is completely deflated before insertion. A cricoid hook can be inserted just under the cricoid and used to lift and stabilize the trachea. The dilator is particularly useful if a larger tube is to be inserted, but if dilation is needed and time permits, obtain surgical consultation. Dilation may require injection of local anesthesia. Become familiar with the cricoid hook and tracheal dilator before using them. To minimize soft tissue damage, use an obturator whenever a tracheostomy tube is replaced. When the obturator is placed within the outer cannula, the tube presents a solid, rounded end that is less likely to damage the neck soft tissue during tube insertion (Figure 247-1). **After placement, quickly remove the obturator and place the inner cannula, because the patient cannot breathe through the tracheostomy tube when the obturator is in place.**

Once the equipment is ready, place the patient supine with a shoulder roll to extend the neck. Remove the old tube and gently suction and examine the stoma. In most cases, the opening in the trachea and the posterior tracheal wall can be seen. Gently direct the fresh tube with the balloon deflated into the opening, curving it downward into the trachea (**Figure 247-4**). The movement should be smooth and gentle. If resistance

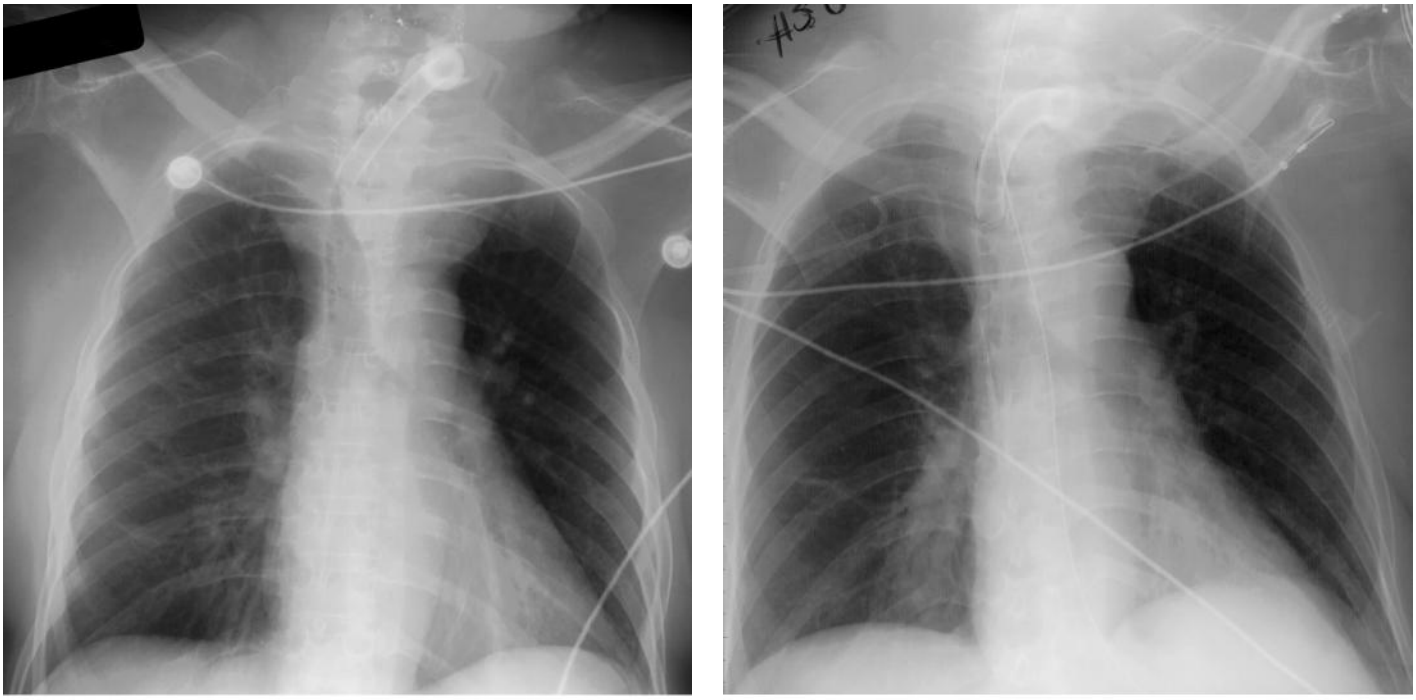

FIGURE 247-3. **A.** Patient with a large goiter and a No. 4 Shiley tracheostomy tube with the tip of the tube outside the trachea and compressing the tracheal wall. **B.** Same patient with a longer No. 6 Shiley tracheostomy tube with the tip of the tube correctly placed inside the trachea.

is met, the tube is likely caught on the cartilaginous tracheal wall. Remove the tube and reexamine the stoma, and again place the tube directly into the tracheal opening. If the tube still cannot be placed, consider placing a smaller tracheostomy tube. **However, a smaller tube will also be shorter and may not be long enough for the patient's neck.** Another helpful method is to place a small suction catheter or nasogastric tube into the trachea and thread the tracheostomy tube over the catheter using a modified Seldinger technique.

Once the tube is in place, verify correct tube position by inserting a suction catheter into the tube or attaching an end-tidal carbon dioxide detector. It should easily pass beyond the length of the tracheostomy tube without resistance. If there is a question about placement, pass a nasopharyngoscope or flexible bronchoscope through the tube for direct visualization of placement or obtain an x-ray.

Patients with accidental decannulation who are not in distress can have the tracheostomy tube replaced as described. **If the tube has been out for several hours, the stoma may begin to close and dilation may be needed before tube insertion.** In these cases, and if the stoma is small or the tracheostomy is the patient's only airway, ear, nose, and throat or surgical consultation is recommended for tube replacement.

LARYNGECTOMY PATIENTS

It is impossible to orally intubate patients who have had a laryngectomy. The only access to the tracheobronchial tree is through the tracheostoma in the neck. Occasionally, laryngectomy patients will have a laryngectomy tube in the stoma, similar in appearance to a tracheostomy tube. Laryngectomy patients can be distinguished from tracheostomy patients by history and physical examination and by the fact that laryngectomy patients are unable to vocalize (or breathe) when the laryngectomy tube is occluded. **Laryngectomy patients can be emergently intubated by placing an endotracheal tube into the tracheostoma.** Do not advance the tube too far, as the carina may be only 4 to 6 cm from the tracheostoma.

TABLE 247-1 Equipment Needed to Change a Tracheostomy Tube

Good lighting directed into the tracheostoma
An appropriate size tracheostomy tube with obturator in place
Another tracheostomy tube one size smaller than planned
Tracheostomy tube tie
Cricoid hook and tracheal dilator (if physician is familiar with their use)

LARYNGEAL STENTS

The surgical management of severe laryngotracheal stenosis often employs the insertion of tracheal stents for various periods of time. Placement of an endolaryngeal stent renders a patient tracheostomy dependent until the stent is removed because the solid stent blocks the airway at the level of the larynx (**Figure 247-5**). **Stents and their associated tracheostomy tubes should only be removed by a surgeon familiar with the devices and their placement.** There are many different endolaryngeal stent designs and materials, including silastic molds secured by cutaneous buttons (a stent secured by a strap that exits the tracheal stoma and is attached to the skin), the Aboulker stent complex (a metal tracheostomy tube wired to a silastic stent used in pediatric airway reconstruction), and the Montgomery T-tube stent (**Figure 247-6**). Although endolaryngeal stents are secured by buttons or straps, dislodgement is a known complication of these devices. If a stent becomes dislodged but the tracheostomy tube remains in position, airway security is usually not an issue. Consult the otolaryngologist for extrusion or dislodgment of a stent.

The Montgomery T-tube configuration is commonly used in adult laryngotracheal reconstruction.[10] It is a modification of a tracheostomy tube that does not have an inner cannula. Humidification and suctioning of the T-tube is essential to prevent mucous plugging. These tubes are also used in tracheal stenosis as a bridge to surgery, a treatment for those patients who are not surgical candidates, and in cases where there is a long segment of stenosis.[10] Airway obstruction should be addressed by first suctioning both the upper and lower limbs of the T-tube (**Figure 247-6**). If suctioning both limbs of the T-tube does not

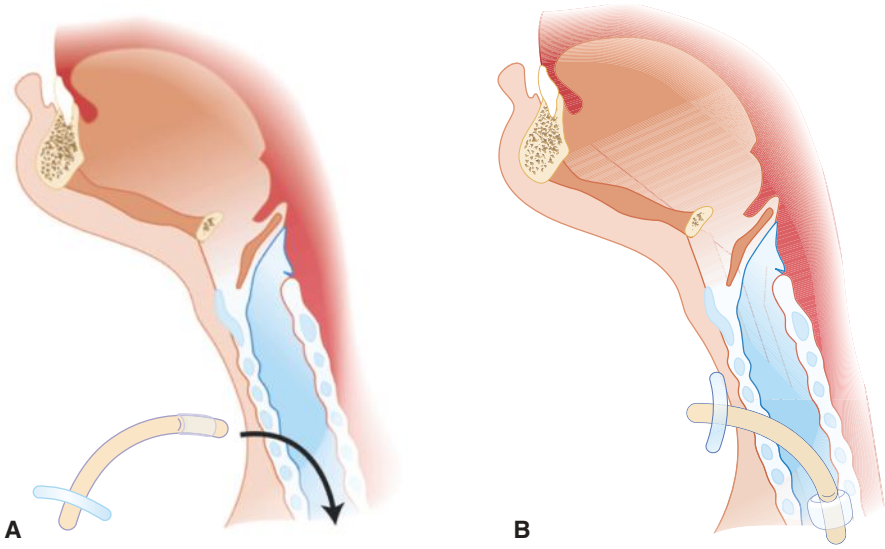

FIGURE 247-4. Insertion (**A**) and placement (**B**) of the tracheostomy tube. Cuffed tubes should be inserted with the cuff deflated.

relieve the obstruction, the T-tube should be removed and the trachea cannulated with an appropriately sized tracheostomy tube or an endotracheal tube. Do not try to use a bag-valve device through the T-tube because most tubes do not take a standard 15-mm connector.[11] Removal requires a strong, steady pull on the T-tube and should only be attempted if the operating surgeon is unavailable or the patient is in airway distress.

SPEECH DEVICES

The Passy-Muir valve is a one-way valve that fits directly over the opening of an uncuffed tracheostomy tube and allows the patient hands-free speech. When the patient inhales, the valve opens and allows air to pass into the trachea and lungs. Speech is created when the patient exhales with enough force to close the Passy-Muir valve. The exhaled air is directed around the tracheostomy tube and through the vocal cords (**Figure 247-7**). Because the patient exhales around the tracheostomy tube, **a Passy-Muir valve should never be used with a cuffed tube.** If a patient with a Passy-Muir valve develops signs of airway obstruction or an inability to speak, the speaking device should be removed from the tracheostomy tube so that air can pass freely during both inhalation and exhalation. If this does not relieve symptoms, check the tracheostomy tube itself for obstruction.

A tracheoesophageal prosthesis allows speech in postlaryngectomy patients. This one-way valve is surgically placed between the posterior wall of the tracheal stoma and the anterior wall of the cervical esophagus. To speak, patients exhale while occluding the stoma with their thumb or finger, thus forcing the exhaled air into the esophagus. The air vibrates the esophagus (as a belch does), and the resultant tone is used to provide speech (**Figures 247-8 and 247-9**).

The most common complication associated with tracheoesophageal prosthetic valves is leakage, either around the valve or through the valve lumen. Both types of leakage may be confirmed by looking at the prosthesis while the patient drinks a colored liquid (e.g., grape juice). Leakage commonly occurs due to enlargement of the tracheoesophageal fistula.[12]

Leakage increases the risk of aspiration pneumonia. A temporary solution to a leaking valve begins with removal of the entire prosthesis and replacement with a larger Foley catheter into the tracheoesophageal fistula. This will prevent the tracheoesophageal fistula from closing completely as the fistula contracts in size. Leakage through a voice prosthesis

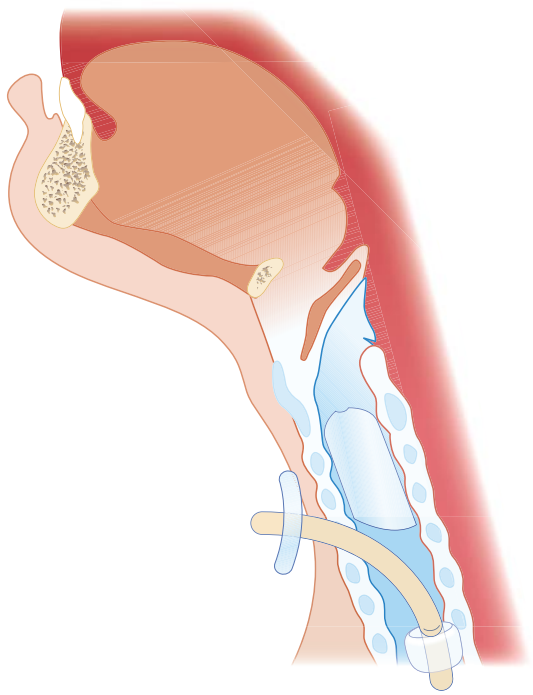

FIGURE 247-5. Relation of the tracheostomy tube to the laryngeal stent. The stent lies within the lumen of the trachea, superior to the tracheostomy tube.

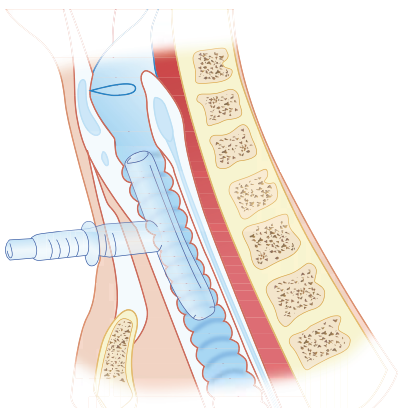

FIGURE 247-6. Suctioning is required of both the upper and lower limbs of the Montgomery T-tube. If necessary, the entire T-tube can be removed.

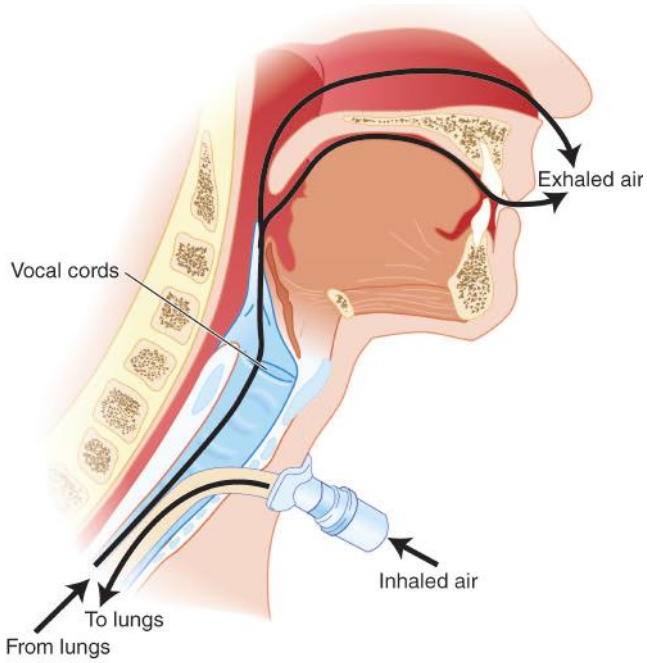

FIGURE 247-7. The Passy-Muir valve is a one-way valve that fits directly on the opening of the tracheostomy tube. Speech is created when the patient exhales as air is passed up through the vocal cords and out of the mouth.

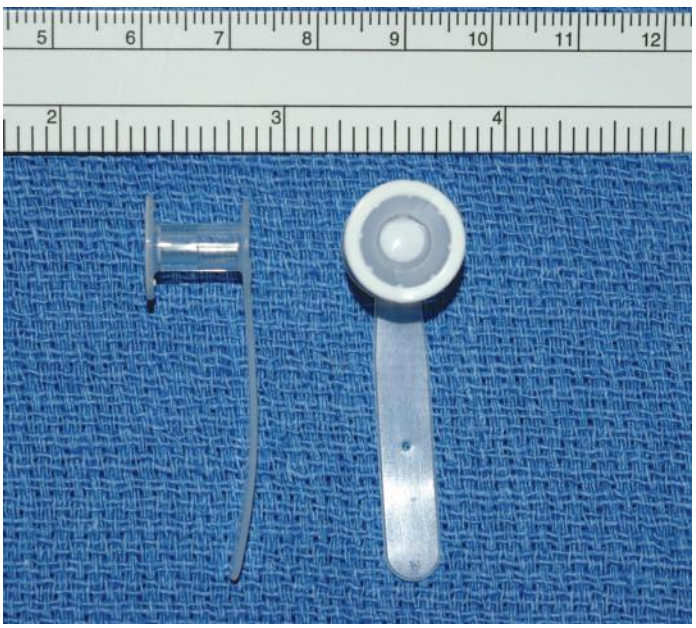

FIGURE 247-8. Tracheoesophageal prosthesis. The bobbin-shaped device is placed with the smaller flange in the esophagus and the tagged flange in the posterior tracheostoma.

FIGURE 247-9. Tracheoesophageal prosthesis in place in a laryngectomy patient. The prosthesis is in place, and the tag is usually held with tape. Finger occlusion of the tracheostoma with exhalation leads to increased airway pressure, which opens the one-way valve and allows air to enter the esophagus. This vibrates and allows the patient to speak.

is predominantly due to valve damage caused by fungal colonization or contact of a duckbill-style device against the posterior esophageal wall and is treated by replacement of the prosthesis with a temporary tube (usually a Foley catheter). Once a Foley catheter is placed and secured, the patient is unable to speak. Arrange otolaryngologist follow-up the next day. Do not inflate the balloon on the Foley catheter, as this will interfere with swallowing.

Another common complication with tracheoesophageal prostheses is valve aspiration or valve extrusion. A loose valve or coughing while changing a valve can result in aspiration of the valve into the airway. Aspiration results in persistent cough, dyspnea with discomfort, and even respiratory distress. If there is suspicion of aspiration or if the prosthesis is dislodged, obtain a chest x-ray to visualize the radiopaque valve and consult an otolaryngologist. The tracheoesophageal puncture tract will close quickly, typically within 24 to 48 hours after the tube is dislodged. A Foley or red rubber catheter inserted into the tract will maintain its patency. **Do not attempt temporary catheter placement if the tract is <2 weeks old, as a false passage may result.**

Pharyngeal stricture and stomal stenosis are other complications associated with tracheoesophageal prosthetic valves.[13] Granulation tissue and polyp formation around the valve prosthesis may also occur and dislodge or obstruct airflow and prevent speech. Application of silver nitrate cauterization will treat the granulation tissue, but it is critical that a portion be sent to pathology to verify the histopathology of the tissue.

Whenever a patient presents to the ED with a complication due to an airway device, the provider should be able to troubleshoot many of the common problems. If there is concern, it is advisable to consult an otolaryngologist.

CHAPTER 248

Initial Evaluation and Management of Skin Disorders

William Rushton
Joseph M. Grover
William J. Brady

INTRODUCTION

Most ED chief complaints involving skin lesions are due to infections, irritants, and allergies.[1] Visual pattern recognition is the key to diagnosis. The recommended approach for the diagnosis of a skin disorder in the ED (assuming resuscitation or stabilization is not required) is to:

1. Determine the chief complaint.
2. Obtain a brief history (duration, rate of progression, and location of lesions).
3. Perform the dermatologic examination (morphology and extent of distribution).
4. Formulate the age-appropriate differential diagnosis based on lesion morphology and distribution.
5. Elicit additional concerns from the history (associated complaints, comorbidity, medications, or exposures), and include or exclude syndromes in the differential diagnosis based on this information.
6. Evaluate for systemic involvement, and consider ancillary investigations, if necessary.
7. Obtain dermatologic consultation, if necessary, and arrange for appropriate referral (primary care or dermatologic).

DIAGNOSTIC APPROACH

HISTORY

Determine the chief complaint and obtain a brief history (discomfort, duration, rate of progression, percentage of body surface involvement, and location of lesions). The secondary history should include issues relating to the lesion: morphology, evolutionary nature, rate of progression, and distribution. Associated systemic complaints and mucosal systems must be identified. Ask about exposures, immunizations, toxins, chemicals, foods, animals, insects, plants, and ill contacts. Sexual history, if appropriate, and medical and family histories should be reviewed. If applicable, a detailed occupational history should be obtained; industrial exposure may be the causative etiology. Asking about medication use, sun exposure, travel history, or particular food ingestion also may yield helpful information. Be sure to include any other housemates or partners in your history of exposures; contact dermatitis can occur from exposure to fragrances or other products that a partner is using.[2] The patient should also be asked about the degree of discomfort of the dermatoses; a painful dermatitis is often a red flag and is not usually associated with a self-limiting lesion.[3]

A detailed medication history is important and particular attention should be paid to recently started drugs or dosage increases. Erythema multiforme, exfoliative dermatitis, photosensitivity reactions, toxic epidermal necrolysis, and vasculitis are common medication-induced drug reactions. Dermal necrosis should prompt consideration of anticoagulant use, whereas a diffuse rash in a patient on sulfa drugs, anticonvulsants, or some antimicrobials may aid the clinician in diagnosing Stevens-Johnson syndrome or toxic epidermal necrolysis.

EXAMINATION

The patient should be gowned and in a room with adequate lighting and appropriate privacy to allow entire skin examination. Inspect all skin and mucosal surfaces, including hair, nails, scalp, and mucous membranes. Then evaluate the specific skin lesions. A magnifying lens and a portable light are helpful aids.

Examine the skin systematically. Determine the **distribution, pattern, arrangement, morphology, extent, and evolutionary changes** of the lesions. **Distribution** is the location of the skin findings, and the **pattern** is their anatomic, functional, and physiologic arrangement. For example, a unilateral band-like arrangement of lesions on the thorax suggests varicella-zoster virus infection. Skin diseases often present with a predilection for certain body areas; the distribution of lesions will assist in narrowing the diagnostic possibilities. From the anatomic perspective, the skin surfaces that are usually considered as separate areas of distribution are generalized body; face and scalp; trunk and axillae; groin and skin folds; and hands, feet, and nails. The extremities may be further subdivided into upper versus lower, proximal versus distal, wrists versus ankles, and hands versus feet.

In a patient with diffuse erythema in whom toxic shock syndrome is suspected, the presence of a foreign body such as a retained tampon should be investigated. Petechia should prompt the investigation of meningococcemia or Rocky Mountain spotted fever. Rashes on exposed portions of the skin should prompt inquiries about sun exposure, jewelry, topical agents, or exposures. See **Table 248-1** for a differential diagnosis of skin lesions as a function of location, including both distribution and pattern considerations.

Use the burn **rule of nines** (see chapter 216, "Thermal Burns") to estimate the degree of skin involvement in disorders with widespread distribution. This calculation also may be used to determine the amount of topical medication required for a specific treatment course or whether an oral medication might be more appropriate. Extensive erythroderma (often >90% of body surface area) is a dermatologic emergency.[3,4] Severe erythroderma can represent underlying severe infectious dermatitis, toxic shock syndrome, cutaneous T-cell lymphoma, drug reaction, psoriasis, or seborrheic dermatitis.

TABLE 248-1 Differential Diagnosis Relative to Lesion Distribution and Pattern

Distribution and Pattern	Differential Diagnosis
Flexor surfaces	Atopic dermatitis, candidiasis, eczema, ichthyosis
Sun exposure (face, upper thorax, distal extremities)	Sunburn, photosensitive drug eruption, photosensitive dermatitis, systemic lupus erythematosus, viral exanthem, porphyria
Distal extremities	Viral exanthem, atopic or contact dermatitis, eczema, Rocky Mountain spotted fever, gonococcemia
Front and back of chest	Pityriasis rosea, secondary syphilis, drug eruption, atopic or contact dermatitis, psoriasis
Clothing covered (thorax and distal lower extremities)	Contact dermatitis, psoriasis, folliculitis
Acneiform (face and upper thorax)	Acne, drug-induced acne, irritant dermatitides

Lesion arrangement refers to the symmetry and configuration. Bilateral symmetry suggests a systemic internal event or symmetric external exposure, as seen in erythema multiforme, with plaque-like lesions on the flexor surfaces of the extremities, or contact dermatitis related to a lotion application. An asymmetric arrangement supports a localized process. *Configuration* may apply to a single lesion with reference to its individual features or, alternatively, to multiple lesions and their relation to one another. For instance, internal configuration is illustrated by the relation between the central papule relative to the erythematous ring in the target lesion of erythema multiforme; on the total-body scale, configuration is demonstrated by clustering of lesions in a herpesvirus infection or by a linear arrangement as with a reaction from poison ivy or oak. Other terms used to describe the lesion configuration are listed in **Table 248-2**.

Recognition of the primary lesion is vital in establishing the diagnosis; the use of the primary lesion's **morphology** is very important regarding the generation of an appropriate differential diagnosis and ultimately the correct dermatologic diagnosis. The primary lesion is the one that has not been altered by secondary issues, including healing, complicating infection, medication application, or scratching. Examples of primary skin lesions are macules, papules, nodules, tumors, cysts, plaques, wheals, vesicles, bullae, and pustules. Careful attention should be paid to a nonblanching lesion. Secondary lesions have had their appearance altered due to disease evolution or various external factors, as noted earlier, and include crusts, scales, fissures, erosions, ulcerations, excoriations, atrophy, scarring, and lichenification. See **Table 248-3** for a listing and descriptions

TABLE 248-2 Lesion Configuration Descriptors

Descriptor	Configuration
Annular	Ring-like or pertaining to the outer edge
Arcuate	Curved or pertaining to the curve
Circinate	Circular
Confluent	Blending together
Dermatomal	Belt-like or limited to one side of the body in anatomic dermatome
Discoid	Solid, round, slightly raised, or pertaining to a disk
Discrete	Separate or individual
Grouped	Clustered
Guttate	Scattered
Gyrate	Coiled or winding
Herpetiform	Creeping
Iris	Concentric circles
Linear	In a line
Polycyclic	Overlapping circles or borders of irregular curves
Retiform	Net-like
Serpiginous	Snake-like

of the various morphologic descriptors of dermatologic lesions; see **Tables 284-4 and 284-5** for a differential diagnosis of the various skin disorders relative to primary and secondary lesion morphologies.

DIAGNOSTIC TECHNIQUES

A potassium hydroxide preparation is used in patients with suspected molluscum contagiosum and dermatophytic infections. The test is performed on loose skin scales, nail parings, subungual debris, short residual hairs, or small pearly globules (from a molluscum body). Test steps are in **Table 248-6**.

The material is then viewed under a microscope at low power, with the condenser and light at low levels. As the slide is scanned, rapidly focus up and down. True hyphae (**Figure 248-1**), seen in dermatophytic infections, are long, branching, green rods of constant width that cross the borders of epithelial cells. Molluscum bodies are oval

discs with homogeneous cytoplasm (**Figure 248-2**). In hair fragments, the organisms appear as small, round spores packed closely within the hair shaft.

Scabies and lice preparations are useful in patients with possible infestation. In scabies infestations, the rash itself may resemble other dermatologic syndromes; microscopic analysis will confirm the diagnosis. The donor site for skin specimen selection is very important. The best sites include burrows (10 mm, elongated papule with a pustule or vesicle) and papules on the fingers, wrists, and elbows (**Figure 248-3**). Within the vesicle or pustule, a small black dot is noted, which is the mite. The point of the scalpel is scraped across the lesion while holding the skin taut; the mite is then removed. A single drop of mineral oil may be applied to the blade to ensure that the scrapings adhere to the instrument. The material is then placed on the microscope slide with an additional drop of mineral oil; gentle pressure on the coverslip will flatten thick specimens. Using low power, the slide is scanned for presence of the mite, eggs, or feces. Mites are eight-legged creatures that are easily identified on thin smears; thick specimens may require additional viewing to look for the mite. Additional findings supportive of the diagnosis include eggs (smooth ovals) and feces (clusters of red-brown pellets; **Figure 248-4**). Lice are usually found on the scalp, eyelashes, and pubic areas and may be visible to the unaided eye (**Figure 248-5**).

TABLE 248-5 Differential Diagnosis of Selected Skin Disorders Relative to Secondary Lesion Morphology*

Lesion Morphology	Differential Considerations	Images
Scales	Psoriasis, pityriasis rosea, toxic and infectious erythemas, syphilis (secondary), dermatophytic infection (tinea), tinea versicolor, xerosis (dry skin), thermal burn (first degree)	
Crusts	Eczema, dermatophytic infection (tinea), impetigo, contact dermatitis, insect bite	
Erosions	Candidiasis, dermatophytic infection (tinea), eczema, toxic epidermal necrolysis, toxic-infectious erythemas, erythema multiforme, primary blistering disorders (bullous pemphigoid and pemphigus vulgaris), brown recluse spider envenomation	
Ulcers	Aphthous lesions, chancroid, decubitus ulcer, thermal or friction injury, subacute or chronic ischemia, malignancy, chancre (primary syphilis), primary blistering disorders (bullous pemphigoid and pemphigus vulgaris), brown recluse spider envenomation, pyoderma gangrenosum, stasis ulcer, factitial ulcer	

*This list is not exhaustive, but it represents the more common syndromes likely to be encountered by the emergency physician.

The **Tzanck smear**, useful in blistering disorders, assists in establishing the diagnosis of a herpes infection: herpes simplex, herpes zoster, and varicella. The choice material for examination is obtained from the base of a recently unroofed lesion; purulent fluid at the base of the lesion is removed with a scalpel and placed on a microscope slide. The material is allowed to air dry and then is stained with Giemsa or Wright stain. Using low power, the slide is scanned for epithelial cells. Multinucleated giant cells (**Figure 248-6**), indicative of a herpes infection, are a syncytium of epidermal cells with multiple overlapping nuclei. The presence of the multinucleated giant cell does not distinguish between herpes simplex, herpes zoster, and varicella syndromes.

Wood's light examination is helpful in several different situations, including erythrasma (a superficial *Corynebacterium* infection of moist skin in the groin, axilla, and web spaces), fungal infections caused by *Malassezia* species or *Microsporum* species, certain pseudomonal skin infections, and porphyria cutanea tarda. Wood's light is an ultraviolet source that emits light at a wavelength of 365 nm. The following fluorescent findings are noted in these conditions: erythrasma, red or pink; tinea, green or yellow; *Pseudomonas*, yellow or green; and porphyria cutanea tarda, urine fluoresces orange or red (**Figure 248-7**).

Ancillary studies may also be required to assess for systemic involvement. Fever and leukocytosis may be indicative of an underlying infectious disorder or an underlying autoimmune reaction. In patients on anticonvulsants, elevated transaminases may represent underlying DRESS syndrome (drug reaction with eosinophilia and systemic symptoms). Furthermore, disseminated intravascular coagulation, thrombocytopenia, and acute kidney injury may alert the astute clinical to underlying bacteremia or toxic shock syndrome.[3] Imaging may be required to rule out foreign bodies or to assess to depth of tissue involvement in conditions such as Fournier's gangrene.

ED TREATMENT

SYSTEMIC CORTICOSTEROIDS

Systemic corticosteroids are the treatment of choice for some generalized conditions and are discussed in the chapters dealing with specific diagnoses. Some severe widespread dermatologic syndromes, such as erythema multiforme, toxic epidermal necrolysis, and vasculitis, are best

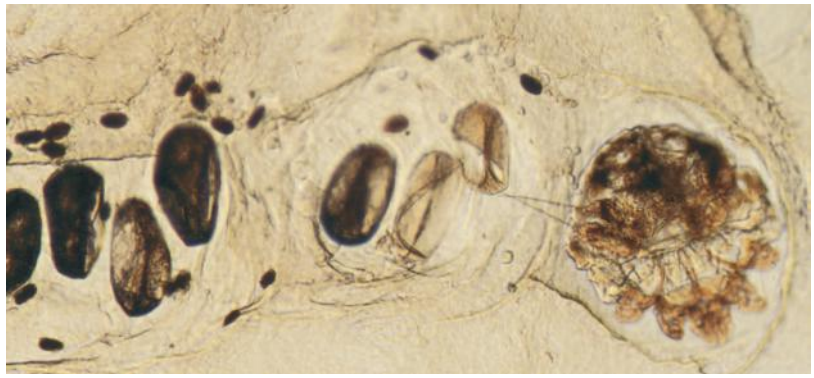

FIGURE 248-4. Microscopic view of a scabies mite with visible eggs and feces. [Reproduced with permission from Wolff KL, Johnson R, Suurmond R: *Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology*, 5th ed. © 2005, McGraw-Hill, New York.]

treated with systemic steroids only after consultation with a dermatologist. Other disorders, including urticaria, angioedema, *Toxicodendron* dermatitis (rhus, poison ivy, or poison oak), and other contact or allergic disorders are potential indications for systemic corticosteroids when an extensive area of skin (>20%) is involved. Patients with severe disease can see significant relief with oral corticosteroids within 12 to 24 hours.[5] In one study, small bursts of prednisone (40 milligrams daily for 4 days) markedly reduced the pruritus and hastened the clinical improvement of urticaria.[4,6] Patients with poison ivy or oak eruptions who require systemic steroids should be treated with oral prednisone (1 milligram/kg body weight) with a slow 2- to 3-week taper to avoid rebound dermatitis. Other contact or allergic dermatitides may benefit from an abbreviated course (4 days) of oral prednisone. However, oral corticosteroids are relatively contraindicated, or must be used with great care, in those with diabetes, hypertension, active peptic ulcer disease, psychiatric disease, and immunodeficiency. Follow-up within 2 to 3 days with the primary care physician or a dermatologist is needed if oral corticosteroids are prescribed to patients with these comorbidities.

TOPICAL CORTICOSTEROIDS

Topical corticosteroids are powerful and useful tools in the management of dermatologic disease. Numerous agents are available for use. They differ in concentration, base components, and cost. Familiarity with a single agent in each potency class is sufficient to treat any steroid-responsive skin ailment safely and effectively. Corticosteroid potency or strength (i.e., the anti-inflammatory property) is measured by the agent's ability to induce vasoconstriction. Agents' strengths are rated by vasoconstricting ability on a scale of 1 to 7 group 1 agents are the most powerful corticosteroids, and group 7 medications are the least potent (**Table 248-7**). In general, ointments are more potent than creams or lotions.

Topical Corticosteroid Strength Marked variation in potency is seen across various corticosteroids, whereas much smaller differences in strength are encountered for different concentrations of individual agents. Many corticosteroids are fluorinated. Fluorination greatly increases the potency but also increases the risk of adverse reactions, and **fluorinated formulations should not be used in pregnancy**.

Use of the appropriate-strength topical steroid is strongly encouraged at the start of therapy. Starting with a less powerful agent is not likely to spare the patient from potential adverse effects or to produce adequate control of the disease. **Hydrocortisone**, perhaps the most frequently used topical corticosteroid in the outpatient setting, is available over the counter in strengths up to 1% and by prescription in strengths to a maximum of 2.5%. Hydrocortisone is safe and may be used on most body surfaces, including the face, genitalia, flexure creases, and intertriginous zones. It also is safe for use in infants and children. For the treatment of diseases involving the palms and soles, hydrocortisone is a poor choice, because the thickened skin does not allow adequate penetration of this relatively low-potency steroid. Corticosteroids of moderate potency, including **triamcinolone acetonide and fluocinolone acetonide**, are useful in treating severely inflamed skin and the thicker skin of the scalp, trunk, extensor surfaces, palms, and soles. These agents should not be applied to the face or genitals or used in infants because of the risk of skin atrophy. See **Table 248-8** for recommendations on the potency of corticosteroid to use in treating various dermatologic diseases. When using agents found in group 6 or 7, consultation with a dermatologist may be advised.

Different skin surfaces respond differently to topical corticosteroid therapy; this differential response relates to the absorption of the steroid into the deeper tissues. The relatively thin skin surfaces of the face respond very rapidly to the use of group 7 agents, whereas the thicker

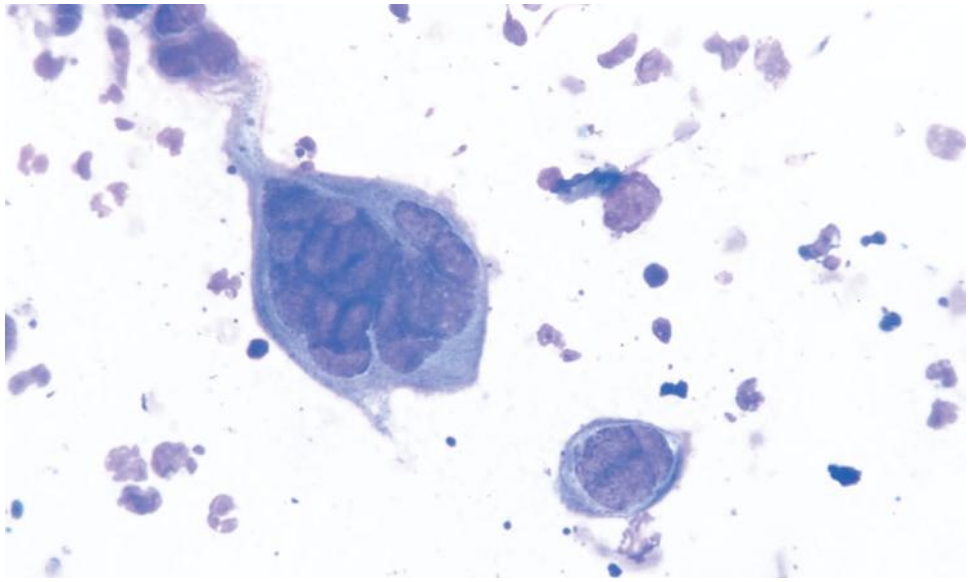

FIGURE 248-6. Tzanck smear under microscopy showing a multinucleated giant cell, indicative of a herpetic infection. [Reproduced with permission from Wolff KL, Johnson R, Suurmond R: *Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology*, 5th ed. © 2005, McGraw-Hill, New York.]

skin of the palms and soles requires a highly potent steroid. Irritations for which a low-potency agent may provide the same treatment effectiveness as a higher potency agent include those involving raw, inflamed skin (such skin absorbs medication more rapidly and readily); treatment regions with skin surfaces in frequent contact, such as intertriginous areas (the apposition of two skin surfaces produces enhanced absorption of drug, similar to the effect of an occlusive dressing); and areas of skin under tight clothing, such as the diaper area (absorption of the agent is enhanced due to the occlusive effect of the garment). In general, lower potency agents are acceptable in these situations.

Application of Topical Steroids The application of creams, ointments, gels, and lotions is relatively straightforward. The medication is applied in a thin layer and should be massaged daily into the skin, as directed. Washing the skin before corticosteroid application is unnecessary. Advise patients to follow directions closely both early and late in the treatment course. Using extra medication per dose or applying medication more frequently early in the treatment period is not desirable; likewise, reducing the frequency of application or decreasing the amount of medication as the disease process responds to therapy can cause relapse. Optimal application regimens have not been determined for topical corticosteroids in most dermatologic syndromes. The more potent agents are best applied two to three times daily for 1 to 2 weeks followed by a drug-free week; additional therapy may be required as determined by the disease and by the particular patient's response to the initial therapy. Agents from the less potent steroid groups may be applied three times daily for 2 to 4 weeks followed by a 7-day steroid-free period.

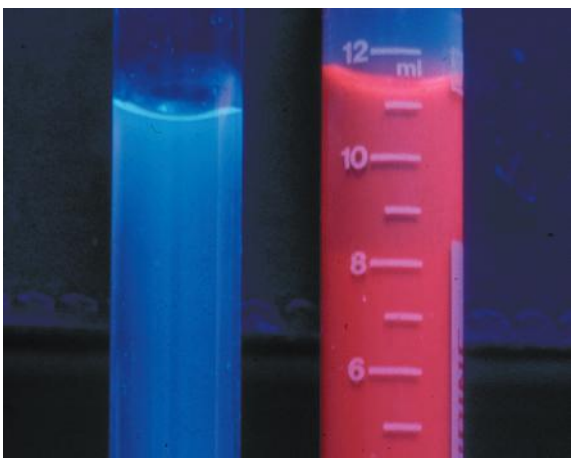

FIGURE 248-7. Pink coloration of the urine of a patient with porphyria cutanea when exposed to the light of a Wood's lamp. [Reproduced with permission from Wolff KL, Johnson R, Suurmond R: *Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology*, 5th ed. © 2005, McGraw-Hill, New York.]

Prescribing the Correct Amount of Topical Steroid Determining the correct amount of topical steroid to prescribe is at times difficult. The burn rule of nines may be used to estimate the amount of topical corticosteroid to prescribe. Calculate the percentage of body surface area requiring therapy and then multiply the percentage by a correction factor of 30. This calculation provides the amount of topical corticosteroid in grams for a single application. Next, determine the number of administrations required in the treatment course. For example, a three-times-daily regimen for a duration of 10 days requires 30 applications. The number of applications is multiplied by the grams required for a single dose to yield the total amount to be prescribed (**Table 248-9**). In general, 9 grams of topical steroid cover 9% of the body surface area for 1 day with a thrice-daily application. See **Table 248-10** for a description of the amount of topical corticosteroid to be dispensed relative to the coverage area and duration of therapy.

Avoid Tachyphylaxis *Tachyphylaxis* refers to the decrease in responsiveness to a drug as a result of enzyme-mediated events. The term is used in relation to topical corticosteroids to describe the early development of tolerance to vasoconstricting ability. In general, vasoconstriction has been demonstrated to decrease progressively over time after a topical steroid has been applied. Such reductions in strength due to tolerance are encountered as soon as 4 days into the treatment course in all potency groups but are thought to be more important for corticosteroids in groups 1 and 2. A reasonable strategy to counter the development of tachyphylaxis is the use of interrupted application schedules. An interrupted treatment course might include an initial three-times-daily application for 2 weeks, followed by 1 week without use of the drug, and then a repeat of the cycle.

ANTIHISTAMINES

Antihistamines (histamine-1 antagonists) are useful to control pruritus. These agents include the first-generation antihistamines such as diphenhydramine and hydroxyzine. These histamine-1 antagonists may be used PO, IM, or IV. The second-generation antihistamine agents, including astemizole, cetirizine, fexofenadine, and loratadine, are newer

TABLE 248-7 Examples of Topical Corticosteroid Agents by Potency Group*

US Classification	British Classification	Representative Topical Agent	Formulation
1: Superpotent	1: Very Potent	Clobetasol (Temovate, Clobex) Halobetasol (Halonate, Ultravate) Betamethasone (Diprolene)	0.05% cream or ointment
2: Potent	2: Potent	Fluocinonide (Lidex,Vanos) Halcinonide (Halog) Mometasone (Elocon)	0.05% ointment 0.1% cream 0.1% ointment
3: Upper mid-strength		Betamethasone (Diprolene) Fluticasone (Cutivate) Triamcinolone (Kenalog)	0.05% lotion 0.005% ointment 0.1% ointment
4: Mid-strength		Mometasone (Elocon)	0.1%cream, lotion
5: Lower mid-strength	3: Moderate	Betamethasone (Diprolene) Fluocinolone (Synalar) Fluticasone (Cutivate)	0.1% cream 0.025% cream 0.05% cream
6: Mild		Alclometasone (Alclovate) Desonide (Desonate, Desocort) Triamcinolone (Kenalog)	0.05% cream or ointment 0.05% cream 0.025% cream
7: Least Potent	4: Mild	Hydrocortisone	1% or 2.5% cream, lotion or ointment

Note: Trade names vary. Strength classification can vary. Strength also depends upon the product itself, amount applied, and nature of skin at the application site.

*Preparations are listed by US and British potency groups: Group 1 is most potent, group 7 (British 4) is least potent.

TABLE 248-8 Recommended Corticosteroid Potency for Treatment of Various Dermatologic Diseases

Groups 1 and 2	Groups 3 to 5	Groups 6 and 7
Psoriasis	Atopic dermatitis	Nonspecific dermatitis of face, eyelids, and perineum
Eczema of hand (severe)	Stasis dermatitis	
Poison ivy dermatitis (severe)	Seborrheic dermatitis Tinea	
Atopic dermatitis (severe)	Scabies Nonspecific dermatitis of face (severe)	

TABLE 248-9 Determination of the Correct Amount When Prescribing Topical Steroids

1. Use burn rule of nines to determine percentage of body surface area affected.
2. Percentage of body surface area × 30 = grams of topical corticosteroid per application.
3. Application times per day × number of days of treatment = total number of applications.
4. Total Grams to Prescribe = [% BSA x 30] x [times per day x number of days].

TABLE 248-10 Amount of Corticosteroid Cream to Dispense*

Body Area	Suggested Potency	Amount to Dispense (grams)
Face	Low	45
Arm	Intermediate or low	90
Leg	Intermediate or low	180
Hand or foot	Intermediate or low	45
Forearm	Intermediate or low	45
Chest or back	Intermediate or low	180

*Based on application three times a day for 10 days of therapy.

agents that may be used in certain circumstances. In general, the newer antihistamines offer the advantages of reduced dosing frequency and less sedative effect, but they are more costly. Comparisons of these new medications with hydroxyzine are generally favorable, but differences are not dramatic; comparisons of the various second-generation agents do not demonstrate significant differences among them.[7,8] Increasing the dosage of these antihistamine medications above their recommended dosages may increase the sedative effect but does not provide greater reduction in itching.[9] The use of topical antihistamine preparations is discouraged, because these agents are readily absorbed and dosing is difficult to predict. Accidental overdosage may result in patients who aggressively apply the preparation or are also using similar oral agents. See **Table 248-11** for suggested dosing, administration schedules, and

TABLE 248-11 Antihistamines Useful in the Management of Dermatologic Disease

Medication (trade name)	Adult Dosage	Pediatric Dosage
Diphenhydramine (Benadryl)	25–50 milligrams PO/IV/IM four times a day	5 milligrams/kg/d PO/IV/IM in four divided doses; maximum dose, 300 milligrams/d
Hydroxyzine (multiple trade names)	25–100 milligrams PO three or four times a day	2 milligrams/kg/d PO in four divided doses
Cetirizine* (Zyrtec)	5–10 milligrams PO once a day	For children ≥6 y, 5–10 milligrams PO once a day†
Fexofenadine* (Allegra)	60 milligrams PO twice a day	For children ≥6 y, 30 milligrams PO twice a day
Loratadine* (Claritin)	10 milligrams PO once a day	For children ≥6 y, 10 milligrams PO once a day†
Famotidine	20 milligrams PO twice daily	0.5 milligram/kg/d in two divided doses; maximum dose, 40 milligrams/d
Ranitidine	150 milligrams PO twice daily	5–10 milligrams/kg/d PO in two divided doses; maximum dose, 300 milligrams/d

*Indication limited to chronic idiopathic urticaria (see package inserts for details).

†Pediatric use is recommended only in children ≥6 y (see package inserts for details).

routes of therapy for these antihistamines. Histamine-2 antagonists (ranitidine or famotidine) also have demonstrated some benefit in patients with an allergy-mediated event, in particular urticaria, and therefore are recommended in combination with histamine-1 antagonists in the more severe allergic reactions.[10,11]

Numerous other antipruritic therapies are recommended, including Domeboro solution (aluminum sulfate diluted 1:10 with water) soaks and oatmeal baths.

ANTIMICROBIAL AGENTS

Topical antibacterial agents are used primarily as adjuncts to wound dressing and are rarely useful as primary therapy for superficial bacterial infections of the skin. The exception to this statement is topical mupirocin, which is as effective as oral antimicrobial agents in the management of impetigo. For wound dressing, the agents commonly used include polymyxin B, bacitracin, neomycin, and silver sulfadiazine. **Do not use silver sulfadiazine on the face because it will stain.** When reapplying silver sulfadiazine, thoroughly wipe off the prior medication before applying a new dose to avoid silver staining of the skin. Benefits of topical antibacterial agents include reduced adherence of bandaging material to the wound, reduced coagulum, and decreased bacterial colonization. The impact on the rate of wound healing and the prevention of wound infection is less well characterized. Another application of topical antibacterial agents is in the treatment of aphthous stomatitis, for which oral tetracycline rinses are used.

Other disorders treated with topical agents include *Candida* infections, dermatophyte infections, herpes simplex, and lice infestations and scabies. Diagnostic features and specific treatment are discussed in other chapters by the specific diagnosis.

NONANTIMICROBIAL TOPICAL AGENTS

In general, the maxim "If it's dry, wet it, and if it's wet, dry it" applies to the initial treatment of many rashes. Water, protein, and lipid losses characterize dry skin diseases. Emollient creams and lotions restore water and lipids to the epidermis, hasten the healing process, and reduce pruritus and pain. Emollients are moisturizers that reduce skin dryness and decrease skin friction and the sensation of tightness. In patients with chronic drying dermatitides, ointments are best, particularly in the winter months. In warm climates, less viscous, less oily preparations, such as a cream, are better tolerated. Open wet dressings using tap water or normal saline not only reduce discomfort due to the drying but also cleanse the skin by painlessly loosening crusts and exudates. The various wet cutaneous syndromes involve similar protein and lipid losses due to excessive flow of transudative or exudative fluid from the diseased skin with leaching of the complex macromolecules of the epithelial cells. Drying agents retard this flow of fluid and associated biologic materials from the body, thus assisting in the curative process.

Topical Agent Medication Base (Vehicle) The **vehicle,** or medication base, is the substance in which the active ingredient is dispersed. The base determines the rate at which the active ingredient is absorbed through the skin. Components of some bases may cause irritation or allergy.

Creams, a mixture of oils, water, and preservative, are white and greasy in texture. Creams are the most versatile vehicle and can be applied to any body surface area. They are particularly useful in the intertriginous areas. Creams are best used for acute therapy only; chronic application may cause excessive drying. Some patients are allergic to the preservatives in creams; in these patients, consider switching to an ointment preparation of the medication.

Ointments are composed of greases such as petroleum jelly and are free of preservative. Little water is added to this vehicle. Ointments are translucent and, when applied to the skin, remain greasy. This greasy consistency lubricates particularly dry lesions. In general, ointment vehicles allow deeper tissue penetration compared with cream bases. Ointments also are occlusive, providing very thorough coverage with deep tissue penetration and allowing little movement in moisture and other material into and out of the skin. Acute exudative syndromes and intertriginous areas of the body should not be treated with topical steroids formulated using an ointment vehicle.

Gels are greaseless mixtures of propylene glycol and water and at times contain alcohol. Gels have a translucent appearance and are described as "sticky." Alcohol-containing gels are best for acute exudative lesions, such as poison ivy dermatitis, whereas alcohol-free combinations should be used for dry, scaling conditions. In denuded areas, the alcohol component may cause discomfort. Gels are sometimes preferred for the scalp, because they do not alter the hair style and are cosmetically tolerable.

Solutions or lotions may contain water or alcohols in addition to other agents. They are clear or milky in appearance and are most useful for the scalp and other dense hair-bearing areas because they leave no significant residue on the hair. In denuded areas, the alcohol component may cause discomfort.

Some topical steroids are available as *foams*. Clobetasol (a very potent topical steroid) is safe and effective as a foam.[12] It is important to note that the absorption rate of clobetasol is greater for the foam vehicle formulation than for the topical solution.[13]

Topical Agent Toxicity Topical agents with certain active ingredients must be used with caution. These ingredients are often very effective, but the delivery is uncontrolled. Although the patient can control the amount and frequency of application, the actual amount of systemic absorption is not easily managed. For instance, certain agents are well absorbed through normal skin and mucous membranes, whereas other medications are absorbed only through irritated skin or mucosa. Topical formulations containing agents absorbed through irritated skin include the Lidoderm patch (containing lidocaine), Caladryl lotion (containing pramoxine, a local anesthetic), Bengay (containing methyl salicylate), and Icy Hot (containing menthol and methyl salicylate). Reports of significant toxicity, including death, have been reported with these and similar agents when excessively applied topically.

SMELLY FEET SYNDROME ("TOXIC SOCK SYNDROME")

A common secondary problem encountered in the ED is that of severely malodorous feet. This issue is often much more urgent from the perspective of the staff than from that of the patient, but may require attention for the benefit of everyone involved. The most extreme cases are seen in patients with poor hygiene who rarely remove or change their socks and shoes, primarily the indigent population. Because the perspiration and moisture collect around the foot, there is no opportunity for the area to dry. This moisture combines with the bacteria present on the skin and results in bacterial proliferation in the area of the poorly cared for feet. The bacteria produce a very strong-smelling compound (isovaleric acid) that can be quite overwhelming in certain circumstances. Isovaleric acid is the same compound that is produced by bacteria during the ripening of Swiss cheese.[14] To improve the odor and neutralize the acidic environment that allows the bacteria to thrive, an antacid solution can be applied directly to the feet. Application of HCO_3 spray to the contaminated skin or the direct applications of oral antacid solutions (such as Mylanta or Maalox) to the patient's feet are two methods that have been used with success.[13,15] Clean socks, disposable foot booties, or any type of foot wrap may be used to keep the medication in place to allow the acidic environment to be neutralized and the odor to be controlled. The key to permanent resolution of the problem is proper foot hygiene, regular changing to clean socks, and avoidance of a prolonged moist environment around the foot.

CHAPTER 249

Generalized Skin Disorders

Mark Sochor
Amit Pandit
William J. Brady

INTRODUCTION

This chapter describes selected serious generalized skin disorders in adults and discusses their dermatologic diagnosis and treatment. Covered are erythema multiforme, toxic epidermal necrolysis, exfoliative erythroderma, the toxic infectious erythemas, disseminated viral infections, Rocky Mountain spotted fever, disseminated gonococcal infection, purpura fulminans, and pemphigus vulgaris. Staphylococcal scalded skin syndrome and meningococcemia are discussed in the pediatric section, in chapter 141, "Rashes in Infants and Children." Staphylococcal and streptococcal toxic shock syndrome are also discussed in chapter 150, "Toxic Shock Syndromes." Disseminated viral infections are discussed in chapter 153, "Serious Viral Infections" and in chapter 141.

The disorders erythema multiforme, toxic epidermal necrolysis, exfoliative erythroderma, staphylococcal and streptococcal toxic shock syndrome, and staphylococcal scalded skin syndrome share some features in common. **Table 249-1** can help in differentiating these disorders.

FIGURE 249-1. Erythema multiforme.

ERYTHEMA MULTIFORME

Erythema multiforme is an acute inflammatory skin disease ranging from a localized papular eruption of the skin (erythema multiforme minor) to a severe, multisystem illness (**Figure 249-1**) with widespread vesiculobullous lesions and erosions of the mucous membranes, known as **Stevens-Johnson syndrome**. The spectrum is defined by the amount of epidermal detachment present, with erythema multiforme minor having no epidermal detachment, Stevens-Johnson syndrome having <10% of the body surface area with epidermal detachment, overlapping of Stevens-Johnson syndrome and toxic epidermal necrolysis having 10% to 30% epidermal detachment, and toxic epidermal necrolysis having >30% epidermal detachment.[1] Morbidity and mortality rise with the amount of epidermal detachment.[2] The highest incidence is in young adults (age range, 20 to 40 years), and erythema multiforme occurs commonly in the spring and fall. Common precipitating factors are infection, especially with *Mycoplasma* and herpes simplex virus; drugs, especially antibiotics and anticonvulsants; and malignancies. However, the cause is often unknown.[3] Most likely, erythema multiforme is the result of a hypersensitivity reaction, with immunoglobulin and complement components demonstrated in the cutaneous microvasculature on immunofluorescent studies of skin biopsy specimens, circulating immune complexes found in the serum, and mononuclear cell infiltrate noted on histologic examination.[3,4]

Symptoms include malaise, fever, myalgias, and arthralgias. Diffuse pruritus or a generalized burning sensation can occur before the skin lesions develop. The morphologic configuration of the lesions is variable, hence the descriptor *multiforme*. Maculopapular (**Figure 249-2**) and target, or iris (**Figure 249-3**), lesions are the most characteristic. Erythematous papules appear symmetrically on the dorsum of the hands and feet and on the extensor surfaces of the extremities. The maculopapule evolves into the classic target lesion during the next 24 to 48 hours. As the maculopapule enlarges, the central area becomes cyanotic,

TABLE 249-1 Comparison of Inflammatory and Infectious Generalized Skin Disorders

Disorder	Appearance	Special Features
Erythema multiforme	Erythematous macules, papules Target lesions Urticaria or vesiculobullous lesions	Cutaneous reaction to drugs or infectious agents. Stevens-Johnson syndrome is the most severe form.
Toxic epidermal necrosis	Painful, tender erythroderma Vesicles and bullae Exfoliation	Nikolsky sign present. Stevens-Johnson syndrome is most severe form. Drugs most common cause.
Exfoliative erythroderma	Nontender erythema Skin flaking and scaling Thickening of skin	Often preexisting eczema or psoriasis; can be drug induced.
Staphylococcal or streptococcal toxic shock syndrome	Staphylococcal: fine punctuate erythematous lesions that become confluent; blanching erythroderma; desquamation first of trunk and face, then extremities Streptococcal: can be indistinguishable from staphylococcal toxic shock; scarlatiniform erythroderma with sheet-like desquamation of skin	Colonization or infection with *Staphylococcus aureus*; menstruation associated with tampon use; nonmenstrual associated with burns, cellulites, sinusitis, wounds, etc. Group A streptococcal cellulitis, puerperal sepsis, any group A β-hemolytic *Streptococcus* infection source.
Staphylococcal scalded skin syndrome	Scarlatiniform rash or erythema Bullae or bullous impetigo Sloughing of skin	Usually seen in neonates or children <5 years of age. Nikolsky sign present.

FIGURE 249-2. Maculopapular erythema multiforme.

occasionally accompanied by central purpura or a vesicle. Urticarial plaques also may occur with or without the iris lesion in a similar distribution. Vesiculobullous lesions, which may be pruritic and painful, develop within preexisting maculopapules or plaques, usually on the extensor surface of the arms and legs and less frequently on the trunk. Vesiculobullous lesions are found most often on mucosal surfaces, including the mouth, eyes, vagina, urethra, and anus; they may also be seen on the trunk. Ocular involvement occurs in approximately 9% of patients with erythema multiforme minor, whereas ophthalmologic lesions are seen in almost 70% of patients with Stevens-Johnson syndrome.[5] The various

TABLE 249-2 Erythema Multiforme and Toxic Epidermal Necrolysis

Lesions of Erythema Multiforme	Lesions of Toxic Epidermal Necrolysis
Erythematous maculopapules	Warm, tender erythroderma
Iris or target lesions	Vesicles and bullae
Urticaria	Exfoliation
Mucous membranes involved	Mucous membranes involved

lesions (**Table 249-2**) develop in successive crops during a 2- to 4-week period and heal over 5 to 7 days. The **differential diagnosis of erythema multiforme** includes herpetic (herpes simplex virus and varicella-zoster virus) infection, vasculitis, toxic epidermal necrolysis, various primary blistering disorders (pemphigus and pemphigoid), urticaria, Kawasaki's disease, and the toxic and infectious erythemas.

Recurrence may be noted on repeat exposure to the etiologic agent, a special concern in cases associated with herpes simplex virus infection or medication use.[6] **The rate of erythema multiforme recurrence is very high in children with herpes simplex virus infection.** For example, 75% of children with a history of herpes simplex virus–related erythema multiforme developed erythema multiforme recurrence after herpes simplex virus reactivation.[6] Fluid and electrolyte disorders and secondary infection from cutaneous sites are the most frequent complications.

Systemic steroids are commonly used for localized disease and provide symptomatic relief but are of unproven benefit in influencing the duration and outcome of erythema multiforme.[7] Many authorities recommend a short, intensive steroid course of prednisone, 60 to 80 milligrams PO once a day, particularly in drug-related cases, with abrupt cessation in 3 to 5 days if no favorable response is noted. Systemic analgesic agents and antihistamines provide symptomatic relief. Stomatitis is treated with diphenhydramine and viscous lidocaine mouth rinses. Do not swallow oral viscous lidocaine because it causes neurotoxicity. Treat blisters with cool compresses of Burow solution (5% aluminum acetate). Ocular involvement should be monitored by an ophthalmologist. Unfortunately, burst steroid therapy does not reduce the chance of development or significance of existing ocular lesions.

Disposition is admission to an intensive care or burn unit. Acyclovir may reduce recurrence of herpes simplex virus infection and therefore lessen the potential for another bout of erythema multiforme; prolonged prophylactic acyclovir therapy may reduce the chance of recurrent erythema multiforme related to herpes simplex virus.[6]

TOXIC EPIDERMAL NECROLYSIS

Toxic epidermal necrolysis (**Figure 249-4**) is an explosive dermatosis characterized by tender erythema, bullae formation, and subsequent exfoliation. Patients are systemically ill. Many authorities consider the Stevens-Johnson syndrome variant of erythema multiforme and toxic epidermal necrolysis to be the same process.[4] Toxic epidermal necrolysis is found in all age groups without predilection for either sex. The syndrome has multiple causes, with medications being the most common cause.[3,4,8] Sulfa and penicillin antibiotics, anticonvulsants, and oxicam nonsteroidal anti-inflammatory drugs are the most frequent drug triggers for toxic epidermal necrolysis.[9,10] Other causes include malignancy and human immunodeficiency virus infection.[8] In many cases, a cause is not found. The pathogenesis is poorly understood and may be partly immunologic and partly genetic.[11]

Symptoms include a 1- to 2-week prodrome of malaise, anorexia, arthralgias, fever, or symptoms of upper respiratory tract infection. Skin tenderness, pruritus, tingling, or burning may be found at this time. Skin signs (Table 249-2) begin with a warm erythema, initially involving only the eyes, nose, mouth, and genitalia, but later becoming generalized. The erythematous areas become tender and confluent within hours. Flaccid, ill-defined bullae then appear within the areas of erythema. Lateral pressure with a finger on normal skin adjacent to a bullous lesion dislodges the epidermis, producing denuded dermis and demonstrating **Nikolsky sign**. Nikolsky sign is slippage of the epidermis from the dermis when slight rubbing pressure is applied to

FIGURE 249-4. Toxic epidermal necrolysis.

the skin. The bullae form along the cleavage plane between the epidermis and the dermis. The epidermis is then shed in large sheets, which leaves raw, denuded areas of exposed dermis. The average time until onset after exposure to the inciting agent is 2 weeks. Cutaneous extension follows an unpredictable time course, ranging from 24 hours to 15 days, with some severe cases demonstrating rapid, extensive involvement within 24 hours.

Perilabial blistering and erosive lesions are disfiguring and often impair adequate oral intake, contributing to hypovolemia. Ocular complications include purulent conjunctivitis, painful erosions, and potential blindness. Anogenital lesions are common. Additional mucous membrane involvement includes the GI, urinary, and respiratory tracts. The two major complications and leading causes of death in toxic epidermal necrolysis are infection and hypovolemia with electrolyte disorders. A broad range of pathogens is usually found, with staphylococcal and pseudomonal species predominating. The mortality rate has been reported as being between 25% and 35%.[8,11] The clinical characteristics associated with poor prognosis include advanced age, extensive disease, idiopathic nature, use of multiple medications, steroid therapy, azotemia, hyperglycemia, leukopenia, and thrombocytopenia.[9] The differential diagnosis of toxic epidermal necrolysis is presented in Table 249-1 and also includes primary blistering disorders (pemphigus and pemphigoid) and Kawasaki's disease in children.

Management of toxic epidermal necrolysis requires hospitalization in an intensive care or burn unit.[9] Immediate concerns center on the airway, because sloughing of airway and respiratory epithelium can occur. Hypovolemia and electrolyte abnormalities should be corrected. Prompt, aggressive antibiotic administration is necessary in suspected or documented infection; initial prophylactic antibiotics are not recommended by most. Solicit the advice of the burn center regarding any topical dressings that are applied before transfer.

PEMPHIGUS VULGARIS

Pemphigus vulgaris is a generalized, mucocutaneous, autoimmune, blistering eruption with a grave prognosis characterized by intraepidermal acantholytic blistering (**Table 249-3**). The primary lesions of pemphigus vulgaris are vesicles or bullae (**Figure 249-5**) that vary in diameter from <1 cm to several centimeters. They commonly first affect the head, trunk, and mucous membranes. The blisters are usually clear and tense, originating from normal skin or atop an erythematous or urticarial plaque. Within 2 to 3 days, the bullae become turbid and flaccid. Rupture soon follows, producing painful, denuded areas. These erosions are slow to heal and prone to secondary infection. The Nikolsky sign is present in pemphigus vulgaris. Mucous membranes are affected in most patients, and in some, the mucous membranes are the primary sites of involvement. Blisters on mucous membranes are more transitory than blisters on the skin in that they are more vulnerable to rupture; this is particularly true in the mouth, where ragged ulcerative lesions readily develop after inadvertent biting of the tissues.

Limited oral intake and accelerated protein, fluid, and electrolyte losses through the involved skin can rapidly lead to hypovolemia and electrolyte disturbances. Admission and aggressive fluid and electrolyte resuscitation, as well as treatment with corticosteroids and immunosuppressive agents, are needed to prevent mortality. Plasmapheresis and IV immunoglobulins may also be needed.

EXFOLIATIVE DERMATITIS

Exfoliative dermatitis is a condition in which most or all of the skin surface is involved with a scaly erythematous dermatitis. It is a cutaneous reaction in response to a drug or a chemical agent or to an underlying systemic or cutaneous disease, Most patients are >40 years old. The cause is unknown.

Exfoliative dermatitis can have an abrupt onset, particularly when related to a drug, contact allergen, or malignancy; exacerbations related to an underlying cutaneous disorder usually evolve more slowly. Exfoliative dermatitis tends to be a chronic condition, with a mean duration of 5 years, when related to a chronic illness; the course is often shorter after suppression of the underlying dermatosis, discontinuation of causative drugs, or avoidance of allergen. Idiopathic and chronic disease–related exfoliative dermatitis can continue for ≥20 years; death is rare.

Generalized erythema and warmth are noted, but skin tenderness is usually lacking. Erythema is accompanied by scaling or flaking, and the patient often complains of pruritus and skin tightness (**Figure 249-6**). The process generally begins on the face and upper trunk with progression to other skin surfaces. The patient usually has a low-grade fever. Excessive heat loss and hypothermia can complicate exfoliative dermatitis.

TABLE 249-3 Characteristics of Lesions of Pemphigus Vulgaris

FIGURE 249-5. Scattered bullous lesions intermixed with erosions and painful inflammatory plaques in a patient with pemphigus vulgaris.

Widespread cutaneous vasodilation may result in high-output congestive heart failure. The disruption of the epidermis results in increased transepidermal water loss, and continued exfoliation can result in significant protein loss and negative nitrogen balance. Chronic inflammatory exfoliation produces many changes, such as dystrophic nails, thinning scalp and body hair, and patchy or diffuse pigmentation changes.

The differential diagnosis of exfoliative dermatitis in adults is found in Table 249-1. Patients generally require admission. Correct hypothermia and hypovolemia. Obtain dermatology consultation before giving systemic corticosteroids.

DRESS: DRUG RASH WITH EOSINOPHILIA AND SYSTEMIC SYMPTOMS SYNDROME

Drug rash with eosinophilia and systemic symptoms (DRESS) syndrome is a severe adverse drug reaction that usually develops within 8 weeks of initiation of drug therapy. Aromatic anticonvulsants (such as phenytoin and phenobarbital), allopurinol, and sulfa medications are the most common culprits; however, other causes include nonsteroidal anti-inflammatory drugs, antiretroviral medications, angiotensin-converting enzyme inhibitors, calcium channel blockers, and other antibiotics.[12]

It is believed that there is a genetic predisposition if exposed to the appropriate medication.[12] Because of the potential genetic risk, DRESS syndrome should be discussed with the family members of any patient in whom it is diagnosed.

FIGURE 249-6. Exfoliative dermatitis demonstrated by generalized, warm erythema accompanied by scaling or flaking.

FIGURE 249-7. Drug rash with eosinophilia and systemic symptoms (DRESS) syndrome caused by phenytoin.

DRESS syndrome is defined by fever, rash, and internal organ involvement, with the liver, kidneys, and hematologic system being most commonly affected.[12] Rash and fever are typically the first signs of the syndrome, and they may have associated lymphadenopathy (**Figure 249-7**). The rash itself can take multiple forms, ranging from an erythematous scaly rash similar to that of exfoliative dermatitis, to a blistering/bullous rash similar to that of Stevens-Johnson syndrome, with varying degrees of severity. Abnormal laboratory findings include eosinophilia, which occurs in about 30% of DRESS syndrome patients,[13] and hepatic and renal dysfunction. Because of the variety of clinical presentations, early diagnosis of DRESS syndrome is difficult and requires a high level of clinical suspicion. The current standard of care involves immediate stoppage of the suspected culprit medication, administration of systemic steroids in severe cases (those with evidence of hepatitis, pneumonitis, or extensive exfoliative dermatitis), supportive care including antipyretic and antipruritic medications, and hospital admission.[13,14]

PURPURIC DISORDERS

MENINGOCOCCEMIA

Meningococcemia is a potentially fatal infectious illness caused by the gram-negative diplococcus *Neisseria meningitidis*. Meningococcal disease presents across a wide clinical spectrum in the acute and chronic forms. The acute entities include pharyngitis, meningitis, and bacteremia. Meningococci are present in mucosal samples from approximately 5% to 10% of the general population (the carrier state).[15,16] In high-risk populations, such as military recruits, the organism may be found in almost half of people without evidence of active disease.[17]

The illness usually strikes patients <20 years of age, with the vast majority of cases occurring in children and infants <5 years old. A rash is frequently noted on presentation and is an invaluable clue to the correct diagnosis early in the disease course. The dermatologic manifestations include petechiae, urticaria, hemorrhagic vesicles, macules, and/or maculopapules (**Figure 249-8**). The classic petechial lesions are found on the extremities and trunk but also are noted on the palms, soles, head, and mucous membranes. The petechiae evolve into palpable purpura with gray necrotic centers, a pathognomic finding for meningococcal infection. The skin findings result from the organism's invasion and destruction of the endothelium. Histopathologic analysis shows an infectious vasculitis. For further discussion, see chapters 141, "Rashes in Infants and Children," and 117, "Meningitis in Infants and Children."

A

B

FIGURE 249-9. Purpura fulminans **(A)** with early skin necrosis and **(B)** later with hemorrhagic bullae. [Photographs used with permission of Kenneth Greer, MD, University of Virginia Dermatology.]

PURPURA FULMINANS

Purpura fulminans is a rare vascular disorder characterized by fever, shock, multiorgan failure, and the rapid development of hemorrhagic skin necrosis. It is associated with dermal vascular thrombosis, vascular collapse, and disseminated intravascular **coagulation**. Purpura fulminans can result from hereditary or acquired protein C deficiency, activated protein C resistance, or protein S deficiency. It may also result from any condition that causes disseminated intravascular coagulation.

Purpura fulminans presents with the dermatologic triad of widespread ecchymoses, hemorrhagic bullae (**Figure 249-9**), and epidermal necrosis. Cyanosis with initial ecchymoses and ultimate necrosis of the tip of the nose, ears, and genitalia frequently occur; in general, distal tissue areas with end circulation are affected. Large confluent ecchymoses can develop, often on the extremities, from distal to proximal, and on the perineum, buttocks, and abdomen. The extremities are often involved symmetrically. Treatment is directed at the underlying cause.

CHAPTER 250

Skin Disorders: Face and Scalp

Dean S. Morrell
Kevin W. Dahle

INTRODUCTION

Many generalized dermatologic conditions can affect the face and scalp. This chapter discusses the acneiform eruptions, seborrheic dermatitis, erysipelas and facial cellulitis, herpes zoster, herpes simplex, tinea capitis and barbae, head lice, allergic contact dermatitis, and photosensitivity/sunburn. Impetigo and bullous impetigo are discussed in chapter 141, "Rashes in Infants and Children."

ACNEIFORM ERUPTIONS

The acneiform eruptions include acne vulgaris, rosacea fulminans, dissecting cellulitis of the scalp, and acne keloidalis nuchae. Pathophysiology of these disorders is similar. Sebum secretion is increased within the sebaceous follicle by androgen stimulation. Keratin accumulates in the hair follicle as well as sebum. Host inflammation occurs, and the bacteria *Propionibacterium acnes* (gram-positive rods) proliferate and accumulate, intensifying inflammation. At this stage, an inflammatory papule or pustule occurs with an influx of neutrophils and helper T cells. In addition, marked inflammation can cause a nodule or cyst, and scarring can occur.

Acne fulminans is the most severe form of nodulocystic acne and may prompt patients to seek emergency medical attention. It usually affects males between the ages of 13 and 16 years. Clinical features include acute onset of suppurative cysts and nodules with ulcerations and hemorrhagic crusting on the face, chest, and back (**Figure 250-1**). Ulcerating lesions can lead to severe scarring. Systemic symptoms also occur and include osteolytic bone lesions of the clavicle and sternum, fever, arthralgias, myalgias, and hepatosplenomegaly. Diagnosis is clinical. Acute treatment includes administration of 40 to 60 milligrams of prednisone once daily. If the patient is already taking isotretinoin, continue the medication in conjunction with corticosteroids. **Isotretinoin should not be started in the acute care setting.** Refer to a dermatologist.

FIGURE 250-1. Nodulocystic acne. [Photo contributed by University of North Carolina Department of Dermatology.]

FIGURE 250-3. Acne keloidalis nuchae. [Photo contributed by University of North Carolina Department of Dermatology.]

Rosacea fulminans, or pyoderma faciale, is an inflammatory cystic acneiform eruption on the central face of young women. The eruption may occur with or without a history of rosacea. Inflamed papules and pustules are present on the centrofacial region and can coalesce into large plaques. Diagnosis is clinical. Severe scarring can occur without treatment. Treatment is similar to that of acne fulminans—oral prednisone, 40 to 60 milligrams once daily, and referral to a dermatologist for consideration of isotretinoin.

Dissecting cellulitis of the scalp, also called *perifolliculitis capitis abscedens et suffodiens*, is an inflammatory and scarring disease of the scalp and neck. It occurs most commonly in young men of African descent. It consists of boggy tender nodules in multiple areas of the scalp and the neck (**Figure 250-2**). It is not a true cellulitis but is an intense inflammatory condition of the scalp. The nodules suppurate and develop interconnecting sinus tracts. Hair loss develops over these nodules, and permanent scarring, alopecia, and keloids can occur. If associated with acne conglobata, hidradenitis suppurativa, and pilonidal cysts, the disease is referred to as the *follicular occlusion tetrad*. Osteomyelitis of the skull has developed under lesions of dissecting cellulitis.[1] **ED therapy** includes antibacterial washes, such as chlorhexidine, which is available without prescription, and oral antibiotics, such as doxycycline and minocycline. Refer to a dermatologist. Dapsone, intralesional corticosteroids, and prednisone can be initiated at follow-up but are often unsuccessful. Treatment with isotretinoin has been successful. Surgical excision, laser treatment, and tumor necrosis factor-α blockers have also been used successfully.[2]

FIGURE 250-2. Dissecting cellulitis of the scalp. [Photo contributed by University of North Carolina Department of Dermatology.]

Acne keloidalis nuchae is a perifollicular inflammation (**Figure 250-3**) consisting of follicular-based papules and pustules on the nuchal region. The individual keloidal papules enlarge and coalesce to form keloidal plaques with an associated scarring alopecia. At the edges of the plaque, hair that is tufted often resembles hair on a "doll's head." The area may also have a bad odor, which may be the patient's primary complaint. **Treatment** includes topical application of clindamycin solution, topical corticosteroids such as fluocinonide or clobetasol solution, and oral doxycycline or minocycline. Refer to a dermatologist for intralesional corticosteroids.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis has both infantile and adult forms. The infantile form is called "cradle cap" and peaks in the first 3 months of life. See chapter 141 for further discussion in infants. Adults with acquired immunodeficiency syndrome and Parkinson's disease are predisposed to severe disease. Common dandruff is a mild form of seborrheic dermatitis. The cause is not known. The disorder occurs in areas of active sebaceous glands. *Malassezia* yeasts and underlying inflammation are implicated[3] and may explain why seborrheic dermatitis responds to both antifungal and anti-inflammatory agents. In adults, the condition is chronic and without any systemic symptoms. Pruritus can be variable but is usually mild. Dandruff may be present. Lesions can extend onto the central upper chest and intertriginous regions. Erythema and scaling are present on the vertex and parietal regions diffusely. On the face, there is symmetric involvement of the eyebrows, nasolabial folds, and retroauricular areas (**Figure 250-4**). The skin is sensitive to sun and heat.

Treat adults with an antidandruff shampoo containing zinc pyrithione, selenium sulfide 2.5%, salicylic acid, or tar. Ketoconazole shampoo can also be used and is available over the counter at 1% and by prescription at 2%. The shampoo should be lathered into the scalp and left on

FIGURE 250-4. Adult seborrheic dermatitis. Erythema and scaling on face and facial skin folds. [Reproduced with permission from Wolff K, Johnson R, Suurmond R: *Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology*, 5th ed. New York, McGraw-Hill, 2005, p. 51.]

briefly before rinsing. Ketoconazole 2% cream can also be used. A topical corticosteroid such as fluocinonide solution may be applied to the scalp in severe cases. For the face, hydrocortisone 2.5% or desonide 0.05% cream or lotion applied twice per day should be the initial management. **The use of higher potency topical corticosteroids on the face can lead to the development of perioral dermatitis or steroid rosacea and should be avoided.** Treatment continues until the dermatitis is cleared. Re-treatment is needed for recurrences.

FIGURE 250-5. Facial erysipelas. [Reproduced with permission from Wolff K, Johnson R, Suurmond R: *Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology*, 5th ed. New York, McGraw-Hill, 2005, p. 605.]

ERYSIPELAS AND FACIAL CELLULITIS

Erysipelas and cellulitis are infections of the dermis and subcutis, respectively. Erysipelas is most often caused by group A *Streptococcus*, specifically *Streptococcus pyogenes*. It usually affects the very young or elderly. Episodes increase in the summer. Bacterial inoculation into the skin may be caused by trauma. Cellulitis extends deeper than erysipelas, although treatment is the same. The two main causes of cellulitis in immunocompetent patients are *S. pyogenes* and *Staphylococcus aureus*.

Erysipelas and cellulitis of the face present as hot, bright red, tender, edematous, indurated plaques that can be unilateral or bilateral (**Figure 250-5**). The area of involvement is sharply demarcated and expands peripherally. There is no central clearing. Vesicles or bullae may be present. Systemic symptoms include fever, chills, regional lymphadenopathy, and malaise. The infection resolves with desquamation and possibly pigmentary change. In children, *Haemophilus influenzae* is a rare cause of erysipelas due to widespread use of the *H. influenzae* type b vaccine.

If unilateral, erysipelas and cellulitis must be distinguished from early herpes zoster infection. When bilateral, these diseases may be mistaken for the malar eruption of systemic lupus erythematosus. If there is eye involvement, consider periorbital cellulitis and obtain a CT scan to exclude orbital cellulitis. Bacterial cultures from the portal of entry should be done when possible for directed therapy. Anti-DNase and anti-streptolysin O titers can be done to confirm group A streptococcal infections. Skin biopsies are not usually helpful.

Unless history is suggestive of an unusual organism, direct **treatment** toward *Staphylococcus* and *Streptococcus* species in adults. Typically, if there is no clinical toxicity, cephalexin is initially prescribed with follow-up in 24 hours. In children, coverage should include these organisms and *H. influenzae*. If the patient does not respond to conventional therapy, other causes should be considered such as *Moraxella* species.[4] If bullous lesions are present, suspect methicillin-resistant *S. aureus* infection and add appropriate antibiotics.[5]

Patients who are toxic, immunocompromised, very young or elderly, or unable to complete the outpatient antibiotic regimen require admission for IV antibiotics.

HERPES ZOSTER INFECTION

Herpes zoster, or "shingles," usually involves the thoracic dermatomes. Eruptions on the face are due to trigeminal nerve involvement, which can have serious sequelae. Herpes zoster results from reactivation of latent varicella-zoster virus. The initial eruption of varicella-zoster virus is chickenpox.

Pain or dysesthesia precedes herpes zoster by 3 to 5 days. Erythematous papules progress to clusters of vesicles with an erythematous base in a dermatomal distribution (**Figure 250-6**). The vesicles evolve to pustules and then crust in about 1 week. Generalized eruptions may occur in immunocompromised patients. Any of three branches of the trigeminal nerve may be involved on the face. Involvement of the ophthalmic branch (V1), especially with vesicles on the tip of the nose indicating involvement of the **nasociliary branch**, raises concern for keratitis and other ocular complications. Emergency ophthalmologic consultation is needed. The virus may spread to motor root ganglia, resulting in motor weakness or paralysis. **Ramsay Hunt syndrome** results from reactivation of varicella-zoster virus in the geniculate ganglion and may present with ear pain, vesicles in the external auditory canal, facial nerve paralysis, and vestibulocochlear dysfunction.[6]

Differential diagnosis includes other blistering disorders, such as herpes simplex infection, bullous impetigo, and contact dermatitis. The key to diagnosis is the unilateral distribution and pronounced pain in the

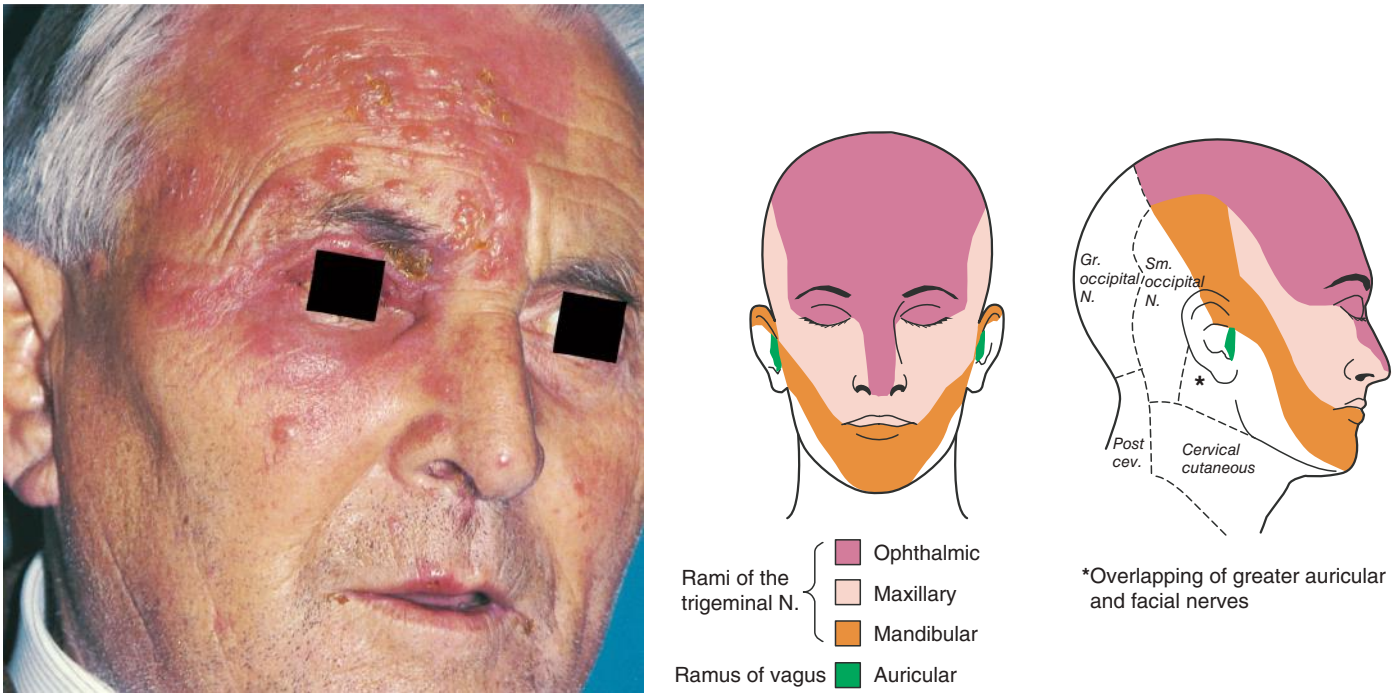

FIGURE 250-6. **A.** Herpes zoster in trigeminal nerve distribution. Note lesion on the tip of the nose, which suggests nasociliary branch involvement. **B.** Dermatomes of the head and neck. cev. = cervical; Gr. = greater; N. = nerve; Sm. = smaller. [**A.** Reproduced with permission from Fleischer A Jr, Feldman S, McConnell C, et al: *Emergency Dermatology: A Rapid Treatment Guide*. New York, McGraw-Hill, 2002, p. 157. **B.** Reproduced with permission from Wolff K, Johnson R, Suurmond R: *Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology*, 5th ed. New York, McGraw-Hill, 2005.]

area of involvement. Diagnosis can be confirmed by a Tzanck preparation showing multinucleated giant cells. However, Tzanck preparations have largely been replaced by polymerase chain reaction analysis of swabs taken from the base of a vesicle. Polymerase chain reaction results are generally available within 24 hours and can differentiate between varicella-zoster virus, herpes simplex 1, and herpes simplex 2.

Treatment is most effective if it is initiated within the first 72 hours of symptoms—this shortens healing time, decreases new lesion formation, and decreases the risk of postherpetic neuralgia. Treatment in an immunocompetent patient is acyclovir, 800 milligrams PO five times a day for 7 days, or valacyclovir, 1 gram PO three times a day for 7 days. In immunocompromised patients, treatment with acyclovir, 10 milligrams/kg IV every 8 hours for 7 to 10 days, is indicated. Valacyclovir should not be prescribed in patients with human immunodeficiency virus/acquired immunodeficiency syndrome due to risk of hemolytic-uremic syndrome. Local care can be provided with aluminum acetate compresses three times daily followed by antibiotic ointment. Narcotic analgesics may be needed. The zoster vaccine markedly reduces morbidity from herpes zoster and postherpetic neuralgia among older adults, reducing the burden of illness by 61.1%, the incidence of postherpetic neuralgia by 66.5%, and the incidence of herpes zoster by 51.3%.[7]

Patients with herpes zoster are contagious to individuals who have not had chickenpox. In the ED, isolation is needed for patients suspected of the disease at triage. In follow-up instructions, patients should be told to cover all open areas when visiting the physician.

HERPES SIMPLEX VIRUS INFECTIONS

Herpes simplex virus (HSV) type 1 most commonly occurs on the face. Initial infection occurs during childhood or adolescence and varies in its presentation. Many individuals experience mild symptoms, whereas a few experience a debilitating eruption. Recurrences tend to be mild and occur primarily on the lips, nose, and oral cavity.

The typical lesions of HSV are painful, grouped vesicles on an erythematous base (**Figure 250-7**). The primary eruption may be preceded by constitutional symptoms. The characteristic primary eruption is a gingivostomatitis with herpetic lesions on the lips and in the oral cavity. It may persist for weeks. Recurrent herpes simplex virus is typically seen as herpes labialis ("fever blisters" or "cold sores"). Individuals often experience a prodrome of localized tingling or burning several hours before the onset of the eruption. The herpetic lesion usually occurs along the lip margin and completely heals within 10 days. Ultraviolet light, fever, or local trauma can induce these eruptions.

In patients with underlying atopic dermatitis, a severe form of herpes infection can occur called *eczema herpeticum* in which herpes simplex virus or varicella-zoster virus can infect active atopic dermatitis lesions (see chapter 141).

FIGURE 250-7. Herpetic gingivostomatitis. [Photo contributed by University of North Carolina Department of Dermatology.]

TABLE 250- 1 Treatment of Herpes Simplex Virus (HSV) Gingivostomatitis (Herpes Labialis)

Condition	Acyclovir Treatment	Valacyclovir Treatment
First episode	400 milligrams PO three times a day for 7 d *or* 200 milligrams PO five times a day for 7 d	1 gram PO twice a day for 7 d
Recurrent episode	400 milligrams PO five times a day for 5 d *or* 800 milligrams PO twice a day for 5 d	2 grams PO twice a day for 1 d
Suppression	400 milligrams PO twice a day	500 milligrams PO daily

Treatment for primary HSV gingivostomatitis works best when given within the first 24 hours (**Table 250- 1**).[8] Treatment can continue for up to 10 days if lesions have not crusted. Immunocompromised patients with severe involvement require hospitalization for IV acyclovir. Suppressive treatment with acyclovir or valacyclovir has been shown to decrease outbreaks of herpes labialis.[8] Patients with recurrent disease should be instructed to avoid triggers, especially the sun, by using sunscreen and a lip balm with ultraviolet light protection.

TINEA CAPITIS

Tinea capitis is a dermatophyte infection of the scalp. Causative agents are usually from the genus *Trichophyton*. The fungi invade the hair shaft and stratum corneum of the skin.

Clinically, there are nonscarring areas of alopecia with broken-off hairs and scale at the periphery (see Figure 141-13). Occasionally, there is intense inflammation, with a boggy, tender, indurated plaque with superficial pustules and overlying alopecia. This reaction, referred to as a *kerion*, may result in permanent scarring and alopecia. Cervical and/or occipital lymphadenopathy may be present. In some cases of tinea capitis, especially after initiation of oral antifungal therapy, patients will mount an immune response to the dermatophyte called an "id reaction" at distant sites. This id reaction appears as widespread, symmetric, and monomorphic eczematous papules and responds to topical steroids.

Diagnosis is based on a positive potassium hydroxide preparation or positive fungal culture. Scraping only the scalp rarely gives a positive potassium hydroxide examination because *Trichophyton* species invade the hair shaft. If fungal culture is necessary to establish or confirm the diagnosis, it usually takes 3 to 4 weeks for the culture to grow. Wood's lamp examination (**Table 250- 2**) is becoming less helpful, because the most common types of dermatophyte infections fail to fluoresce. **More than 90% of dermatophyte cultures are due to *Trichophyton*, which do not fluoresce**. A positive culture will help to exclude other conditions such as atopic dermatitis or seborrheic dermatitis.

Topical treatment alone is not effective for tinea capitis. **The current first-line therapy is oral griseofulvin.** Higher doses of griseofulvin are needed to treat *Trichophyton* species, which represent the most common cause of tinea capitis. Liquid microsize griseofulvin, 20 to 25 milligrams/kg/d (maximum, 1 gram/d), is an effective treatment. Ultramicrosize griseofulvin (tablets only), 10 to 15 milligrams/kg/d (maximum, 750 milligrams/d), can also be used if patients are able to swallow pills. Individuals should be treated for a minimum of 8 weeks. At that point, patients should be reevaluated to determine whether therapy should be continued. Alternative treatment is with terbinafine granules, which are given at 125 milligrams/d for patients weighing <25 kg, 187.5 milligrams/d for patients weighing 25 to 35 kg, and 250 milligrams/d for patients weighing >35 kg for 6 weeks. To decrease contagiousness and scale, patients should also wash hair with antifungal shampoo (ketoconazole 2% or selenium sulfide 2.5%) three times per week for the first 2 weeks of therapy.

TABLE 250- 2 Fluorescence with Wood's Lamp

Nits
Lice
Microsporum
Malassezia

Other family members, especially children, and other close contacts, such as classmates at school or day care, should be evaluated. Other affected members should be treated simultaneously to prevent reinfection. If *Microsporum* is diagnosed by culture, pets (cats and dogs) should be examined by a veterinarian. Follow-up with a primary care provider or dermatologist is crucial, because persistent infection may only be manifest as scale and go unrecognized by caregivers.

TINEA BARBAE AND SYCOSIS BARBAE

Tinea barbae is a dermatophyte infection involving the beard area of the face and neck and occurs in postpubertal males. Etiology usually involves the genus *Trichophyton.* Predisposing factors to tinea barbae include use of topical steroids, contact with infected pets, and diabetes mellitus.[9] Sycosis barbae is a deep folliculitis within the beard area. Perifollicular inflammation also occurs. The causative agent is usually *S. aureus*.

In tinea barbae, severe inflammatory plaques and follicular pustules occur in the beard area (**Figure 250-8**). A kerion-like lesion can develop as well as abscess and sinus tracts. Hairs are usually loosened or broken off.

In sycosis barbae, discrete pustules, usually involving *S. aureus*, with perifollicular inflammation are evident (**Figure 250-9**). Unlike tinea barbae, the hairs are usually not loosened or broken off.

The diagnosis is clinical, but tinea barbae sometimes can resemble acne vulgaris or bacterial folliculitis. A potassium hydroxide preparation or fungal culture can be done to confirm the diagnosis. Permanent alopecia and scarring can result if left untreated.

Treatment of tinea barbae requires oral antifungals. Microsize griseofulvin, 500 milligrams PO daily, or ultramicrosize griseofulvin, 375 milligrams PO daily, for 4 to 6 weeks can be used. Terbinafine can also be used, but baseline liver function studies should be drawn in adults prior to starting the medication. Supportive care is done with shaving or depilating the hair along with warm compresses to remove the crust.

For sycosis barbae, initial treatment with warm compresses and mupirocin ointment may be sufficient. If lesions are chronic, treatment usually requires systemic antibiotics with adequate *S. aureus* coverage.

HEAD LICE (PEDICULOSIS CAPITIS)

Head lice, or pediculosis capitis, is a common worldwide infestation that usually occurs in children age 3 to 11 years but can occur at any age. It is caused by the head louse, *Pediculus capitis*, which is approximately 2 to 3 mm in size. Lice need a blood meal every 4 to 6 hours and live for 30 days while laying numerous eggs. Adults cannot survive more than 24 hours without a blood meal. The eggs are cemented to the hair by a proteinaceous matrix (**Figure 250-10**). Transmission occurs by head-to-head contact and by brushes and combs.

Head lice are limited to the scalp, behind the ears, and on the back of the neck. Intense pruritus is a feature. Diagnosis is made by identification of nits and/or adult lice in the scalp hair. Nits are oval, gray-white egg capsules. If all nits are located >7 mm from the scalp surface, active infestation is unlikely. Nits and lice fluoresce with a Wood's lamp.

Topical application of permethrin cream is the first-line treatment and should be repeated 1 week later to kill any surviving active nits. Apply 1% or 5% permethrin cream to the hair and leave it on overnight. The next morning, follow with a shampoo. Or, apply pyrethrin cream or ivermectin lotion for 10 minutes and then rinse out. Malathion 0.5% cream is another alternative and is applied to the scalp overnight, but malathion is flammable, so be careful in application. Do not use malathion in children <6 years old. Application of thick moisturizing creams to hair followed by drying with a blow dryer has also been used for resistant cases. Children with head lice do not need to be removed from school, because "no-nit" policies have been shown to be excessive.[10]

ALLERGIC CONTACT DERMATITIS

Two types of contact allergies are likely to result on the face. The first is the result of an aerosolized allergen. The second is direct physical contact that is most prominent on the sensitive parts of the face. Examples of aerosolized contactants include poison ivy and poison oak when the plant has been burned. Examples of common direct contactants affecting the face include nickel, nail polishes, toothpaste, preservatives in makeup, contact lens solutions, eyeglasses, and hair care products. Chemical-splash injuries are a common cause of facial irritant contact dermatitis. A thorough history is necessary to uncover the offending agent. Referral to a dermatologist or allergist may be necessary if the history is unrevealing.

Clinically, allergic contact dermatitis from an aerosolized allergen presents as erythema and scale with or without vesiculation (**Figure 250-11**). The involvement is diffuse, with upper and lower eyelids affected. This distribution is in contrast with photosensitive eruptions in which non–sun-exposed areas, such as the upper eyelids and the upper lip, are spared. Direct allergic contact dermatitis tends to be most prominent on the most sensitive skin, such as the eyelids.

Medical treatment is of little value if the offending agent is not removed from the patient's environment. Depending on the severity, topical or oral corticosteroids and oral antihistamines are used in medical management. Aluminum acetate (Burow solution, available

commercially as Domeboro®) compresses can be beneficial as well. Short duration (3 to 5 days) of medium- to high-potency topical corticosteroids can be used on the face. Often, extensive and severe periocular involvement requires oral prednisone. See chapter 253, "Skin Disorders: Extremities" for further discussion of treatment of rhus, or poison ivy or oak.

SUNBURN AND PHOTOSENSITIVITY

Reactions to ultraviolet light are varied. In many disorders, ultraviolet light aggravates but does not cause disease. Examples of this type of reaction include lupus erythematosus, dermatomyositis, porphyria cutanea tarda, dermatitis of niacin deficiency (pellagra), and recurrences of herpes simplex virus. Other disorders are caused by the sun, the most common of which is a sunburn reaction. A sunburn reaction is the inflammatory response to skin injury as a result of ultraviolet radiation. Individuals with fair skin, light eyes, and naturally light hair color are more susceptible to sunburns; however, darker pigmented skin can develop skin injury with sufficient ultraviolet light exposure.
